Undaria pinnatifida  
... ..  
... ..

INTRODUCTION

Undaria pinnatifida is one of the original seaweeds of Japan. It grows in coastal waters of the greater part of the Japanese islands and it has been a popular sea-food for Japanese people from old times. Of late years, the demand for Undaria pinnatifida has increased, because its nutritive value such as vitamins, minerals, and protein (Table 1) are thought much of and because of its low price.

Table 1. Nutritive Value of Undaria pinnatifida

| Components              |     | Dry Products | Wet Products |
|-------------------------|-----|--------------|--------------|
| calorie                 | cal | 75           | 4            |
| water                   | g   | 17.41        | 96.73        |
| protein                 | g   | 12.45        | 0.65         |
| fat                     | g   | 0.88         | 0.03         |
| sugariness              | g   | 4.42         | 0.25         |
| cellulose               | g   | 4.15         | 0.20         |
| ash                     | g   | 19.70        | 0.55         |
| calcium                 | mg  | 389          | 18           |
| phosphorous             | mg  | 636          | 24           |
| table salt              | mg  | 5.737        | 33           |
| vitamine A              | IU  | 400          | -            |
| vitamine B <sub>1</sub> | mg  | 0.10         | -            |
| vitamine B <sub>2</sub> | mg  | 0.15         | -            |
| vitamine C              | mg  | 15           | -            |

After "Shokuhin Eiyoka Yoran," (Handbook of Nutritive Value of Food), Kokuritsu Eiyō Kenkyūsho and Kokumin Eiyō Kyokai edi., 1956.

Concerning the production of Undaria pinnatifida, it is a very important resource for fisheries propagation industries because of its wide occurrence and the higher rank among seaweeds resources of our country. The importance of Undaria pinnatifida is followed by those of seatang (Laminaria), purple laver (Porphyra), and agar-agar (Gelidium and allied species). Recent production of Undaria pinnatifida, including Undaria undarioides and Undaria peterseniana, is shown in Table 2 after "The statistical table of fisheries, cultivation industries and fisheries catch." This table shows how the harvest of Undaria pinnatifida varies from year to year. There are several reasons <sup>for</sup> on the variation <sup>in production</sup> of the produce; the most important reason is the variation in amount of resources, which is controlled by natural conditions.

Fisheries propagation industry had been practiced by setting stones on the sea bottom from the Meiji era (1868-1912). Since 1952 the industry has been studied based on a long-term and large-size project as one of the government supported inshore (and off shore) fisheries industries. However, the propagation techniques and the plans practiced currently can not control the harvest of Undaria pinnatifida. In addition to that, they are not effective enough for the larger production. There are several reasons for the ineffective culture practice; among them the lack of research and effort to unveil the ecology of Undaria pinnatifida may be responsible. The ecology of Undaria pinnatifida, however, has <sup>been</sup> ~~being~~ revealed, so in the future propagation plan studies the natural conditions of the shore where Undaria pinnatifida will be propagated and applies proper methods to the conditions. Thus, "fields in sea" will be developed and improved.

Table 2. Fiscal year produce of Undaria pinnatifida\*  
(Weight in raw or wet, metric ton)

| Sea District  | District or state | Fiscal Year Produce |        |        |        |        |        |        |        |        |

Note: the produce of 1953 - 1957 was converted to metric ton from an unit used in the statistical table.

Recently the cultivation industry of Undaria pinnatifida <sup>has</sup> become<sup>x</sup> important as one of the projects for intensive fisheries and for stabilizing the fisheries management. Artificial <sup>reproduction</sup> ~~sporing~~ and cultivation of Undaria pinnatifida have been studied since the beginning of the Showa era (1926-): Messrs. Toraichiro Kinoshita (Hokkaido) and Yojiro Ootsuki (Kanto-shu) primarily established the techniques in 1942-1943, following the research by Mr. Toshizo Sudo. As a result of their studies, <sup>production</sup> ~~manufacture~~ of seedling became possible in sea or indoor at many culture stations. And the cultivation of Undaria pinnatifida is spreading over the country after the successful industrialization <sup>on</sup> ~~in~~ the ~~seas~~ shores of Tohoku district. The figures of cultivation of Undaria pinnatifida are shown in Table 3 for the fiscal years of 1962 and 1963.

In the following chapters the cultivation of Undaria pinnatifida will be described. <sup>For</sup> ~~To be~~ successful ~~for the~~ cultivation, first we must know the ecology of the seaweed. The ecology of Undaria pinnatifida and the techniques of its cultivation will be described in details in separate chapters.

Table 3. The present figure of cultivation industry of Undaria pinnatifida

| Sea District  | State     | Fiscal year 1962                    |                                  |                             |                             | Fiscal year 1963         |                                     |                                  |  |
|---------------|-----------|-------------------------------------|----------------------------------|-----------------------------|-----------------------------|--------------------------|-------------------------------------|----------------------------------|--|
|               |           | Number of seedlings culture station | Amount of seedlings cultured (m) | Number of cultivation rafts | Produce in weight (raw, kg) | Produce in price (¥1000) | Number of seedlings culture station | Amount of seedlings cultured (m) | (Prescribed) Number of cultivation rafts |
| Pacific Ocean | Hokkaido  | 7                                   | (25,000)                         | 370                         | 6,000                       | (489)                    | 7                                   | (21,000)                         | 300                                      |

Ecology of Undaria pinnatifida

Undaria pinnatifida grows on reefs and stones in coastal waters faced <sup>ing</sup> to or close to a warm open sea. Along the west coast of Kyushu and the Sea of Japan, Undaria pinnatifida occurs in the coastal waters of Tozakibana, Kagoshima-ken, Kyushu and northward, all coasts of the Sea of Japan, west coast of Hokkaido, Rishiri island, and Rebun island. The straits of Sohya is the north <sup>low</sup> limit. And also the seaweed occurs in the coastal waters of the Pacific Ocean: Yamakawa in Kagoshima Bay (very small amount), north of Kadokawa Bay, Miyazaki-ken, eastern coast of Kyushu, all coasts of the Seto-naikai inland sea, most Pacific coasts of Honshu, and east of Muroran, Hokkaido. Along the coast of Shikoku, the seaweed occurs in the coastal waters of Yurazaki (western coast) and northward and Hiwasa, Tokushima-ken (eastern coast) and northward, but not of Kohchi-ken. Along the coast of Kii Peninsula, the seaweed occurs ~~in the~~ north of Sakaiura, Wakayama-ken (west coast) and of Mugizaki, Mie-ken (east coast), but not in the Sea of Kumano-nada. Generally, Undaria pinnatifida does not occur in the deep <sup>water</sup> inside of a bay nor around the mouth of a river where the bottom of the sea is sandy or muddy. The seaweed occurs in the coastal water of Korean Peninsula: south; east (south of Zozan Bay); and west coasts (south of Daisei Island).

Undaria pinnatifida can be classified into the following two types based on the shape of frond and its occurrence (another classification shows three types: the following two types and Naruto wakame).

Southern wakame (wakame) ---- generally smaller in size, short stem, shallower emarginated frond, ~~too~~ many leaflets for the frond length. The

reproduction frond has few waves (2 to 4 waves). The reproduction fronds and the nutritive fronds are often continuous, and sometimes small tongue-like fronds can be seen on the edge of the reproduction frond. This type of Undaria pinnatifida grows mostly in the coastal waters of the middle-south of Honshu Island (Pacific coast) and of the Sea of Japan, especially in the shallow <sup>places.</sup>

Northern wakame (Nanbu wakame) --- larger in size, longer stem, deeper emarginated frond, few leaflets for the frond length. The reproduction frond has many waves (6 to 20 waves). This <sup>variant of</sup> Undaria pinnatifida grows in the coastal waters of Sanriku coast of the north of Inubo-zaki and of Hokkaido. ~~This~~ <sup>It</sup> also grows in other coastal waters, where is deep and strong current.

Undaria pinnatifida is an annual seaweed and its life cycle is shown in Fig. 1. The full-grown Undaria pinnatifida <sup>forms</sup> ~~gets~~, at the lower part of

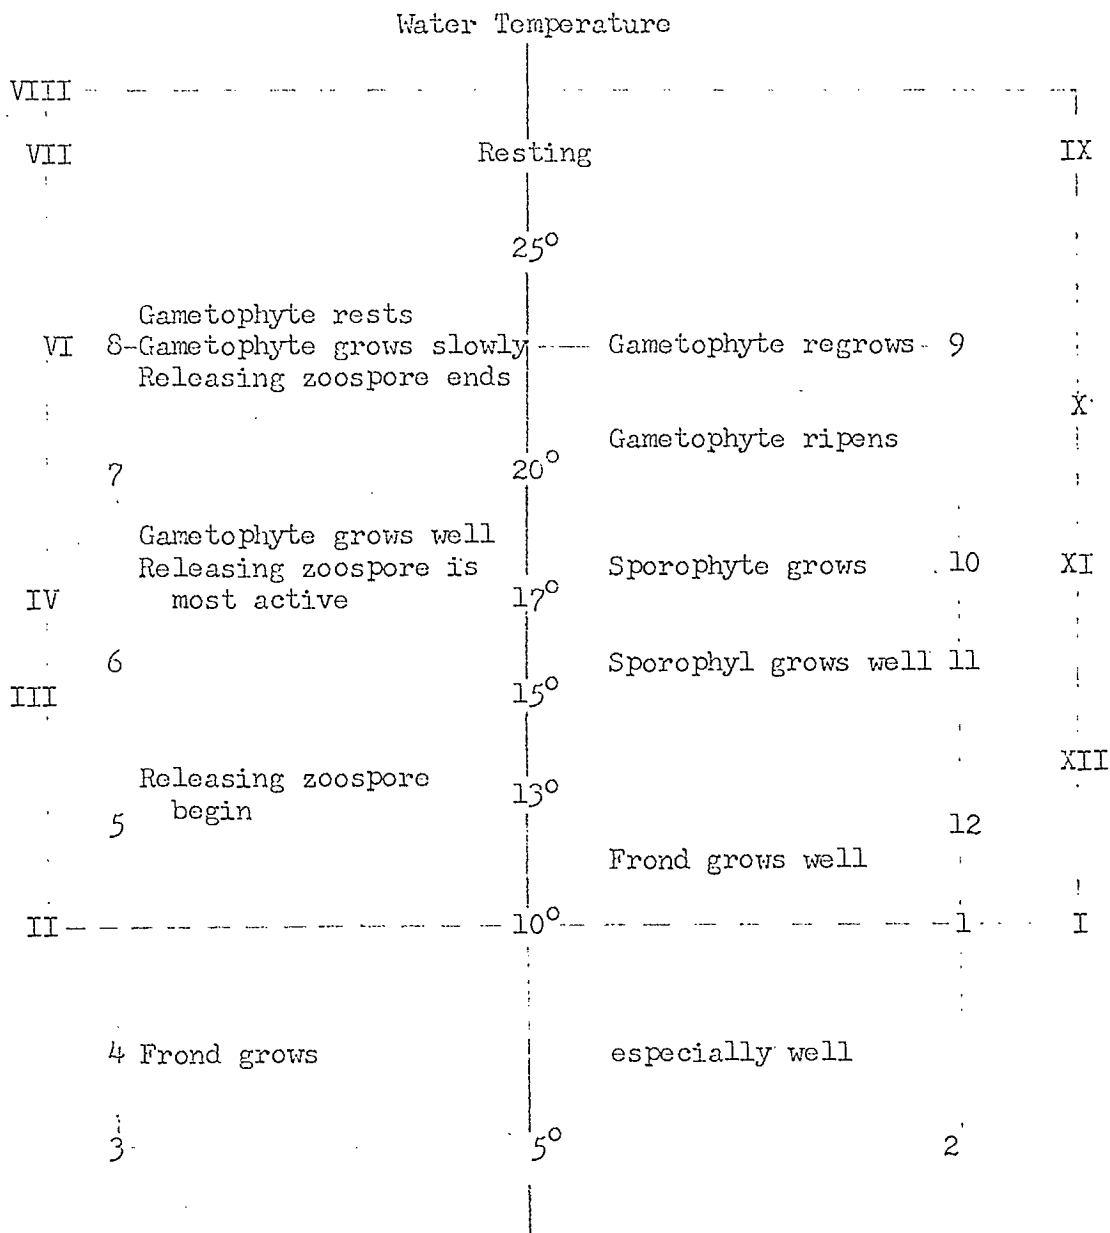

Fig. 1. Life cycle of Undaria pinnatifida

its stem, the pleasts called reproduction<sup>ve</sup> fronds which shapes<sup>are</sup> are different from those of a nutritive frond. Zoosporangia are formed on the reproduction fronds and when time comes, the cusp of the zoosporangium is broken and zoospores produced in the zoosporangium come into the sea water with a viscous liquid<sup>are released</sup> in it. The zoospore, about 9 micron long, is pear-shaped with two hairlines<sup>cilia</sup> on its side and can swim by ~~waving the hairlines~~<sup>ciliary action</sup>. As the hairlines<sup>When cilia</sup> reach to a foundation<sup>touch something solid</sup> in the sea water, ~~germination~~<sup>attachment</sup> of the zoospore occurs. The zoospore, thus, loses the hairlines<sup>cilia</sup> and becomes round; after this, it grows a pipe-like process (germination organ) into ~~where~~<sup>which</sup> the contents of the zoospore body moves, then a new cell ~~will be~~<sup>is</sup> formed at the ~~point~~<sup>tip</sup> of the process. As the result of the division of the new cell, the cells called gametophytes successively (sometimes branched) grow forming a thready body (its size is generally microscopic, but in some cases it grows to a large size ~~to be~~<sup>as</sup> observed with ~~naked~~<sup>the</sup> eyes). There are two types of gametophyte<sup>s</sup>: a male gametophyte having thinner, longer, and more cells and a female gametophyte<sup>s</sup> having fatter, shorter, and ~~less~~<sup>fewer</sup> cells. When they ripen, the former will have an antheridium and the latter an oogonium. One male gametophyte produces numerous antheridia ~~on it~~<sup>on its</sup>, which are seen as a racemose shape sometimes; each antheridium produces one antherozoid, which has a similar shape to that of <sup>a</sup> zoospore. The oogonium is formed at the ~~point~~<sup>tip</sup> of the female gametophyte or by extending newly divided cells to a ~~bat-like~~<sup>club</sup> form; each oogonium has one egg. ~~Staying~~<sup>Remaining</sup> in the female gametophyte, the egg is fertilized with an antherozoid which is swimming in the sea water and germinates (a sporophyl is called a sporophyte when it is microscopic <sup>in</sup> size and consists of a single layer of cells). At the beginning, the sporophyl ~~stays~~<sup>remain</sup> on the foundation

by means of a rhizoid which is an extension of cells at the base of sporophyll, then it grows a stem; subsequently the cells of the sporophyll become multi-layer<sup>s</sup> around the border of their stem and frond. The sporophyll becomes a lanceolate or oval single young-frond with a complete histology until the sporophyll grows to several centimeters<sup>in</sup> length. ~~Around~~<sup>about</sup> this time the stem of the sporophyll also has a complete histology and the sporophyll grows fibri-form roots around its base so that it sticks to the foundation (Refer to Plate I). Then the sporophyll grows at its growing region at the boundary of stem and frond; the growing region will have comb-like leaves on both sides; the comb-like leaves grow to the<sup>larger</sup> fronds as the body length of the sporophyll grows. The grow<sup>ing</sup> frond ripens to have the reproduction<sup>develops</sup> fronds, dispatches zoospores, falls, and ends its life. Undaria-pinnatifida has this life history, however, time of its ripeness and growth differ in each sea district because of its wide occurrence. Nevertheless, according to the detail<sup>s</sup> studies by the fisheries experiment stations in each state (ken), water temperatures are about same at the time of releasing zoospore<sup>s</sup>; the appearance of sporophyll, and growing<sup>th</sup>. The relation<sup>ship between</sup> among the ecology, water temperature, and time(month) is diagrammatically shown in Table 4 for northern and middle-southern sea districts, respectively.

The reproduction<sup>ve</sup> fronds start to grow without the relation to the water temperature, however, releasing<sup>s</sup> zoospores begins above 14°C of the 10-day average temperature, continues up to about 22°C, and is most active between 17 and 22°C. Experimental results in an indoor water current shows that releasing zoospore<sup>s</sup> has a clear-peak once a day and ~~in~~<sup>at</sup> other time the number of zoospores released is small. The number of zoospores released in one

Table 4. Ecology of Undaria pinnatifida

Arabic on a loop indicates a month in the northern sea district;  
Roman in the middle-southern sea district.

peak is 100,000 to 1,000,000 per one gram of ripe part of the reproduction<sup>ves</sup> frond; only one day per three days or more, one to ten millions are released. The peak frequently appears between 9 a.m. and 4 p.m., but not between 0 a.m. and 9 a.m. The time of appearance of the peak changes from sample to sample; generally the peak disappears within two hours. The direct observation<sup>≡</sup> of the release of zoospores has not been reported in the natural sea; however, a similar phenomenon is supposed and a large quantity release (one to ten millions) is expected <sup>in</sup> at a four- to five-day period. The large quantity release has not been observed in two- to three-days<sup>plus 2-3</sup> after bad weather; re-releasing period of one reproduction<sup>ves</sup> frond is 20 to 40 days. When released zoospores contact ~~with~~ <sup>SUBSTRATE</sup> a foundation in the sea water, <sup>but</sup> most of them swim along the surface of the <sup>SUBSTRATE</sup> foundation and move against the water current. Along a glass surface they can <sup>with</sup> stand up to 8 cm/sec of a water current; some of them are washed <sup>away</sup> down above 8 cm/sec; all of them are completely washed <sup>away</sup> down at 14 cm/sec. On the other hand, when the zoospores have no chance to contact ~~with~~ <sup>SUBSTRATE</sup> a foundation, they swim continuously for a long time (1 - 2 days). However, their swimming area is small; their swimming directions are at random; they don't have any light tendency. Therefore, zoospores are accidentally <sup>caused</sup> ~~flow~~ to <sup>the region</sup> neighbour of a <sup>substrate</sup> foundation by the water current, then they swim to germinate on it. The swimming <sup>period</sup> ~~hour~~ and the efficiency of germination depend upon the temperature, the specific gravity, and pH of the sea water: generally at a higher water temperature and in the sea water with lower specific gravity, the swimming <sup>period</sup> ~~hour~~ is short; a good efficiency of germination is observed at or below 20°C of water temperature and in the sea water with 20 or more of specific gravity (at 15°C); an extremely weak efficiency at or above 25°C and with or lower than 10.

Zoospores germinated become gametophytes. The germination and the growth of the gametophytes are best at 17 - 20°C, but above 27°C the germination doesn't occur. The gametophytes grow at a temperature of up to 23°C; at above 23°C they stop <sup>growing</sup> to grow; their cells become round and cell walls become thick; they get into resting stage. The resting gametophytes can bear a high water temperature <sup>withstand</sup> like 30°C <sup>such as</sup> (See Plate I. B and C). Concerning the specific gravity of the sea water, the germination and the growth of zoospores are active in the sea water with <sup>22 - 24</sup> of specific gravity; those are extremely poor with lower than 12; at higher water temperatures these are poor with 20 or below. The effect of light on the germination and the growth of zoospores also depend upon water temperature: at or below 20°C the growth is better <sup>on</sup> in brighter days (clear, daylight average 2,000 - 6,000 luxes); at a higher water temperature the germination prefers weaker light (below 1,000 luxes around 28°C).

The ripeness of gametophytes and the germination of sporophytes occur below 20°C and the growth of sporophyte is good below 17°C. Under a bright light, the ripeness of gametophytes, the germination and the growth of sporophytes are active, but under a dark light (below 150 lux) even the ripeness doesn't occur. In ~~the~~ sea water with below 20 of a specific gravity, the ripeness, the germination, and the growth become slow. Moreover, the ripeness of gametophytes is likely relating <sup>ed</sup> to the length of daylight, probably a short daylight (8 - 12 hours) affects ~~the~~ ripeness.

According to the results of <sup>from</sup> an indoor culture, an egg cell moves to a pointed <sup>tip</sup> edge of an oogonium and is fertilized; the egg cell germinates to sporophyte as staying on the pointed <sup>tip</sup> edge (Plate I, D); cells at the

base of sporophyte grow to be a rhizoid; the sporophyte sticks to a <sup>substrate</sup> foundation by means of the rhizoid. The egg cell ~~so~~ seldom germinates away from its oögonium. Although the reproduction of Undaria pinnatifida has been supposed to be <sup>caused out</sup> preceded only by its zoospores, the effect-determination-  
 10 study of the fisheries propagation industry or other experimental results show that Undaria pinnatifida occurs in the growing period of the following year on the stones and on the foundations which were thrown into the sea  
 11 and the place where reef-blastings were performed, when the time is not a zoospore releasing period. This indicates that the reproduction of Undaria pinnatifida is <sup>caused out</sup> preceded by something <sup>other</sup> rather than zoospores. The result of ~~an~~ indoor experiments revealed that the gametophytes in a resting stage are easily removed from a foundation and they ~~hardly~~ <sup>attach to</sup> germinate on it again without any conditional change. At a lower water temperature the gametophytes are not removed easily; very few gametophytes are removed by the water current of 3 cm/sec. On the contrary, the gametophytes removed artificially <sup>attach</sup> germinate easily again and also the gametophytes, <sup>when</sup> which removed naturally from the <sup>substrate</sup> foundation at a higher water temperature and are floating, can easily <sup>attach</sup> germinate again when the water temperature comes down. Fertilized egg cells and sporophytes which do not <sup>yet</sup> have rhizoids are <sup>hardly</sup> removed <sup>able</sup> from the pointed edges <sup>tips</sup> of their oögonium by a weak water current, however, when some of them are removed, they germinate well. It is hard to conclude that the results of these indoor experiments are quite similar to the situation of the reproduction of Undaria pinnatifida in the natural sea, but these phenomena might occur in nature.

As for the growth of the frond of Undaria pinnatifida, its natural condition has not yet been revealed because of few observation<sup>s</sup> reports,

Date cultivation began: X - Sept. 14; ⊙ - Oct. 25; △ - Nov. 21; □ - Dec. 14, 1956.
- B. Cultivated in Matsushima Bay, Miyagi-ken (1952 - 1953), after Kuroki and Akiyama, Tohoku Sea District Fisheries Experiment Station (cf. Bibliography).  
Date cultivation began: ○ - Aug. 12; ⊙ - Sept. 27; △ - Nov. 14; ⊠ - Dec. 16, 1952; □ - Jan. 19; ⊠ - Feb. 19; ⊙ - Mar. 17, 1953.

nevertheless, the following phenomena are known by cultivation experiments. Two examples of the relation <sup>between</sup> growth, water temperature, and time are shown in Fig. 2. The young fronds (sporophyl) <sup>at the stage of</sup> sporophytes <sup>from</sup> and a single leaf <sup>with</sup> grow over entire fronds; this growth is good in the water temperature range of 15 - 17°C, slow below the temperature range, and extremely slow below 10°C. The growing region of the young frond moves to the boundary between its stem and frond and the young frond has a midrib and comb-like leaf. The growth of the young Undaria pinnatifida is good below 12 - 13°C; the growth is comparatively good up to 15°C; the rate of growth becomes very slow above 15°C; the growth is extremely little but still exists at about 20°C. <sup>penetration</sup> Lightness in the sea water, which depends upon the insolation, the transparency of the sea water, and the depth of the sea also governs the growth of Undaria pinnatifida. Probably, not only lightness but also period of sun shine affects the growth. The lightness and the water temperature correlate <sup>with</sup> on the growth of Undaria pinnatifida: it grows well <sup>in</sup> at less-lighted area (deeper area) when the water temperature is high, or <sup>in</sup> at well-lighted area (shallow area) when the temperature is low. Fig. 3 shows the relation between the water depth where Undaria pinnatifida is <sup>or</sup> cultivated and the growth of Undaria pinnatifida which are germinated <sup>at</sup> in different times (seedlings whose growth were controlled to a similar degree were transplanted from a pilot plant to the sea to be cultivated). The figure shows the correlation of <sup>between</sup> the lightness and the water temperature, mentioned above.

When the upper part of the frond of Undaria pinnatifida is cut off leaving the main growing region at the boundary between the stem and the

frond to its stump and when the stump is large enough to grow, it re-grows well. The relation among the re-growth, water temperature, and lightness in the sea is similar to that of the initial growth of the frond. This can be seen in Plat II. D and E.

Undaria pinnatifida occurs forming a sheaf (several fronds grow<sup>ing</sup> at a point) or a group. When Undaria pinnatifida grows in a small area, several groups are formed according to the different<sup>ial</sup> growth: a group showing the best and fastest growth grows well without any relation to the growth density in the area; a group showing slower growth is affected by the growth density and the group always has many small fronds. This phenomenon can be seen when it is observed in a very small area. On the contrary, if it is observed in a large area the growth density affects the water current and other circumstances and the growth of Undaria pinnatifida will be different in each area (c.f. Fig. 7).

Figure 3. Relation <sup>between</sup> among the growth of Undaria pinnatifida, the water depth, and the germination time. (Designations and the water temperature are referred to Fig. 2, A)

Broken lines indicate the unusual growth, which are caused by the mechanical interference or by the extremely delayed germination time, in those water depth.

As mentioned previously, the frond shape of Undaria pinnatifida is briefly classified into northern and southern types, besides other characteristic shapes in different areas. Not only the frond shape but also the degree of growth,  $\lambda$  color, and the softness of frond show characteristics in each area. These properties, naturally, would be altered with the circumstances in the area, where Undaria pinnatifida grows. However, some properties show little change when circumstances are <sup>greatly</sup> largely changed. Experimental results which Undaria pinnatifida from different origins are cultivated in <sup>one</sup> station are shown in Table 5-1. In Table 5-2, the comparison between natural and cultivated Undaria pinnatifida, which are obtained from the same origin, is shown. The tables indicate that the shape of a young frond,  $\lambda$ /stem length to  $\lambda$ ' frond length, and the degree of growth show characteristics of the originals. This observation does not change until at least the third generation in cultivation; these properties are thought hereditary. Quality of Undaria pinnatifida <sup>is</sup> are not yet clear because of few experimental data, however, <sup>there is</sup> they ~~seem to~~ have a tendency that the thickness and the softness of a frond vary little but the color ~~of a frond~~ varies greatly in the different circumstances.

## Cultivation

The purpose of the cultivation of Undaria pinnatifida is to intensify the fishery and to stabilize its management. The cultivation cannot take the place of harvesting the natural Undaria pinnatifida, because the natural produce is very <sup>rich</sup> ~~large~~, therefore, to practice the cultivation industry one should work <sup>to</sup> for stabilizing his management by clarifying the purpose and the goal of the cultivation. When the cultivation is performed, ~~with an~~ <sup>of</sup> industrial size, the goal of the cultivation will be changed according to the circumstances: the cultivation as a seasonal principal occupation or the cultivation as a side occupation, and the ~~area~~ special problems as to the different locations. In case of the principal occupation or very close to the principal occupation, generally it is necessary to aim the following things for the cultivation of Undaria pinnatifida:

(1) Early harvest --- Prices of Undaria pinnatifida greatly differ from early season to late. In the early season the quality is excellent and the production is small, so the price is high. Afterwards, the price, which is quite changeable <sup>according to</sup> by the quality and quantity of the produce, generally decreases. Therefore, the cultivation of Undaria pinnatifida should be cultured early and harvested early so that the ~~cultivated~~ <sup>it</sup> produce can be harvested before or in the early season of the natural production, when the price is not governed by the natural rich or poor harvest <sup>of the natural product</sup>.

(2) Mass cultivation and improvement of the quality --- The growth and the quality of Undaria pinnatifida are affected by the environment conditions at the cultivation ground. As mentioned in the previous chapter,

the shape and the quality of the original species are kept well, therefore, the cultivation should use good original species having the good growth and the good quality which are proper to the secondary use so that the high earnings may be expected. For that purpose, it is necessary to cross or transplant the proper Undaria pinnatifida to the environment of the cultivation ground.

(3) Marketing --- If the cultivated Undaria pinnatifida is utilized to manufacture products which is similar to the products made <sup>from</sup> of natural Undaria pinnatifida and if the products made of cultivated Undaria pinnatifida are sold on the same market route with those made of the natural products, excepting the early harvest, <sup>u</sup> cultivated products are overwhelmed by the natural products and cannot <sup>result in</sup> make good earnings. Even if the special market such as selling the raw or wet produce is opened, when the amount of the cultivated products exceeds a definite quantity, <sup>an</sup> expected earnings cannot always be obtained. Therefore, a cultivator should always try to <sup>develop</sup> make new secondary products and to open the new market. He must also try to cultivate Undaria pinnatifida with proper quality <sup>for his</sup> <sup>specific</sup> purposes.

In case the cultivation is taken up as a side occupation, a cultivator must consider the ecology of Undaria pinnatifida as well as the changes of the environment conditions of the cultivation ground, what is more, he should consider the allocation of the labor for the principal occupation in an effort to perform the <sup>reasonable</sup> management. The techniques of the cultivation are described below. In any case, the most important thing is to understand the relation between the ecology of Undaria pinnatifida and the varieties of the environment conditions of the cultivation ground.

1) Sporing (seeding)

In the northern sea coast the sporing of Undaria pinnatifida is sometimes operated directly on cultivation beds, however, in most cases the sporing is done on proper seedling beds which are convenient to culture seedlings. Materials for the beds are as follows:

For cultivation by direct sporing --- timbers of pine, Japanese oak, etc., ropes (2 cm or more in diameter) made of wisteria vines, palms, or rice straws, split bamboo.

For seedling; outdoor culture --- palm ropes, coil-yarns (3 - 5 mm in diameter).

For seedling; indoor culture --- fiber yarn made of Vinylon or its family: polyvinyl alcohol, (No. 20 count, 36 to 45 yarns in a three-plying thread, etc.), porous tubings or plates, shell.

Among these bed materials, most kinds of ropes are used for the seedling culture. The ropes are popular as "seedling ropes." As for the seedling culture techniques the seedling ropes will be described in detail. For convenience of care requirement the seedling ropes are prepared in the seedling devices as shown in Fig. 4. A frame type (1) is common, but for outdoor culture types (2) and (3) are better because of the large amount of miscellaneous germinations. In case of the small amount of culture, hanks of ropes, only by decreasing the overlaps of the ropes, can be used for the sporing and the culture.

When a ten-day average water temperature is 14 to 22°C which is the zoospore releasing temperature, the sporeling may be performed any time, however, for the best result for the shortening of the culture period and also for the growth of gametophytes, the water temperature 20°C, the most

active zoospore releasing time, should be chosen.

The selection and the amount of the reproduction frond of Undaria pinnatifida should be carefully prepared. At the time mentioned above most of the reproduction fronds is well ripe, but it is not known whether the release of the huge amount of zoospores occurs on that day when the seedling ropes are set. Avoiding the time just after the bad weather, a cultivator should select the reproduction fronds which are larger, thicker, brown or dark brown, especially dark-colored edges, softer, and rich with a viscous liquid in order to expect the huge amount of release (about 1/2 to 1/3 of the reproduction fronds prepared will release a huge amount of zoospores). The reproduction fronds which are yellow-brown, hard, and poor with the viscous liquid finished their zoospore release. The number of the reproduction fronds prepared can be determined by using the following equation:

$$A \times B \times \frac{1}{10^6} \times \frac{2-3}{10} = N$$

where N: number of reproduction frond to be prepared

A: number of zoospores germinated per 1 cm of a seedling rope

B: length of a seedling rope (cm).

Fig. 4. Seedling devices for Undaria pinnatifida

According to the above equation, when A is 1000, several reproduction fronds per 100 m of B are enough to prepare and if the culture is in a good condition, at least ten germinations are observed per 1 cm of a seedling rope.

Upon the <sup>isolation</sup> sporing of Undaria pinnatifida the important thing is to prepare the sea water with a dense liquid of zoospores. To do this, it is recommended to <sup>that the reproduction</sup> minimize the quantity of sea water to be used and to let <sup>the</sup> the reproduction fronds release their zoospores at one time by drying the reproduction fronds in the shade in advance. Time for the drying, which depends on weather, is about one to several hours, which are just enough to dry up water on the surfaces of the reproduction fronds by spreading them flatly in the airy and cool shade. If the reproduction fronds change their color to green or droop, they are over dried.

Procedure of the <sup>isolation</sup> sporing is as follows. A proper quantity of sea water is poured into a container so that the materials may be just covered with the sea water when the materials for the sporing bed (seedling rope) is dipped into the container (the materials may be placed in the container first and then sea water can be poured into the container as an alternate way). The sea water should be clean and fresh. Its density should be 20 or more. The temperature is preferably 20°C or lower and should not be 23°C or more during the sporing. The place for the <sup>isolation</sup> sporing is preferably <sup>a</sup> the light place but not under the direct sun light. Reproduction fronds dried in <sup>a</sup> shade in advance are dipped into the sea water for a quick wash and immersed into the container. Zoospores begin to be released into the sea water <sup>about</sup> around five minutes after the immersion. As the releasing zoospores becomes active, (ten to fifteen minutes later) the sea water turns pale

brown or yellow brown. At this time, if the small amount of the sea water is examined microscopically, actively swimming zoospores can be observed. Then the materials for the sporing bed are immersed into the container. By slowly stirring them occasionally or by turning over the materials, the zoospores are uniformly attached to the material. In 20 to 30 minutes after the immersion of the reproduction fronds into the sea water, the reproduction fronds finish the release of their zoospores for that day and afterwards they deteriorate the quality of the sea water by pouring out a viscous liquid from their breaks. The reproduction fronds should be taken out of the container at 30 minutes after their immersion. The materials for the sporing keep immersed in the container for a while so that the enough amount of zoospores germinate on them. In 40 to 60 minutes after the beginning of the sporing, the sea water is slowly changed with fresh sea water, or the materials is replaced into another container filled with fresh sea water, or the material is dipped into sea. The sporing of Undaria pinnatifida ends. In case the seedling device is left in the sea water where the sporing was done, the zoospores germinated in the device will be weakened, because the sea water contains a viscous liquid bearing tannin, dirt, and other substances. For the reason mentioned above the seedling device must be removed into a fresh sea water after the sporing. When a glass plate is immersed into the container where sporing is progressing, the glass plate will help observing the germination and the growth of zoospores.

In case of a direct sporing on cultivation materials, the timing of sporing and the selection of reproduction fronds (larger number is better) are similar to the previous method. The procedure is as follows. Reproduction fronds are directly inserted into cultivation ropes, which are called

main ropes, with 30 cm spacing and the cultivation ropes are set in the sea. An alternate way is that <sup>in addition</sup> the reproduction fronds <sup>via</sup> which are inserted into ropes made of rice-straw <sup>which is better</sup> are set in the sea along with materials for the cultivation. Drying the reproduction fronds in the shade is thought to be effective, however, if a release of zoospores occurs before the cultivation materials becomes dirty, all requirements for the sporing are satisfied, therefore the drying is unlikely to be effective.

## 2) Culture of seedling

There are two methods of the culture of Undaria pinnatifida seedlings: the sea culture (outdoor) <sup>or</sup> which set the seedling ropes <sup>as net</sup> in the sea, and the indoor culture which are performed in a tank or in a proper container. The former has several merits such as simple facilities and utilizing the seedling ropes made of low priced natural fiber, on the contrary, this method has a couple of weak points such as the risk of washed-away and <sup>attachment</sup> germination of the miscellaneous <sup>organisms</sup> livings and the dirt on the seedling ropes. This method is <sup>of little value</sup> improper in the middle southern Honshu, where <sup>its</sup> water temperatures are comparatively high and the <sup>period</sup> of ~~the seedling~~ is long, and many miscellaneous <sup>attachment</sup> germinations exist; this method is practiced only in the northern area. However, even in the middle southern Honshu the former method is not impossible by preventing the <sup>ments</sup> attachings of miscellaneous <sup>organisms</sup> germination on the seedling rope. For example by sealing the seedling ropes, the filtered sea water, and the air in a strong polyethylene bag (the amount of air is adjusted to float the bag), the miscellaneous <sup>attachment</sup> germinations can be prevented. The bags are <sup>hung</sup> hanged from a raft by means of a rope; the water depth for the bag is adjusted by a weight balance.

The latter requires <sup>facilities</sup> facilities in most cases. Another weak point of this method is the seedling ropes made of natural fiber cannot be used, because the culture of Undaria pinnatifida seedlings is performed with a small quantity of sea water. The several merits of this method are <sup>the</sup> the water temperature, the light, and the nutrients are controlled artificially; the method can be practiced in any area and is especially good in the middle southern Honshu. In some cases a culture room is specially built as one of the facilities. The lighting and the ventilation of the room should be carefully considered; the lighting should avoid the direct sun light (a semitransparent glass or a plastics plate are used <sup>to</sup> to shade); the lighting is similar to the light at the sea surface during the daytime <sup>of</sup> of a fine day and should be adjustable over the range of 300 to 10,000 luxes according to the time. A water tank for the culture is made of wood or concrete, <sup>but</sup> but which must not contaminate the sea water in it. The depth of the water tank is preferably up to 80 cm to decrease difference in the light at the top and the bottom of the sea water in the tank. Moreover, a skylight is preferably installed above the water tank (despite <sup>of</sup> of the skylight, difference in the growth of seedlings exists, therefore, the interchange of the sporing devices resting the top and the bottom of the tank is necessary). The maximum water temperature in the water tank is preferably up to 28°C with a good ventilation. A sea water flow or circulation device or a water temperature regulator is not necessary, but <sup>acceptable</sup> if the water tank is equipped with them, it is very favourable. For a small quantity of culture, a small water tank made of glass or wood (a polyethylene sheet is placed in it for better results) is used; the small water tank is moved to proper places to adjust the conditions for the culture depending on the time; in some

stations ditches are used to place the small water tank.

The stage of culture is classified into three, the initial, the middle, and the final, according to the degree of the growth of Undaria pinnatifida; each stage has its own method to control the culture.

The initial stage is about 10 to 20 days after the sporing; this stage is the period to grow zoospores germinated on seedling ropes to the gametophytes. The water temperature in this period is preferably 20°C or lower and should not be 23°C or higher. The light, 2000 to 6000 luxes, is needed. Accordingly, in case of the indoor culture, the water temperature should be minded, the direct sun light should be avoided, but the room kept lighted, and the seedling devices should be interchanged up and down occasionally. In some cases, 0.1 g of sodium nitrate and 0.02 g of sodium phosphate per one liter of the sea water are added as nutritive salts into the culture tank. In case of the sea culture (outdoor), the seedling devices are generally set in shallow sea water. After 10 to 20 days under these conditions a male gametophyte will be 5 to 10 cells, female 3 to 5, thus the initial stage of the culture is over. However, if the gametophytes are left under the good condition, they grow long and in some cases they will ripen to grow sporophytes. These gametophytes often result useless, because the longer gametophytes easily drop off from their seedling ropes in the middle stage. When the good conditions still continue, it is better to depress the growth of the gametophytes by reducing the light. For the seedling, the gametophyte may be only one cell, but judging from the experiments, to grow a gametophyte to the size mentioned above is recommended.

The middle stage is the period of high water temperature; the stage requires a good control to keep a high survival ratio of seedlings of Undaria

pinnatifida. Accordingly, the stage does not exist in the northern sea district where the water temperature is low or even if it exists, it's out of consideration for the very short period of time. On getting the stage, the light must be reduced in proportion to the increase of the water temperature. Gametophytes rest at about  $24^{\circ}\text{C}$  or higher of the water temperature and some of them will die at about  $28^{\circ}\text{C}$  or higher, therefore, keeping the water temperature between  $25$  and  $26^{\circ}\text{C}$  is ideal. The light for ~~the~~ good survival ratio is 1000 luxes or less at  $25$  to  $26^{\circ}\text{C}$  and 200 to 500 luxes at  $27^{\circ}\text{C}$  or higher. The density of the water largely affects ~~on~~ the growth of the gametophytes at the high water temperature; the density is preferably kept at 20 or more. Concerning ~~to~~ the sea water change of the indoor culture at the middle stage, it may be better that the sea water change is not performed unless the quality of the sea water has been deteriorated, because the resting gametophytes easily drop off from the seedling ropes. If the dropping-off is few, changing a whole or one-third of the sea water per day by the water-flow or circulation device prevents the increase of the water temperature and likely results in a high <sup>survival</sup> ratio. In the sea culture (outdoor), the seedling devices are set in a deep place at the initial stage and the depth is not definite. They ~~are~~ depending on the conditions of the culture ground. The middle stage is the period <sup>during</sup> which gets many miscellaneous <sup>organisms attach</sup> livings on the seedling ropes, the light as well as the water depth which gets least <sup>fouling</sup> miscellaneous-livings must be determined. The kind and the amount of the <sup>organisms</sup> ~~livings~~-germinated on the seedling ropes <sup>is</sup> are different in each area, seasons, and the water depth: in the northern area they are mussels, Mytilus edulis, and Polyzoa or Bryozoa; in the middle southern area barnacles, ascidians, and Polyzoa or Bryozoa. The livings <sup>organisms</sup>

which cover tightly and perfectly the surfaces of the seedling devices kill the seedlings; they should be kept away from the seedling devices.

The final stage is the period<sup>in</sup> which gametophytes ripen and grow sporophytes and the seedlings of Undaria pinnatifida are completed. If the cultivation of Undaria pinnatifida is begun and developed at the progressing stage of the seedlings, the fertilization ratio decreases and the growth of sporophylls<sup>is</sup> ~~are~~ often unsatisfactory. The finished seedlings are those which at least grow sporophytes or sporophylls which can be observed by the naked eyes<sup>is</sup>. The first step<sup>in</sup> for the control of the seedlings at this stage is to increase the light gradually from 2000 to 4000 luxes when the water temperature reaches to about 23°C or lower. Under these conditions the resting gametophytes begin their re-growth and ripen at about 20°C, and grow to sporophylls. ~~While~~<sup>When</sup> the sporophytes are seen the light should be increased again to 4000 to 10000 luxes. At the beginning of the final stage of the indoor culture that the sea water change has not been performed through the summer, ripeness of the gametophytes and the growth to sporophytes can be promoted by performing the sea water change or circulation, or by adding the nutritive salt (same<sup>as</sup> to those for the initial stage). Despite of an adequate sea water temperature for ~~the~~ cultivation, if decreasing the water temperature<sup>in the</sup> of culture tank delays and if the ripeness of the gametophytes and the growth to sporophytes<sup>is</sup> delay<sup>is</sup>, the water temperature must be artificially lowered to about 20°C to promote the growth of seedlings. The ripeness of the gametophytes and the growth to sporophytes are retarded<sup>is</sup> sometimes in spite of these controls. In this case, if the water temperature in the sea is about 22°C or lower,

the ripeness and the growth are promoted by setting a <sup>u</sup>bundle of the seedling devices in ~~the~~ shallow <sup>water</sup> sea. (This procedure is called a ripeness operation or a sporophyte operation). In ~~the~~ indoor culture, when the sporophytes grow about 100 to 1000 micron<sup>s</sup>, their growth terminates in most cases. In the northern area the sporophytes easily grow to sporophylls observable by the naked eyes in a culture tank; in the middle southern area this is difficult. If the water temperature in the sea is 20°C or lower at this time, the seedling devices are preferably set in the sea. The seedlings which have been cultured in the sea (outdoor culture) are reset in shallower depth according to the decreasing<sup>e</sup> of the water temperature in the sea. The seedlings which have been cultured in a polyethylene bag are taken out of the bag and are reset directly in the sea when the water temperature reached<sup>s</sup> to 20 to 22°C.

<sup>s</sup>Timing to start the cultivation and the degree of growth of the seedlings will be mentioned later.

In any case the seedlings which ~~fit~~<sup>match</sup> to the water temperature of the beginning of cultivation should have been cultured.

### 3) Cultivation

(a) Selection of the cultivation ground. The cultivation ground may be the <sup>areas</sup> places, where Undaria pinnatifida grows naturally, or ~~any other~~ places where it does not grow naturally, but the reasons why it doesn't are clear and they can be removed artificially. There are several limits for the effective cultivation.

(1) Water temperature. Undaria pinnatifida grows even at 15°C or higher of the water temperature; the seaweed grows well below that temperature,

especially at 10°C or lower (c.f. the chapter of the ecology; the minimum ~~of the~~ adequate water temperature is about 5°C for ten-day average). The longer the period at 15°C or lower, the more <sup>suitable</sup> effective for ~~the~~ cultivation. Where the low temperature period is long Undaria pinnatifida grows well.

Thinning and <sup>tiny</sup> cut harvests are possible and a larger produce<sup>tion</sup> can be expected.

(2) Water density. The fronds of Undaria pinnatifida can <sup>withstand</sup> bear with a <sup>area</sup> very decreased specific gravity of the sea water, but ~~the place~~ <sup>is</sup> ~~is~~ <sup>is</sup> 15 or lower for long periods is unsatisfactory or ~~is always or for a long period 15 or lower is inadequate.~~

(3) Nutritive substances. <sup>Requirements of</sup> Nutritive substances for the growth of the seaweed may be very <sup>slight</sup> little. The concentrations of the nutritive salts, which are the <sup>necessary</sup> necessities for the better growth and the better quality of the fronds of the seaweed, <sup>may be</sup> are hardly determined. Generally speaking, the good concentrations can be found where the ocean water and the bay

water meet rather than the ~~cultivation ground~~ where the ocean water washes ~~the~~ <sup>cultivation grounds</sup> directly.

(4) Water current. As the water current in the cultivation ground affects the supply of nutritive substances and the gas exchanges by ~~the~~ assimilation and ~~the~~ respiration, the water current is a very important factor for the growth and ~~the~~ quality of Undaria pinnatifida. The water current relates to many other conditions. As it has not been studied so much, an <sup>adequate</sup> proper velocity of the water current is still unknown. With the exception of <sup>areas</sup> ~~the place~~ like a strait where the water current is extremely fast, generally, ~~the~~ places with a moderate <sup>ly</sup> fast water current are preferred. The current is commonly obtainable in a bay or <sup>on</sup> at a coast. The velocity of the water current and the <sup>a action</sup> ~~waves~~ are not ~~only~~ the factors for the selection of the cultivation ground but also the factors for the determination of the method, the size, and the density of the cultivation.

(5) Water depth and sea bottom. The water depth in the cultivation ground will be discussed in detail later. Although the water depth depends upon the cultivation method and the sea bottom, it is preferred <sup>able</sup> to ~~measure more~~ <sup>have a depth</sup> than one meter <sup>for</sup> ~~from~~ an adequate depth for the cultivation <sup>on</sup> ~~to~~ the sea bottom. In some cases the quality of the sea bottom limits the cultivation facilities. <sup>Generally</sup> ~~It~~ has no relation to the cultivation.

(b) Cultivation facilities. The cultivation facilities for Undaria pinnatifida are devised in many forms at each cultivation ground all over the country. Here, the major methods are taken up and explained briefly (Structures and specifications of the facilities shown in the following figures are only standard. Actually there are too many ways. It is necessary to devise proper ways for the circumstances of each cultivation ground).

(1) Preparation of main ropes. Undaria pinnatifida grows as it holds the foundation with its fibriform roots. When the base of the frond of the seaweed is not firm because of the improper holding of the foundation, the growth of the seaweed is poor. The cultivation requires <sup>a</sup> ~~the~~ foundation <sup>to which</sup> that the roots hold well and the fronds become stable. Accordingly, the direct sporing culture method performs the cultivation by <sup>allowing</sup> ~~springing~~ on a larger gauge rope. For the seedling method, the seedling ropes with a smaller gauge are mostly employed for ~~the~~ <sup>the</sup> conveniences. Therefore, the seedling ropes must be set on the ropes with larger gauge, stones, or concrete blocks to give the seedlings a sound foundation. The ropes with a large gauge are usually employed; they are called the main ropes. The main ropes are 10 to 30 mm in diameter and are made of rice <sup>a</sup> ~~straws~~, manila (these two are dyed with coal tar in some cases), hemp palms, palms, or

synthetic fibers. There are two ways, winding and inserting, to attach the seedling ropes to the main ropes as shown in Fig. 5.

Fig. 5. The methods to attach the seedling ropes to the main ropes.

Winding --- This method winds the seedling ropes around the main ropes with or against the twists of the main ropes. The winding interval is commonly one wind of the seedling rope per 10 to 15 cm of the main rope. This method gets Undaria pinnatifida on the main rope continuously. When a number of the germination<sup>s</sup> is small on the seedling rope, the winding method is proper. When a number of the germination<sup>s</sup> is large, this method causes a waste of the seedlings because of the high density of the seedlings. The winding method also requires long seedling ropes (the length depends on the <sup>method</sup> way of winding. The length of the seedling rope is required to be 1.1 to 1.2 times that of the main rope). The method is not suited to begin an early cultivation at a cultivation ground where <sup>there is much salt</sup> the dirt is much and the water current and waving are less. The germination of sporophytes sometimes is impeded when the water temperature is too high or the growth of the seedlings is delayed, or much dirt attaches to the main ropes.

Inserting --- The seedling rope is cut at the length of about 2 cm longer than the diameter of the main rope to be used; the cut is commonly 3 to 5 cm; the cuts are inserted in the main rope at ~~the~~ intervals of about 15 cm. The ways of inserting are shown in Fig. 5. The merits of inserting are that <sup>reduced</sup> less amount of the seedling rope is required (25 to 30 m per 100 m of the main rope) and that the germination of sporophytes is favorable even at a dirty cultivation ground. A low labour efficiency is the weak point of the method. When the cuts of the seedling rope are too long, Undaria pinnatifida will not be firmly <sup>held</sup> held on the main rope. The seedlings are scratched off from the seedling rope during the insertion, so the special <sup>care</sup> cautions are needed for the inserting.

In either ways, the seedlings are very weak <sup>if dried</sup> against dryness (under the direct sun light, they die 5 to 6 minutes after drying). To prevent this, devices and tools for these procedures should be made to improve the labour efficiency. And the main rope should be set in the sea one by one right after ~~the~~ attaching of the seedling rope.

(2) Cultivation facilities (methods). As shown in Fig. 6, there are many <sup>forms of</sup> ways in the cultivation facilities. They can be classified briefly into two groups: horizontal and vertical methods. The former sets the main ropes (or other materials) horizontally; the latter sets them vertically by hanging them down or by floating one end of the main rope with a float and the other end set near the sea bottom. Another classification is raft-, rope-, lattice-, laver rack-type, etc. One type from each classification is combined <sup>with</sup> to other types for a practical use. Generally, the horizontal method can be set in the right water-depth for the growing Undaria pinnatifida so that the growth will be uniform. At a cultivation ground where

its circumstances are changeable from time to time, the main ropes can be conveniently reset in the best water-depth for the time. <sup>In</sup> The vertical method <sup>has</sup> ~~has~~ <sup>there is</sup> a difficulty in the adjustment of the water-depth for the cultivation; the growth of Undaria pinnatifida shows <sup>a</sup> difference at the top and the bottom of the main rope. The vertical method is useful to ~~know~~ <sup>discover</sup> the best water-depth for the cultivation and shows better <sup>collection of</sup> ~~germination to~~ sporophytes and better growth of Undaria pinnatifida than those by the horizontal method at a cultivation ground where the water current and ~~waving~~ <sup>are</sup> are weak.

i. Raft type --- The raft type has a slightly large <sup>resistance</sup> ~~against~~ waves. This is good in a bay where <sup>action</sup> ~~waving~~ is less. Any number of rafts may be connected parallel to the direction of the water current. It is ~~not~~ <sup>clear</sup> preferable to connect <sup>clear</sup> perpendicular to the direction; a proper interval should be set for the connection.

Horizontal method. The rafts (called simple rafts) are made of bamboo or strong ropes; the main ropes are stretched horizontally, using bamboo floats (this is practiced all over the country, especially in Tohoku district). The interval of main ropes is commonly one meter; at a cultivation ground where the water current and the <sup>as</sup> ~~waving~~ are strong, the interval may be 0.75 m. The size of the raft is 1.5 m wide and 100 m (or 50 m) long for two lines of the main rope, 2 m wide and 50 to 60 m long for three lines, or 2.5 m wide and 50 m long for four lines. This is standard and the line is reduced <sup>in areas</sup> ~~at a place~~ with <sup>reduced wave action.</sup> ~~weak water currents and less waving.~~ The horizontal method is desirable in a ~~sea~~ district where the water-depth ~~of the cultivation~~ is shallow. On the contrary, in a sea district with

## 1. Stool --- Mie-ken

## 2. Building block --- Hyogo-ken

the deep water-depth this is not suitable, because hangers are needed between the main ropes and the bamboo floats. The main ropes also could contact each other because of a large slack <sup>in</sup> of the main rope. The horizontal method uses a net which is directly spored or tied with the main ropes on each knot of the net (Toba-shi, Mie-ken).

Vertical method. The raft may be a simple type, ~~the raft is~~ made of bamboo or timbers and drum cans as the floats in most cases. The main ropes are cut to fit the best water-depth of the cultivation and are hung with a weight at one end and about one meter apart each other (the interval should be changed depending on the water current and the waving <sup>ing</sup> at the cultivation ground). The sporing of Undaria pinnatifida is done on shells or porous ceramic plates. The shells or the plates are tied in series with a No. 8 gauge wire by spacing with the bamboo or ~~the~~ vinyl tubings of 15 to 20 cm ~~long~~ length.

ii. Rope type --- This has a small resistance against waves and is <sup>useful</sup> proper for a cultivation ground with <sup>from the</sup> high waves ~~faced to an~~ ocean. The ropes with the main ropes can be parallellled 10 m apart, ~~each other~~.

Horizontal method. Commonly one line (rarely two lines) of the main rope is set near to the sea surface or at the middle between the sea surface and the bottom with vinyl floats or drum cans as floats (Miyagi-ken, etc.). This is similar to the simple raft-horizontal method. <sup>On</sup> ~~At the~~ rocky cultivation ground a large anchor (stone, etc.) is placed at the center of the main ropes, which are extended radially (B. l., Fig. 6). The main ropes are set along the sea bottom by means of the smaller anchors which are tied at the middle and the end of each main rope (<sup>Case</sup> ~~cautions~~ should be

taken to avoid the contact between the main ropes and the bottom rock). To avoid ~~the~~ contact, the main ropes are floated in the middle water by floats in some cultivation grounds (Naruto-shi, Tokushima-ken, Hyogo-ken, etc.).

Vertical-horizontal combined method. There are two ways: floating rope type (B. 2. a, b, Fig. 6, Hamajima-cho, Mie-ken, Hyogo-ken, Iwate-ken, etc.) and sinking rope type (B. 2. C, Fig. 6, Tokushima-ken etc.). Branch ropes (made of the main rope) which are vertically hung down with ~~the~~ weights or hung up by ~~the~~ floats from a stem rope, are <sup>or</sup> major part of this method. The stem rope extended horizontally <sup>and</sup> is only utilized as the main rope in some cases, or ~~the~~ wire rope is employed instead. The stem rope is usually set near the sea surface; it is seldom set in ~~the middle~~ <sup>mid-</sup> water. The length of the branch rope depends upon the conditions of the cultivation ground as described in the raft-vertical method. The branch ropes are tied to the stem rope at intervals of about one meter; too narrow intervals or too long branch ropes causes ~~a~~ contact or ~~an~~ entanglement ~~with~~ each other. In case of the floating rope type which is set <sup>or</sup> ~~at~~ a very windy cultivation ground<sup>s</sup>, the branch ropes sometimes entangles the stem rope; this can be prevented by attaching heavier weights to the branch ropes so that one end of the branch rope, which is longer than the usual length, may ~~be reached to~~ the sea bottom or by setting the stem rope in ~~the middle~~ <sup>mid-</sup> water rather than close to the sea surface. In case of the sinking rope type, where the sea bottom is not rocky, the stem rope and the part of the branch rope (up to one meter from the sea bottom) cannot be utilized as the

main rope. In other words<sup>s</sup>, those parts cannot be utilized as the main rope. The former is <sup>satisfactory</sup> ~~proper~~ at a cultivation ground where ~~the~~ wind and ~~the~~ wave are not strong; the latter is <sup>satisfactory</sup> ~~proper~~ where the sea bottom is rocky even if the wind and the wave are strong.

iii. Square type (C, Fig. 6) --- This is a method which employs the merits of the raft-horizontal and the floating rope types and makes up <sup>for</sup> the weak points of those types; this is <sup>workable</sup> ~~proper~~ at a cultivation ground where the sea bottom is not rocky (Aichi-ken). A rope makes a square (standard, 10 m square) with floats such as glass balls, wooden barrel<sup>s</sup>, or vinyl products on the four corners. Each corner is anchored. The main ropes are horizontally set in the square so that they make a net of 1 m x 1 m or 1 m x 2 m mesh. There are two ways to set the net in the square: <sup>tying</sup> ~~tying~~ the main ropes to the square rope and hanging the net previously made of the main rope from the square rope (the latter is convenient <sup>for</sup> ~~to~~ adjust <sup>ing</sup> the water-depth ~~for the cultivation~~). One float on each corner or one more at the center of the net is enough <sup>at the start</sup> ~~in the beginning~~ of the cultivation. The number of floats is increased to prevent sinking of the net with the growth of Undaria pinnatifida on the main ropes. An alternate method of this type is as follows: the main ropes are set to make a net of 2.5 m x 2.5 m mesh and about 1.5 m long branch ropes are hung from the net at intervals of 0.5 m. This is a vertical-horizontal combination. By connecting several of these nets in series the cost of the cultivation can be ~~cut down~~, <sup>reduced</sup>.

iv. Laver rack utilization type --- This method utilizes the lower part of a supporting pole type laver rack. The main ropes are horizontally set among the poles of the laver rack at the lowest level of the tide. At a cultivation ground where the sea bottom is muddy or sandy, the main ropes

are preferably set at more than 0.5 m above the sea bottom (D. 1., Fig. 6, Aichi-ken, Tokyo-to, etc.). In the Sea of Ariake, Nagasaki-ken, a net with 40 to 50 cm mesh is made of the ropes with 10.6 mm in diameter and with a hard twist; the main ropes are tied to each knot of the net; the net will be set so that the net can be moved up and down with the tide. The cultivation is done successfully at the water depth where the net can be seen above the sea surface only at the night of a major tide (D. 2., Fig. 6).

v. Others --- None of <sup>the</sup> previously mentioned cultivation methods can be practiced at some cultivation grounds <sup>because</sup> for their own special circumstances. If they have the rocky sea bottom, the cultivation of Undaria pinnatifida is possible by the methods mentioned below. These methods are somewhat inconvenient to control <sup>and</sup> and cannot be said to be the perfect <sup>method of</sup> cultivation. The cultivation facilities cannot be taken ~~out~~ from the water and are not adequate for a midterm harvest. In some area<sup>s</sup>, these methods can still get <sup>a</sup> better harvest than ~~the~~ cutting the natural Undaria pinnatifida; these are desirable for ~~an~~ union-unit management rather than private ones.

Net type. Sporing is applied directly to an old net of the laver cultivation; the net is set on the rock so that Undaria pinnatifida can grow on the rock and the net. The method has been practiced in Aichi-ken. Recently, the method is improved: 10 m x 10 m or 10 m x 5 m of net with a large mesh (0.6 to 0.9 m) is made of a large gauge rope (4, 6, or 9 mm in diameter) similar to that of the square type (the net made of 9 mm in diameter rope may be used for the square type cultivation); sporing is practiced directly on the net, or <sup>tying</sup> ~~tying~~ the main ropes to each knot of the net, <sup>which</sup> ~~then, the net~~ is set on the rock for the cultivation. Nets for this purpose are commercially available.

Concrete block type (E. 1, 2, Fig. 6). The main ropes are wound around the concrete blocks of many different shapes and sizes (cautions should be taken to prevent damage of the main rope from the abrasion or the dropping of seedlings). The concrete blocks should be between the rocks so that they may not be moved. This method is not impossible even at ~~the~~ places where the sea bottom is sandy or mud-sandy by taking the devices so that the concrete blocks may not be <sup>u</sup>barried in the sand or so that the germination of sporophytes may not be disturbed <sup>by</sup> with the sand or the mud.

(c) Water depth of cultivation. As mentioned in the chapter <sup>one</sup> of the ecology of Undaria pinnatifida, the growth of the seaweed depends upon the water temperature, the light in the water, and other environment <sup>al</sup> conditions of the cultivation ground and also the best condition depends upon the age of the seaweed. Accordingly, the water depth of cultivation will have been changed with the environment conditions of the cultivation ground, the degree of growth of the seedlings and/or the state of growth of Undaria pinnatifida. 28

Stricly speaking, since the environment <sup>al</sup> conditions differ from time <sup>to time</sup>, the best water depth for the growth <sup>will also</sup> vary from time. However, the water depth of the cultivation has no need to be the best, always. To aim <sup>at</sup> the cultivation with <sup>a</sup> least labor, the best water layer through the entire period of the cultivation should be found; it is taken up as the water depth of the cultivation. From this point of view the water depth of the cultivation in each area is shown in Table 6 by the experimental results. In Hokuriku-, Sanin-district, etc, where the amount of the sun light is largely changeable with the season, the water depth of cultivation should be changed according to the season. In case the cultivation starts with the seedlings <sup>whose</sup> which degree

of growth does not fit the water temperature at that time or starts under the special circumstances or at the time <sup>when</sup> ~~such as~~ the water surface is always low, a different water depth from the standard ones as listed in Table 6 must be considered. To study the best water depth of a cultivation ground, the cultivation experiments should be done by means of a vertical type or a horizontal type at several depths. The results from only one experiment does not always show the best water depth of the cultivation ground. The environment <sup>at</sup> <sub>X</sub> conditions differ from each year. The best water depth of cultivation depends upon the water temperature at the beginning of the cultivation and the state of the seedlings. By examining the all <sup>variable</sup> changeable factors the standard water depth of the cultivation <sup>may</sup> should be determined.

(d) Time for the beginning of cultivation and seedlings. For an early harvest the cultivation should begin early. If the seedlings of Undaria pinnatifida have grown to a proper degree to <sup>suit</sup> fit the water temperature at the cultivation ground, the beginning of the cultivation may be delayed a little. Commonly, at a cultivation ground where miscellaneous germinations are few, the cultivation is preferably begun at about 20°C of water temperature with the seedlings grown to sporophytes. On the other hand, at a cultivation ground where miscellaneous germinations are many, the cultivation is desirably begun at 17 to 18°C with the seedlings grown to sporophylls of 1 to 3 cm long. The cultivation begun with the latter case will not fail <sup>on</sup> at any cultivation ground. As it is after the state of the germination of the seedlings on the main rope is examined, the following advantages can be observed: there will be no main ropes that the germination and the growth of Undaria pinnatifida do not occur; an uniform growth can be expected; the

Table 6. Proper Water Depth of Cultivation for Each Area

| State (Place experiments done)                  | Proper water depth of cultivation | Note  |

| Yamaguchi-ken (Senzaki)                         | 2 - 3 m                           | ibid  |
| Kyoto-fu (miyatsu)                              | 0.5 - 1 m<br>2 - 3 m              | ibid, March or before<br>ibid, March or after |
| Niigata-ken (Sado)                              | 3.5 - 4.5 m                       | Raft-vertical(hanging)type                    |

loss of the main ropes is little. On the other hand, the seedlings grown to the large sporophylls are not suitable because the seedlings may be mechanically injured during the cultivation operations or the edge of the frond may be dried up and the seedlings may die.

(e) Transplantation. Transplantation of Undaria pinnatifida is practiced not only for the transfer and the distribution of the seedlings but also for the cultivation of the seaweed, having a good degree of growth, or an excellent quality, or the proper qualities for its use (c.f. the chapter of the ecology of Undaria pinnatifida). There are two ways of transplantation: the first, transplanting the original Undaria pinnatifida, then sprouting and culturing the seedlings, and the second, transplanting the seedlings (main ropes). In the former method the reproduction<sup>VE</sup> fronds are cut off from the well ripe<sup>wt</sup> original seaweed in the sea, taken out of the sea, then transferred avoiding ~~A~~ extreme dryness<sup>x</sup> and a temperature rise. The reproduction<sup>VE</sup> fronds are packed in open boxes and preferably transferred during the night. A three- to four-day postal delivery has been successfully reported with this method. The method is generally suitable for the area where it can be reached by a 12- to 24-hour delivery under the conditions mentioned above. A long distance or a long <sup>period</sup> ~~hour~~ delivery prefers the latter. Seedlings can be transplanted almost any time with the following precautions; an allowable water temperature range depends upon the degree of growth of the seedlings, so an adjustment of the water temperature is needed; large seedlings have some difficulties such as ~~the~~ mechanical injuries. The safer and the simpler transplantation would prefer ~~the cultivation ground to be~~ transplanted<sup>ation along</sup> with the proper <sup>culture</sup> ~~facilities~~ for the ~~culture~~ of gametophytes. The reasons are that the gametophytes have a wide allowable temperature range and can be conveniently

transferred in a saturated water vapour immediately after taking out of the sea. In case the facilities are not available, of course depending upon the season, the transplantation should be done just before the beginning of the cultivation while the seedlings are sporophytes or sporophylls (up to 2 cm long). In this case, adjustment of ~~a~~ water temperature is especially important. When the amount of transplantation is small, a Dewar jar can be used for transfer.

(f) Harvest. As mentioned in the chapter of the ecology of Undaria pinnatifida, the seaweed does not always germinate and grow all at once, according to the experimental observations on the growth of the seaweed on a main rope (seed rope; the seaweed as an example observed at a certain time shown in Fig. 7, grows by forming the several groups varying in their degree of growth. The reasons are that the fertilizations and the germination

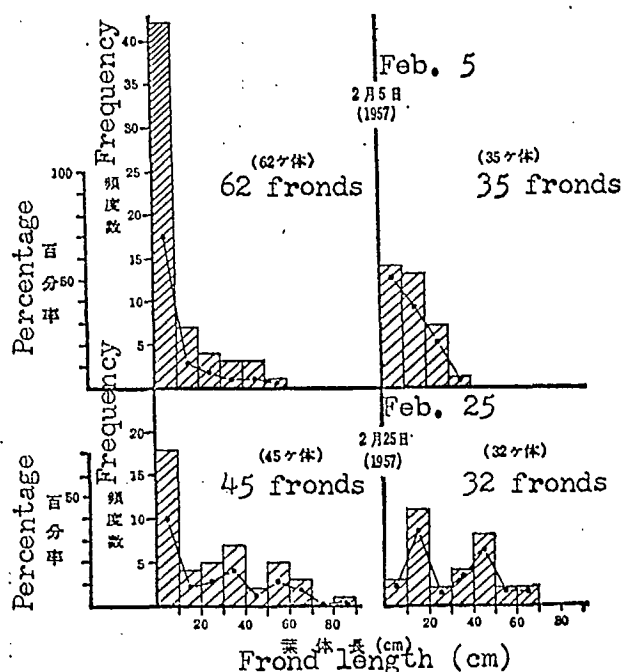

Fig. 7. Structure of the growth of Undaria pinnatifida grown on each oyster shell (30 cm<sup>2</sup>): left --- higher growth density, right --- lower growth density.  
Date of the beginning of cultivation: October 25, 1956.

to sporophytes last for a fairly long time at 20°C or lower water temperature; the seedlings which germinated to sporophytes at 15°C or lower have a long period as sporophyls; and even if the germinations occur at the same time, the difference in growth <sup>occurs</sup> happens for some reason and the seedlings growing slowly are checked <sup>in</sup> to grow <sup>as</sup> by the ones growing quickly. However, these phenomena depend upon the sea conditions such as the water temperature at the cultivation ground and the growth density of sporophytes. The seedlings germinated late do not grow well enough at a cultivation ground where its water temperature is slightly high (the period at 15°C or lower is short). For that reason the growth of Undaria pinnatifida which <sup>is the</sup> ~~are~~ objects of harvest tends to <sup>be</sup> uniform. At a low-water temperature, number of groups being different in growth tends <sup>to be</sup> high. ~~The~~ low growth density of the seedlings has a tendency to grow uniform <sup>ly</sup> and <sup>at</sup> ~~the~~ high density to grow <sup>less</sup> ~~un-~~uniform <sup>ly</sup>. When the upper part of the fronds of Undaria pinnatifida are cut off leaving the main growing area between the stem and the frond <sup>as</sup> ~~to its~~ stubbles, the remainders <sup>can</sup> grow again. Accordingly, there are three ways of harvests of Undaria pinnatifida:

i. Simultaneous harvest --- when most of the Undaria pinnatifida grows <sup>large</sup> enough to harvest at a cultivation ground, they are harvested all at once by cutting their stems. This is mainly practiced when the growth ~~density~~ is low or where the water temperature at a cultivation ground is comparatively high.

ii. Cut harvest --- the fronds are cut at the upper part of the growing area leaving about 5 cm of comb-like leaves <sup>as</sup> ~~to its~~ stubbles. The remainder will be harvested later <sup>after</sup> ~~when~~ re-grows <sup>the</sup>. This can be practiced when the growth ~~density~~ of seedlings is low, or where the period of low water temperature

is long, and where the water temperature stays at 15°C or lower at the time of cut and after (at least about one month).

iii. Thinning harvest --- fast growing Undaria pinnatifida are harvested by thinning to promote the growth of slow ones. The harvests ~~are~~<sup>is</sup> repeated by thinning. This can be practiced when the growth ~~density~~ of the seedlings is high, and where the period of the low water temperature is long, and also the water temperature is at 15°C or lower for a long period after the thinning, and the growth of the slow <sup>er</sup> ones is good.

The method chosen among ~~these~~<sup>the</sup> three must be determined by the growth density of the seedlings and by the sea conditions at the cultivation ground. When the seaweeds become old, their weight increases, and their quality ~~degrades~~<sup>decreases</sup> because of the harder fronds, the top withering, or the decoloration. Moreover, ~~the~~ consideration should be ~~taken~~<sup>given to</sup> on the changes of the market price and the uses (selling fresh (raw) or secondary products) for the best harvest method. The comparison tests considered <sup>by</sup> all those factors have not yet been reported, but a comparison test clearly indicating the number of the seedlings and the changes of the water temperature has been reported by Izu Branch, Shizuoka-ken Fisheries Experiment Station. According to the report, when <sup>an</sup> average <sup>of</sup> 20 to 30 seedlings per 10 cm of a main rope germinate and grow (the main ropes are inserted at intervals of 15 cm and cultivated by a raft-horizontal type), the produce ratios of simultaneous to thinning harvest are as follows: the simultaneous harvest (harvested fronds of 40 cm or longer on March 28 or on April 11) to the thinning harvests (case 1: thinned fronds of 40 cm or longer on February 20 and 28 and simultaneously harvested fronds of 40 cm or longer on March 28, case 2: thinned on March 7 and harvested the remainder on April 11, case 3: thinned

on March 16 and the remainder on April 11) are 1 : 0.37, 1 : 0.69, and 1 : 0.88, respectively. As for ~~the~~ quantity of the produce is concerned, the highest <sup>production</sup> ~~merit~~ can be obtained by a simultaneous harvest at their season. If thinning is practiced, it should be done <sup>about</sup> ~~around~~ at their season. In this case, the number of the seedlings is comparatively small, and the growth is <sup>good</sup> ~~very~~ well, and the ratio of the number of the grown-up weeds into good size to the total number of the weeds is high, and the water temperature is comparatively high (the last ten days of February 13.3°C, the first ten days of March 13.9°C, the second ten days 14.3°C, the last ten days 14.7°C, and the first ten days of April 14.4°C). The experimental results indicate the reasons mentioned above. Generally speaking, if the <sup>decrease in</sup> ~~degradation of~~ the quality of the produce is not considered, the highest quantity of the product<sup>ion</sup> ~~x~~ will be expected by the simultaneous harvest at their season. According to the author's experimental results<sup>s</sup>, when 14 seedlings of Undaria pinnatifida <sup>are</sup> ~~grow~~ <sup>on</sup> ~~per~~ about 50 cm of a main rope (the main rope is wound around a rope and adjustments were made so that the seaweeds in the same length grow uniformly on the main rope), the three methods of the harvest are compared as shown in Table 7. The number of seedlings was small and the simultaneous harvest was done at the time when the growth reached to the maximum and while the <sup>decrease in</sup> ~~degradation of~~ the quality did not occur. In addition to that, the thinning harvest was done based on the same conditions. As a result, these results were obtained. If the timing of the simultaneous and the thinning harvests is delayed, the differences between the product<sup>ion</sup> ~~x~~ of those two and that of the cut harvest would be smaller or might be reverse. <sup>of</sup> Considering the change of the market prices, it can be said that the cut harvest is more effective than others when the number of seedlings

Table 7. Comparison of produce<sup>Time</sup> by the harvest methods  
(Results of cultivation in Toyohama Port, Aichi-ken, 1960)

A: Frond length B: Stump length C: Produce

| Method               | Feb. 18        |                     |           | Mar. 12        |                    |            | Apr. 14         |    |             | May 6        |   |     | Total |
|----------------------|----------------|---------------------|-----------|----------------|--------------------|------------|-----------------|----|-------------|--------------|---|-----|-------|

| Simultaneous harvest | 32~168<br>77.7 |                     |           | 84~226         |                    | 2030       |                 |    |             |              |   |     | 2030  |
| Thinning harvest     | 32~168<br>77.7 | 32~72<br>(10)<br>47 | 84<br>(4) | 72~112<br>95.2 | 72~99<br>(5)<br>85 | 590<br>(5) | 85~117<br>100.0 |    | 1300<br>(5) |              |   |     | 2730  |
| Cut harvest          | 51~121<br>83.5 | 20                  | 1075      | 29~70<br>56.7  | 20                 | 1553       | 26~52<br>36.1   | 20 | 1309        | 21~49<br>260 |   | 547 | 4484  |

The second number for each frond length indicates an average.  
The figure in the parentheses indicates the number of weeds.

are small and the water temperature is low as in this case. As seen in the examples above, the best method of the harvest <sup>may</sup> could be determined by the length of the low temperature period, 15°C or lower. However, it <sup>C</sup> would be hardly determined by the number of ~~the~~ seedlings. Although there are some differences in each case, in case of the inserting, the number of Undaria pinnatifida which grows very well and fast does not depend ~~much~~ <sup>greatly</sup> upon that of the seedlings and is likely about 5 to 10 per main rope (in case of winding, per 15 to 20 cm <sup>or</sup> of a main rope). Therefore, if more than 10 seedlings <sup>occur</sup> exist, it is preferable to thin the weeds until the number reaches to 5 to 10 <sup>with</sup> as far as the water temperature stays in <sup>the</sup> a proper range. If the number of the weeds is less than that, depending upon the water temperature, the simultaneous or the cut harvest is considered ~~as~~ <sup>to</sup> be the better.

Table 8. Standard Product<sup>tion</sup> of Each State  
 (Per 1 m of main rope or per a net; weight in wet (raw))

| State         | Production | Cultivation method employed   |
|---------------|------------|---|
| Iwate-ken     | 10 kg      | Raft-horizontal   |
| Miyagi-ken    | 7.5 - 15   | Raft-horizontal   |
| Tokyo         | 0.4 - 1.2  | Transplantation experiment by the Miyagi-ken origin seedlings.                  |
| Shizuoka-ken  | 7.5        | Raft-horizontal   |
| Aichi-ken     | 5 - 10     | Square  |
| Tokushima-ken | 2 - 3      | Transplantation of the Miyagi-ken origin seedlings, rope and vertical (hanging) |
| Tokushima-ken | 2 - 17     | The Naruto origin seedlings, rope and vertical (hanging)                        |
| Kumamoto      | 2.2 - 3.9  |   |
| Nagasaki-ken  | 4.1 - 5.7  | Vertical (hanging)  |
| Nagasaki-ken  | 5.8 - 9.2  | Horizontal  |
| Nagasaki-ken  | 180        | Per a net (laver rack)  |

Note: the number of the germination<sup>s</sup> on a main rope depends upon the state of the culture. The number of the seedlings changes ~~as it grows~~ <sup>with</sup> it grows. According to the reports by the several fisheries experiment stations, the average number of the seedlings per 1 cm of a main rope after immersing into sea, are 16, 2 to 3, 2 to 3, 1 to 2, and 30 to 10 for Tokushima-, Shizuoka-, Miyagi-, Gotoh, Kumamoto-, and the Sea of Ariake, Kumamoto-ken, respectively. The last case, the Sea of Ariake, indicates that one month after the immersion the number was 30, but three months after decreased to 10.

The produce of Undaria pinnatifida per ~~an~~ unit length of the main rope for the cultivation quite differ<sup>s</sup> from case to case. Table 8 shows the produce<sup>tion</sup>, based on the report submitted by each state. prefecture.

(g) Commercialization (Calculation of profit). It is difficult to set the standard for the expenditures, because the cultivation facilities vary in types, methods, and in sizes, besides the price of seedlings is variable in each state. As for the expenditures (excluding the labour) for each method reported, Table 9 can be a standard.

The standard income for each cultivation method or for each sea district is also difficult to be ~~determined~~ <sup>tion</sup>, because the produce<sup>tion</sup> by the same cultivation method and in the same size is variable in each sea district (or at each cultivation ground). In addition to that, the price of the produce is variable in each sea district and also <sup>according to</sup> ~~in the~~ season.

Accordingly, to discuss the possibility of the commercialization by a profit calculation is good only for each case. The summary of the profit calculations reported up to date and estimated possible profit calculations for each cultivation method are listed in Table 10. According

to the examples reported and estimated, in most cases, the profit rates are 2 to 7 or 1 to 5, excluding or including labour, respectively. This indicates that the cultivation of Undaria pinnatifida is profitable enough. Depending upon the method and the size employed, the profit is about 30,000 to 40,000 yen per 200 m of main rope (1,000 yen = \$3.00). Therefore, with ~~the~~ family labour and the cultivation of 1500 to 2000 m of main ropes, a seasonal professional management can be established. However, the examples in the table are ~~the~~ cases <sup>in</sup> which Undaria pinnatifida germinated uniformly on a main rope and grew very well. Taking some negative factors for the seedlings and the harvest into account, more facilities should be ~~considered~~ <sup>and</sup> ~~to be set~~ for a practical management.

Table 9. Material cost for cultivation facilities

1. Simple raft-horizontal type  
(1.5 m wide, 30 m long, 3 lines of main rope, Iwate-ken)

| Item                       | Quantity | Unit price<br>yen | Price<br>yen | Durable<br>years | Annual cost<br>yen | Remarks* |
|----------------------------|----------|-------------------|--------------|------------------|--------------------|----------|
| Rope (used)                | 37 kg    |                   | 2,500        | 1                | 2,500              | A        |

|----------------------|-----------------------|---------------|---------------|-------------|--------|----------------|
| Size*                | 200 m                 | 200 m         | 200 m         | 300 m       | 180 m  | (1000 m)       |
| Cost A: total (yen)  | 20,000 ¥              | 54,000        | 35,000        | 24,000      | 15,400 | 80,000         |
| B: annual            | 12,000 ¥              | 19,000        | 12,000        | 12,000      | 6,800  | 30,000         |
| C: price at landing  | 60,000 ¥              | 50,000        | 60,000        | 60,000      | 45,000 | 200,000        |
| D: profit(C - B)     | 48,000 ¥              | 31,000        | 48,000        | 48,000      | 38,200 | 170,000        |
| Profit rate(D/B)×100 | 400 %                 | 163 %         | 400 %         | 400 %       | 562 %  | 567 %          |
| Remarks**            | (1)                   | (2)           | (3)           | (4)         | (5)    | (6)            |

\* The price of spring rope is 10 yen per meter. Winding type is employed. The length of spring rope is estimated to be needed as long as that of main rope.

\*\* (1) Northern area: price of raw(wet) product, 10 kg/m at 30 yen/kg; middle and southern areas: 6 kg/m at 50 yen/kg. (2) Northern area: price, 8 kg/m at 30 yen/kg; middle and southern areas: 5 kg/m at 50 yen/kg. (3) The stem rope is made of wire rope and the branch rope is major for the cultivation. (4) ibid. (5) Price of raw(wet) product, 5 kg/m at 50 yen/kg. (6) Concrete block for building, 20 x 40 x 150 cm, 400 (converted to the length of main rope).

## Conclusion

The cultivation of Undaria pinnatifida has not ~~come out of the~~ <sup>emerged from</sup> ~~region of~~ the experiment <sup>as a crop</sup> or has just been commercialized recently, except Tohoku district. The popularization and the development of the cultivation in the future are expected; there are many problems to be solved or improved for the development. The followings <sup>is</sup> are the list of the problems which should be considered. They are summarized from the experimental results reported up to date. Solving these problems and putting the effort for the development of the cultivation industry of Undaria pinnatifida are urged in future.

- (1) Culture of <sup>high quality</sup> excellent seedlings --- to culture seedlings which germinate uniformly.
- (2) Proper ground and proper species --- (a) to define the special properties of the Undaria pinnatifida in each sea district throughout the country and transplant them rationally. (b) to cultivate crossed species among Undaria pinnatifida, Undaria undarioides, and Undaria peterseniana, which belong to <sup>the</sup> Undaria pinnatifida family. <sup>groups</sup>
- (3) Pioneering of market <sup>ing</sup> --- to aim <sup>to</sup> the increase of the profit and prevention of the over-production by the proper sales for the conditions in each market.
- (4) Fertilization --- to <sup>at</sup> intend <sup>and</sup> the improvement of the quality and the promotion of the growth by fertilization.
- (5) Extermination of <sup>fouling</sup> noxious livings --- to discover and exterminate the <sup>fouling</sup> livings which harm <sup>s</sup> sporophylls and to exterminate Amakusa seahares.
