Canadian Manuscript Report of Fisheries and Aquatic Sciences

These reports contain scientific and technical information that represents an important contribution to existing knowledge but which for some reason may not be appropriate for primary scientific (i.e. *Journal*) publication. They differ from Technical Reports in terms of subject scope and potential audience: Manuscript Reports deal primarily with national or regional problems and distribution is generally restricted to institutions or individuals located in particular regions of Canada. No restriction is placed on subject matter and the series reflects the broad interests and policies of the Department of Fisheries and Oceans, namely, fisheries management, technology and development, ocean sciences, and aquatic environments relevant to Canada.

Manuscript Reports may be cited as full publications. The correct citation appears above the abstract of each report. Each report will be abstracted by *Aquatic Sciences and Fisheries Abstracts* and will be indexed annually in the Department's index to scientific and technical publications.

Numbers 1-900 in this series were issued as Manuscript Reports (Biological Series) of the Biological Board of Canada, and subsequent to 1937 when the name of the Board was changed by Act of Parliament, as Manuscript Reports (Biological Series) of the Fisheries Research Board of Canada. Numbers 901-1425 were issued as Manuscript Reports of the Fisheries Research Board of Canada. Numbers 1426-1550 were issued as Department of Fisheries and the Environment, Fisheries and Marine Service Manuscript Reports. The current series name was changed with report number 1551.

Details on the availability of Manuscript Reports in hard copy may be obtained from the issuing establishment indicated on the front cover.

Rapport manuscrit canadien des sciences halieutiques et aquatiques

Ces rapports contiennent des renseignements scientifiques et techniques qui constituent une contribution importante aux connaissances actuelles mais qui, pour une raison ou pour une autre, ne semblent pas appropriés pour la publication dans un journal scientifique. Ils se distinguent des Rapports techniques par la portée du sujet et le lecteur visé; en effet, ils s'attachent principalement à des problèmes d'ordre national ou régional et la distribution en est généralement limitée aux organismes et aux personnes de régions particulières du Canada. Il n'y a aucune restriction quant au sujet; de fait, la série reflète la vaste gamme des intérêts et des politiques du Ministère des Pêches et des Océans, notamment gestion des pêches; techniques et développement, sciences océaniques et environnements aquatiques, au Canada.

Les Manuscrits peuvent être considérés comme des publications complètes. Le titre exact paraît au haut du résumé de chaque rapport, qui sera publié dans la revue *Aquatic Sciences and Fisheries Abstracts* et qui figurera dans l'index annuel des publications scientifiques et techniques du Ministère.

Les numéros de 1 à 900 de cette série ont été publiés à titre de manuscrits (Série biologique) de l'Office de biologie du Canada, et après le changement de la désignation de cet organisme par décret du Parlement, en 1937, ont été classés en tant que manuscrits (Série biologique) de l'Office des recherches sur les pêcheries du Canada. Les numéros allant de 901 à 1425 ont été publiés à titre de manuscrits de l'Office des recherches sur les pêcheries du Canada. Les numéros 1426 à 1550 ont été publiés à titre de Rapport manuscrits du Service des pêches et de la mer, Ministère des Pêches et de l'Environnement. Le nom de la série a été changé à partir du rapport numéro 1551.

La page couverture porte le nom de l'établissement auteur où l'on peut se procurer les rapports sous couverture cartonnée.

ABSTRACT

Ketchen, K. S. 1981. Reconstruction of Pacific ocean perch (Sebastes alutus) stock history in Queen Charlotte Sound. Part II. Catch per unit of effort as a measure of abundance. Can. MS Rep. Fish. Aquat. Sci. 1599: 72 p.

Statistics of the Canadian fishery for Pacific ocean perch (Sebastes alutus) in Queen Charlotte Sound have been used to develop a new CPUE measure of relative abundance. This index is positively correlated with an earlier one based on the performance of a U.S. fishing fleet and is compatible with independent, provisional estimates of available biomass. A rapid decline in abundance occurred between 1965 and the early 1970s, a period of relatively heavy removals. By the late 1970s catch as well as total effort had reached its lowest point since the inception of fishing in the early 1950s. It is too soon to conclude that a modest reversal of the CPUE trend is a reflection of stock recovery.

The new index of abundance has been applied to a range of estimates of total removals (required because of uncertainty about the reliability of reported foreign catch) to obtain a range of estimates of total fishing effort. These data are to be used in further stock assessment studies and reported in this publication series.

Key words: Pacific ocean perch, CPUE, relative abundance, standardized effort.

RÉSUMÉ

Ketchen, K. S. 1981. Reconstruction of Pacific ocean perch (Sebastes alutus) stock history in Queen Charlotte Sound. Part II. Catch per unit of effort as a measure of abundance. Can. MS Rep. Fish. Aquat. Sci. 1599: 72 p.

Les statistiques sur l'industrie canadienne de la pêche du sébaste du Pacifique (Sebastes alutus) dans le détroit Reine-Charlotte ont servi à élaborer une nouvelle mesure de l'abondance relative basée sur les prises par unité d'effort (PUE). Cet indice est directement lié à un indice précédent basé sur le rendement d'une flottille de pêche américaine et est compatible avec les données distinctes, provisoires de la biomasse disponible. Une baisse rapide de l'abondance s'est produite entre 1965 et le début des années soixante-dix, période d'exploitation relativement forte. Vers la fin des années soixante-dix, les prises ainsi que l'effort total avaient atteint leur point le plus bas depuis le commencement de la pêche au début des années cinquante. Il est encore trop tôt pour conclure qu'un modeste renversement de la tendance des PUE constitue une indication du rétablissement des stocks.

Le nouvel indice d'abondance a été appliqué à un éventail de prévisions de l'exploitation totale (nécessaire à cause de l'incertitude face à l'exactitude des prises rapportées par les étrangers) en vue d'obtenir un éventail de prévisions pour l'effort de pêche total. Ces données seront utilisées pour des évaluations des stocks et rapportées dans la présente série de publications.

Mots clés: Sébaste du Pacifique, PUE, abondance relative, effort normalisé.

INTRODUCTION

The trawl fishery for Pacific ocean perch (Sebastes alutus), in Queen Charlotte Sound, began in the early 1950s largely as a United States operation based in the State of Washington. Until 1970 the Canadian share of the catch by the two nations rarely exceeded 20%, but more recently (1975-77), because of improved markets in Canada and declining U.S. fishing effort, the share has ranged from 51-77%. In 1978, there was negligible fishing for ocean perch by U.S. vessels, as a result of the failure of the two countries to reach accord on an interim reciprocal fishing privileges agreement. This situation continued through 1979.

Cooperative stock assessment studies (Gunderson et al. 1976) based on catch per unit of effort (CPUE) as an index of abundance have depended heavily on data from the predominant U.S. fishery. However, now that the Canadian fishery has achieved equal or greater prominence, along with the prospect that Canada may soon become the sole participant in the fishery, there is need to develop an independent Canadian CPUE index, in order to continue the monitoring of ocean perch stock size.

Thus the purpose of this report: (1) to conduct a detailed examination of historical catch and effort data on the Canadian trawl fishery for Pacific ocean perch in Queen Charlotte Sound; (2) to determine as far as possible whether Canadian CPUE provides a valid measure of relative abundance by comparing results with U.S. estimates and independent measures of stock size (e.g. biomass estimates), (3) to reconstruct a Canadian CPUE index for the years prior to significant Canadian involvement in the fishery, and (4) to assemble estimates of total catch and calculated total fishing effort in a form which may be used in future stock assessments.

BACKGROUND

Because of the many pitfalls which attend calculation and interpretation of CPUE it is important to review what is known of the distribution and movements of ocean perch, definition of stocks/populations and general features of the fishery. This information provides a useful background to the problems of analysis and to the development of appropriate methodology.

FISHING GROUNDS

Queen Charlotte Sound is defined as that part of Canadian coastal waters lying between the northern end of Vancouver Island (ca 50°30'N) and the southern extremity of the Queen Charlotte Islands (ca 52°00'N). Within the Sound are three banks (Cook, Goose Island, and Middle) separated by

three gullies (Goose Island, Mitchell's, and Moresby) (Fig. 1). It is in or around the perimeter of the first two of these gullies that the main domestic (Canada-U.S.A.) fishery takes place. With the arrival of fishing fleets of the USSR (1965) and Japan (1966) extensive fishing for rockfish including Pacific ocean perch occurred in the outer (westerly) portions of Goose Island and Mitchell's gullies and also on the slopes to seaward of the three banks mentioned above (see Ketchen 1980b). In 1971 Canada imposed a fishery closing line running from Cape St. James on the southern tip of the Queen Charlotte Island group to Triangle Island off the northern tip of Vancouver Island (Fig. 1). This discouraged, but did not entirely prevent, further foreign fishing within Goose Island and Mitchell's gullies.

Goose Island Gully Grounds

As shown in Figure 2, Goose Island Gully is comprised of six more or less confluent fishing grounds. Historically, those lying along the southern margin of Goose Island Bank (NE corner to the SE edge and corner) have been the most important ones to the North American fleet. Those lying in the easterly horns of the gully ("Virgin Rocks", "Stump Ranch", and "Cape Scott") and the "Triangle Ground" near the seaward entrance to the gully have been irregular and relatively minor producers as far as the Canadian fleet is concerned (Fig. 3).

Farther to the westward on the southwest slope of Goose Island Bank (Fig. 1), the bottom is rough and although never fished to any great extent by North American trawlers, appears to be largely untrawlable with conventional domestic gear. Large foreign trawlers have been observed on the southwest slope fishing for rockfishes which characteristically occur on or over rough bottom (Sebastes reedi, S. proriger and others). However, it is apparent from reports of observers aboard Japanese trawlers (Leaman et al. 1978) that S. alutus is present during summer months in moderate quantities on a ground here defined as "slope ground" (see Fig. 2).

On the southerly side of the seaward entrance to Goose Island Gully, about 18 miles true west of Triangle Island, is another area which has attracted a great deal of attention by foreign trawlers. Here the bottom is rough from a depth of about 100 fathoms (183 m) to the sharp drop off beyond 150 fathoms (275 m) and research vessel catches as well as those observed on Japanese vessels contain little if any S. alutus during summer months (Westrheim 1967; Leaman et al. 1978), but the area may be an important producer in wintertime. For present purposes this area will be identified as the "West Triangle" ground (Fig. 2) to distinguish it from the Triangle ground farther eastward in the gully. The intervening ground apparently is untrawlable with conventional bottom gear.

Mitchell's Gully Grounds

Mitchell's Gully is narrower and shorter than Goose Island Gully and appears to possess less trawlable bottom. Its inner reaches, extending from the NW corner to the SW corner of Goose Island Bank (SW edge is shown in Fig. 2), have been fished extensively by U.S. trawlers at least since 1965. Canadian activity was comparatively light and sporadic until

the fall of 1972 when discovery of trawlable bottom towards the westward and deeper parts of the gully (Westrheim 1972, 1974b) led to a significant shift in Canadian fishing effort in subsequent years.

SEASONAL MOVEMENTS OF OCEAN PERCH

It is well known that in the vicinity of British Columbia S. alutus engages in substantial seasonal bathymetric movements (Alverson 1960; Gunderson 1971). In the southwestern Vancouver Island area and off the Washington-Oregon coast, where the species can be tracked over its entire depth range, Gunderson (1971) noted mean depth of commercial catch to be 120 fm (220 m) or less during summer months and 160-180 fm (290-220 m) during winter months. However, Westrheim's 1973 study of age and growth revealed a significant complication, viz. ocean perch encountered in deep water in winter are not necessarily of the same stock encountered in shallow water in summer. He postulated the existence of mutually exclusive sub-stocks of shallow-water, fast growing ocean perch which disperse or otherwise become relatively unavailable during winter, and deep-water, slow growing fish which are relatively unavailable in summer. Further tests of this hypothesis are required.

In any event, the annual bathymetric range of ocean perch in Queen Charlotte Sound has not yet been fully described. One of the difficulties, as identified by Gunderson (1971) is that there is little ground below a depth of 150 fm (275 m) available to conventional North American trawling gear. Thus, unlike areas off Vancouver Island and Washington, the commercial fleet loses contact with schools of fish as they move to deep water in winter and re-establishes contact only when the spring migration to shallow water is well underway. The same cannot be said for certain with regard to Soviet and Japanese vessels which, during their periods of most active winter fishing (1966-68 and 1972-76, respectively), were equipped with both rough-bottom and mid-water trawling gear. The possibility that ocean perch were vulnerable to these types of gear during winter has been taken into consideration in estimating foreign catches (Ketchen 1980b).

Information collected from trip reports and logbook records of Canadian commercial fishermen provides an interesting comparison between the apparent behavior of ocean perch in the Goose Island Gully and Mitchell's Gully. In the former area, the migration to relatively shallow water appears to be completed by the month of May (Fig. 4). However, it may well be that at the beginning of the Canadian fishing season, vessels do not operate over the entire depth range where the species is available. Indeed observations by Gunderson (1971:421) on the U.S. fishing operations for an earlier period of years (1961-65) show a weighted mean depth of catch at about 120 fm (220 m) in April, 110 fm (201 m) in May with shallowest depths of about 100 fm (183 m) being achieved in June-July.

Canadian data suggest that depth distribution in Goose Island Gully remains fairly stable (ca 110 fm or 200 m) through August after which there is a progressive movement to deep water. The descent is more rapid

than that observed by Gunderson (1971)¹. For neither the Canadian nor U.S. fishery is there adequate information on the ultimate depth reached in winter, because of the abrupt drop in bottom depths beyond 150 fm (275 m), roughness of the terrain, lack of mid-water trawl effort, and onset of winter storms.

Gunderson (1971), again referring to Queen Charlotte Sound as a whole and to the 1966-69 period, noted that male ocean perch predominated (80-87%) in the February-April period, suggesting that they do not accompany females on their spawning migration to deep water. As the inshore season progresses the proportion of females increases, reaching parity by October-November. However, in Canadian market samples for this period, as well as for later years, it is apparent that in Goose Island Gully parity is reached usually in June-July. This is supported by research vessel observations during the month of June (Harling et al. 1970; Westrheim et al. 1974a).

Data on the bathymetric movements of ocean perch in Mitchell's Gully (Fig. 5), as indicated by Canadian commercial fishing operations, cover a broader span of months than those for Goose Island Gully. Schools are intercepted in deep water (ca 150-160 fm or 275-295 m) well before they reach their minimum depth range in the June-August period (ca 120-125 fm or 220-230 m). This is nearly 15 fm (27 m) deeper than the mean depth of occurrence for the corresponding period in Goose Island Gully--a depth differential which is more or less maintained throughout the succeeding fall months as the schools of fish retreat once again to deep water. This difference possibly indicates a difference in temperature structure in the two gullies, or may merely reflect the difference in bathymetry and distribution of habitable bottom.

As in Goose Island Gully, male fish predominate in the spring but the sex ratio reaches parity in June-July.

DEFINITION OF STOCKS

For present purposes it is assumed that ocean perch inhabiting Goose Island and Mitchell's gullies belong to two separate stocks or groups of stocks.² Grounds for such an assumption are: (i) the gullies are separated by a 15- to 40-mile wide area where depths and/or bottom type are those not normally associated with the spring-autumn occurrence of adult ocean perch, (ii) North American fisheries in the two gullies are more or less contemporaneous and at somewhat different depths, (iii) otoliths

¹Disparities between the U.S. and Canadian observations may arise from the fact that the former made no distinction between the fisheries in Goose Island and Mitchell's gullies.

²"Groups of stocks" acknowledges the possible existence of shallow-water and deep-water components in each area, in keeping with the Westrheim hypothesis.

collected for age-determination from ocean perch caught in Mitchell's Gully are distinctively more difficult to read, because of accessory checks, than those from Goose Island Gully (Westrheim, pers. comm.), and (iv) although no quantitative comparisons have been made, it is believed that there is a significantly lower incidence of the trematode parasite Proisorhynchus in the ocean perch inhabiting Goose Island Gully (Harling, pers. comm.).

There remains the question of the whereabouts of these stocks during the winter months. Westrheim (personal communication) is of the opinion that, following the autumn migration out of the gullies to deeper water, they disperse in midwater at some depth below 150 fm. Wintering of the Goose Island Gully stock probably takes place in the general vicinity of the West Triangle ground and on the SW slope of Goose Island Bank (Fig. 2). The Mitchell's Gully stock presumably occupies either the SW slope of Middle Bank, the northern part of the SW slope of Goose Island Bank, or both.

MATERIALS AND METHODS

STATISTICS OF CATCH

North American fishery

Monthly statistics of Canadian and United States landings of Pacific ocean perch are combined and published annually by the staff of the Pacific Marine Fisheries Commission (PMFC). Landings originating in Queen Charlotte Sound are represented in records of PMFC Statistical Areas 5A and 5B (Fig. 6). For present purposes the two areas have been combined and landings by country have been obtained by subtracting Canadian landings from the totals published by PMFC. Records of the North American annual and monthly landings since 1956 are summarized in Tables 1 and 2, respectively. Table 3 shows annual North American removals by the two major sections of Queen Charlotte Sound: Goose Island and Mitchell's gullies, and is an extension of information contained in Gunderson et al. (1976: Table 2).

Foreign fishery

Statistics on production by vessels from distant-water nations shown in Table 1 are approximations derived by Ketchen (1980b) from information provided by the USSR and Japan on catches of all rockfish combined³.

³These estimates supersede figures used by Gunderson et al. (1976) in their assessment of the state of ocean perch stocks in Queen Charlotte Sound.

Estimates of foreign removals from the stocks associated with Goose Island and Mitchell's gullies, as shown in Table 3, are likewise based on Ketchen's (1980b) derivation. The figures used are those classed as "intermediate" by Ketchen. "Minimum" and "maximum" estimates will be dealt with in another section of the text.

STATISTICS OF CATCH PER UNIT OF EFFORT (CPUE)

As mentioned at the outset, statistics of the United States fishery hereto have constituted the base for calculation of annual considered more reliable than Canadian data for earlier years because of the predominance of the U.S. fishery and the stability of the fleet's composition, the data may have been weakened by an obvious reduction in U.S. fishing interest in years subsequent to 1974. Thus, development of a Canadian CPUE index has become imperative.

Method of calculating Canadian CPUE

Qualifying fishing effort

The first step in the analysis was to make certain that fishing effort used in the calculation of ocean perch CPUE was indeed directed at that species and not diluted by effort on other target species. Throughout the history of the Canadian fishery in Queen Charlotte Sound it has always been relatively easy to identify fishing effort on ocean perch by the depth of fishing, because, at least until 1977-78, there was usually a sharp distinction in terms of depth between the fisheries for ocean perch and for other species (mainly Pacific cod, lingcod and several species of flatfish)--85-180 fm for the former and usually less than 60 fm for the latter. With the belated development of Canadian interest in species of rockfish other than ocean perch the separateness of the shallow-water and deep-water fisheries is becoming less obvious. In any event, establishment of a minimum depth for selection or rejection of fishing effort is one method of qualification.

Another is to set a minimum limit on the percentage that ocean perch constitutes of the total catch reported by a vessel from a given locality and depth range (i.e. establishment of a catch qualification).

As yet no statistical technique has been developed to enable one to determine which depth and catch qualification levels are likely to provide the most reliable estimate of directed (effective) effort. However, from examination of Canadian statistics on the fishery in Queen Charlotte Sound, it was decided that only those landing data would be considered in

which the catch of ocean perch (a) was made at an average depth of 85 fm or greater and (b) constituted 60%⁴ or more of the catch in the locality for which such depths were specified.

For purposes of consistency a further constraint has been placed on the data by limiting the analysis to fishing conducted during the months of May through December. Canadian catches in the first four months of the year have been negligible and at best erratic (Table 2).

Standard vessel class

While the size and gross tonnage composition of the United States fleet has remained relatively constant over several decades, the Canadian fleet has undergone a spectacular shift to larger vessels (Fig. 7). On the assumption that CPUE is positively correlated with vessel gross tonnage and/or horsepower (verified for numerous trawl fisheries around the world, and even locally--cf Ketchen 1979), there is an obvious need to standardize the unit of Canadian fishing effort. For analytical purposes Canadian trawlers involved in the fishery for ocean perch in Queen Charlotte Sound are separated into the following categories:

| <u>Class</u> | <u>Gross tons</u> |
|--------------|-------------------|
| 3 | 25-49 |
| 4 | 50-74 |
| 5 | 75-99 |
| 6 | 100-149 |
| 7 | 150-199 |
| 8 | 200-299 |
| 9 | 300-399 |
| 10 | 400+ |

Table 4 shows that Class 6 vessels have the longest unbroken record of participation in the fishery, yet that class ceased to be well represented after 1970, being relegated to a minor role by successively larger classes of vessels in more recent years. Since the past decade is the most critical period for evaluating changes in abundance, Class 7 will be used as the standard vessel class, and the effort expended by Class 6, 8, and 9 will be expressed in terms of the standard class (performances of Classes 3, 4, 5, and 10 will be ignored because of their low and erratic involvement in the fishery).

⁴This qualification level (threshold) was deemed necessary to eliminate "extraneous" and irregular deep-water fisheries for turbot in earlier years, and, particularly in 1977-79 the growing fisheries for certain species of rockfish whose bathymetric ranges during summer months may overlap those of ocean perch.

Fishing power factor

Beverton and Holt (1957:29) defined fishing power as the catching power of an individual vessel as measured by the ratio of the quantity of fish caught per unit time to that of a vessel selected as a standard. Each vessel of a fleet can then be allocated a power factor (P.F.). In the present study, no one vessel (and skipper) fished throughout the period under consideration. Thus as a less desirable alternative, a class of vessels becomes the standard, and other classes are assigned a P.F., which is some value greater or less than 1.00. When the fishing effort of a class is multiplied by the P.F., the effort, in theory at least, is thereby expressed in terms of the standard class.

To arrive at the power factor for a particular class of vessel (say Class 8), an average ratio of the CPUE of Class 8 to Class 7 vessels, weighted to effort expended by the two classes, was obtained from monthly pairs of observations over the number of years where such pairs existed. The weighting formula, as recommended by D. Fournier, is a refinement of the one used by Ketchen (1979) in that it involves a logarithmic transformation namely,

$$\text{Log (P.F.)}_{ij} = \frac{\sum_{km} \frac{E_{ikm} \cdot E_{jkm}}{E_{ikm} + E_{jkm}} \cdot \text{Log} \frac{C_{ikm} E_{ikm}}{C_{jkm} E_{jkm}}}{\sum_{km} \frac{E_{ikm} \cdot E_{jkm}}{E_{ikm} + E_{jkm}}}$$

where P.F. is the power factor for the *i*th vessel class in terms of the *j*th (standard) class, *E* is fishing effort in hours and *C* is catch in metric tons in the *k*th month and *m*th year for each of the vessel classes *i* and *j*. An example of the calculation procedure is given in Appendix 1.

Table 5 contains the basic information for calculation of power factors, which in turn are provided in Table 6. Using the weighted average power factors of 0.89 for Class 6, 1.16 for Class 8, and 1.36 for Class 9 vessels, total May-December fishing effort can now be expressed in terms of the Class 7 standard⁵.

These power factors have been applied to Goose Island and Mitchell's gullies alike, even though it would be more correct to compute

⁵It is of interest to note in Table 6, that there is virtually no difference between weighted and unweighted estimates of power factors. A similar situation was observed in the standardization of Strait of Georgia fishing effort (Ketchen 1979), which raises the possibility that an elaborate weighting process is not necessary in analyses of Canadian west coast trawl fishery data. However, because of the uniqueness of the ocean perch fishery and the special features of the general trawl fishery in the Strait of Georgia, it would perhaps be wise to defer such a conclusion until the standardizing exercise has been applied to one of the other open coast fisheries.

them separately. The problem arises from a paucity of data, e.g. for the period of significant Canadian participation in the Mitchell's Gully fishery (1972-78) there were only 3 pairs of monthly average CPUEs comparing Class 7 with Class 6, 17 with Class 8 and 18 with Class 9. Fragmentary though the data are the latter two sets of comparisons yielded power factors of 1.14 and 1.28, respectively, which suggest that errors are not likely to be large in using the estimates provided in Table 6.

RESULTS

ESTIMATION OF STANDARDIZED CPUE

Table 7, col. 5 shows the total standardized fishing effort of the Canadian fleet of Class 6-9 vessels operating in Goose Island Gully, standardized to Class 7 by multiplying nominal effort recorded for each class by the corresponding power factor in Table 6. The total catch of Classes 6-9 (col. 6) was then divided by the standard effort to obtain a standardized CPUE (col. 7) for the 1962-79 period. Calculations for years prior to 1962 are included in the table, but these are provisionally dismissed because of the low level of the Canadian fishery in those earlier years.

A similar treatment has been applied to the brief run of data on the Canadian fishery in Mitchell's Gully during the period 1972-78 (Table 8).

RELIABILITY OF STANDARDIZED CPUE ESTIMATES

Before trying to relate standardized CPUE estimates for the two gullies to those calculated from catch-effort data on the U.S. fishery, it is desirable to determine whether the estimates are a reasonably reliable reflection of changes in relative abundance--not necessarily on a year-to-year basis, but over a span of several years, to accommodate short-term changes in availability. To do this requires some independent measure of abundance and fortunately such may exist in estimates of the available biomass of marketable sized ocean perch in Goose Island Gully as determined by surveys carried out aboard the R/V. G.B. REED. The methodology, involving a swept-area technique, has been described by Westrheim (1972).

Biomass estimates for the period 1965-77 (Ketchen, Ed. 1980a) are compared in Table 9 with estimates of standardized CPUE derived from the Canadian commercial fishery. The correlation coefficient, $r=0.665$, is marginally significant at the 5% level and therefore provides only borderline support for the reliability of the CPUE values. In any event,

caution must be exercised at this time because the biomass estimates are subject to further examination and possible revision⁶.

An alternative method of estimating available biomass is to be found in sequential computation of stock size (cohort analysis) as described by Pope (1972). Details of the application to Pacific ocean perch will be reported elsewhere (Ketchen MS). For present purposes it is sufficient to say that, using (a) total catch in numbers of fish by age, (b) an assumed instantaneous natural mortality rate (M) of 0.13, and (c) a trial, terminal instantaneous fishing mortality rate (F) of 0.3, the resulting estimates of available biomass for the years 1963-1971, inclusive⁷, are strongly correlated with corresponding estimates of CPUE (Fig. 8).

Thus we can say that available independent evidence supports the view that standardized CPUE is a reasonably reliable indicator of changes in relative abundance of the ocean perch stock available to the fishery in Goose Island Gully.

Intuitively one would expect CPUE to underestimate relative abundance at high stock levels. Conceivably the numbers of fish entering a trawl net could be so great as to reduce the opening gape of the net and/or, by their sheer weight, reduce the distance covered by the net in a given period of time. Whether or not such actually occurred during years of relatively high abundance cannot be ascertained. Data in Figure 8 are too sparse to suggest anything other than a straight line relationship.

At the other extreme, CPUE might be over-estimated because it fails to take into account the amount of time spent by fishermen searching for schools before they set their nets. Increasing length of searching time theoretically should manifest itself in information on catch per fishing day and a plot of CPUE against such data would tend to be convex upward. The relationship shown in Figure 9 is only marginally curvilinear, and thus we may conclude that over the range of abundances occurring during the middle to later years of the fishery, distortion of CPUE by changing length of searching time was negligible. Such a conclusion, of course, assumes that the length of the fishing day did not increase. While there is no way of checking this possibility, it is likely that the length of a fishing day is determined by the amount of daylight which in turn determines the diel

⁶Westrheim (pers. comm.) is concerned that in the early years of the biomass surveys, and even as late as 1973, numerous schools of Pacific ocean perch were observed in mid-water. As biomass estimates were based on results of on-bottom trawling, he is of the view that absolute abundance was under-estimated. This being true, it clearly invalidates any conclusion about the relationship of CPUE to absolute abundance. However, it invalidates the relationship of CPUE to relative abundance only if mid-water schools remained at all time beyond the range of the commercial fishery. If, on the other hand, it were assumed that mid-water schooling was merely a reflection of a general on-bottom-off-bottom behaviour pattern that varied from week to week if not from day to day (i.e. mid-water schools seasonally are as available to the fishery as on-bottom schools), then it would not be unreasonable to conclude that the comparison is valid.

bathymetric movement of schools and hence the length of time each day that bottom trawling remains worthwhile.

Another factor which may affect the reliability of a so-called standardized estimate of CPUE lies in the number of hauls comprising a given number of hours of fishing. When abundance is high, the skipper could be expected to make relatively short hauls to avoid overloading his gear or exceeding the rate at which the deck crew could handle a catch before the next haul came aboard. Theoretically, as abundance declines, the length of haul would be expected to increase and this appears to have been the case in the Queen Charlotte Sound ocean perch fishery. When abundance was high in 1965-66 the length of haul was about 2 3/4 h, but during the 1970s it rose to an average of more than 3 1/2 h (Fig. 10). These two questions arise: For a given level of abundance and given number of hours of fishing, would CPUE based on hauls of relatively long duration remain the same as that based on hauls of short duration? If abundance were declining, would CPUE based on hauls of relatively long duration remain the same as that based on hauls of short duration? If abundance were declining, would CPUE continue to be proportional to abundance given constant total number of hours of fishing and increasing duration of hauls? Doubtless there are many opinions on these matters. Certainly, under conditions of high abundance long hauls would be less efficient than short hauls if nets tended to become overloaded. Thus for a given number of hours of fishing long hauls would result in a lower CPUE than would short hauls. Whether or not the observed change in duration of haul has been sufficient to influence the present analysis is unknown. To quantify the error would require well designed experimental fishing at differing levels of abundance.

MONTHLY TRENDS IN CPUE

As an offshoot from the CPUE analysis, data on the performance of the several classes of Canadian trawlers was examined on a monthly basis to determine whether there are seasonal changes in CPUE. A generally upward trend from May through November is noted (Fig. 11) with a drop occurring in December. The rising trend could be attributed to the delayed immigration of females (as claimed by Gunderson (1971), but only partially supported by the present analysis) and/or to the progressive concentration of schools as breeding season approaches. The decline in December, although based on fragmentary data, is probably the result of a combination of declining availability as the schools move into deep water and increasing severity and frequency of winter gales which presumably reduce vessel efficiency.

This seasonal pattern of CPUE is in conflict with that described by Gunderson (1971) who noted for the 1955-65 period a peak in CPUE in May, followed by a slump during the summer months and then a rising trend through

⁷Reliable estimates could not be extended beyond 1971, because cohort analysis was limited to year-classes in which the oldest age was no less than 13 yr (a tentative estimate of the age of entry into the fishery).

November. To this sequence of events, also reflected in catch, Gunderson attributed biological significance. However, it is possible that the summer slump resulted from withdrawal of more efficient vessels in the U.S. fleet to engage in other fisheries. In the Goose Island Gully fishery by Canadian vessels there usually is a drop in catch for this reason (Fig. 4a) but there is little indication of a decline in CPUE.

Strictly speaking, if there are substantial annual variations in the months of peak production (and this is evident in Table 2), the annual average CPUE should be weighted to allow for within year (monthly) changes in catch rate. However, such has not been attempted because of the labor involved and the questionable benefit of such a refinement when the data on seasonal trends year-by-year are of varying quality.

COMPARISON OF CANADIAN AND U.S. CPUE ESTIMATES

The primary intention of this study, as mentioned earlier, is to develop a Canadian index of the relative abundance of ocean perch in Queen Charlotte Sound. We have already demonstrated that it is in reasonable accord with estimates of available biomass. Its reliability would be further strengthened if exhibited trends in the Canadian standard are in reasonable accord with those derived from data on the U.S. fishery. If this can be established then there is a basis for projecting the Canadian index backward in time to years when the Canadian fishery was of insufficient magnitude to provide a usable measure of abundance.

Canadian and U.S. CPUE values for 1962-77 in Goose Island Gully and 1972-77 in Mitchell's Gully are provided in Table 10, together with data on their correlation. Each set of data has a significant correlation coefficient. Thus, with due recognition of the hazards of extrapolation, we may now estimate U.S. CPUE (in terms of the Canadian standard) for earlier years of the fishery. Estimates for Goose Island Gully (1959-61) and Mitchell's Gully (1965-71) are obtained by substituting values given in the last two columns of Table 3 in equations 1 and 2, respectively, in Table 10. The results are given in Table 11 and illustrated in Figures 12 and 13 along with the historical record of the North American catch from Table 3.

COMPUTATION OF TOTAL FISHING EFFORT

The final step in the analysis is to introduce the estimated catches of Pacific ocean perch by foreign fleets to provide a more complete picture of the relationship between total catch and CPUE, and, from these statistics, to calculate total fishing effort in terms of the Canadian standard.

For Goose Island Gully total catch from Table 1 is plotted in Figure 14 along with previously presented estimates of standard CPUE

(Tables 6 and 9). Also shown is the calculated total effort derived from Table 12. Mitchell's Gully is similarly treated in Fig. 15.

In his estimation of foreign catches, Ketchen (1980b) considered it necessary to provide minimum, intermediate and maximum estimates of the catch by Soviet and Japanese trawlers during the years 1965-1976 when they were engaged in the fishery, because of the questionable accuracy of reported information. Intermediate estimates have been incorporated in the totals shown in Tables 1 and 12. For convenience of future analyses of the response of stocks to changing fishing effort, the minimum and maximum estimates of total removals in the 1965-76 period from Goose Island Gully are provided in Table 13 along with re-computed estimates of total effort. Similar data for Mitchell's Gully are given in Table 14.

CANADIAN FLEET EFFICIENCY

A by-product of the exercise to estimate power factors for the several classes of Canadian trawlers (p. 8) is information on the possible magnitude of change in fishing efficiency of the fleet over the long term. It cannot be determined with high precision because many changes in the over-all efficiency of trawlers are difficult to quantify (changes in design of nets and auxiliary gear, improved charts, navigational aids, etc.). In the present analysis we have observed that the average gross tonnage of vessels has increased markedly since 1960 (Fig. 7). Having at hand the power factor for each of the four main classes of vessels participating in the fishery (Table 6)⁸ and the average gross tonnage of vessels occupying each class, we can determine the relationship between relative fishing power (relative efficiency) and gross tonnage, as in Fig. 16. This in turn provides us with a clue to the change in efficiency which has occurred (in association with increase in average gross tonnage alone) since the early years of the fishery. As shown in the figure the increase appears to have been about 30%. To say more about this relationship, especially to explore the possibly more direct relationship to engine horse-power, strays too far from the main purpose of this report. Suffice it to say that the apparent increase in efficiency of 30%, probably is an under-estimate, in view of the fact that no allowance has been made for various unquantifiable improvements which have been made over the past two decades.

DISCUSSION

In the development of a Canadian index of changes in the relative abundance of Pacific ocean perch, the technique of standardizing fishing

⁸Plus the power factors of classes 4 and 5 which historically have been only marginally involved in the ocean perch fishery.

effort is but one of several that could have been used. It contains the implied reservation that fishing power of a particular vessel class relative to that of other classes remains constant with time (or at least varies without obvious trend over the long term). While this assumption appears to have been reasonably satisfied during the 1959-79 study period, it may not continue to be so. Furthermore, with the inevitable changing composition of a particular vessel class, due to withdrawals from or new entries into the fishery, its relative power factor may change and it might even be necessary to establish a new standard vessel class if fleet composition continues its recent trend. Thus it would be misleading to claim that standards and power factors used in this report are in any way final. They should be continuously monitored and, where necessary, revised to assure that the abundance index retains some semblance of reality.

The trend in relative abundance, especially during the peak years of the fishery (1965-72), as reflected by the new Canadian index, is positively correlated with results obtained by two independent yet still provisional estimates of biomass. The index is also correlated with that derived from CPUE in the U.S. fishery, though the latter could have been afflicted with the same unknown biases contained in the Canadian index. In general, however, there is some basis for confidence that the Canadian index for Goose Island Gully provides a reasonably reliable measure of the impact of the fishery during the years of heaviest removals.

Less confidence can be attached to the index for years prior to 1962, because it involved an extrapolation from U.S. data and conversion to the Canadian standard. Such a procedure may have embodied bias or sources of error of which the writer was unaware. However, it is to be noted in Figure 13 that CPUE estimates for the years 1959 to 1965 showed an irregular upward trend (more obviously so from the U.S. index given in Table 3). If the trend is a true reflection of relative abundance, the inference is that the biomass of commercial-sized fish was increasing during this period. This is supported at least in part by evidence from age composition that during most of this period a group of relatively strong year-classes (1952, 1951, and 1950) was being recruited to the stock (Gunderson et al. 1976). On the other hand, this rising CPUE was accompanied by increasing fishing effort which could mean that fishermen were becoming increasingly adept at fishing ocean perch. Thus, it is perhaps unwise to assume that all of the rise in CPUE between the early years and 1965 can be explained by increased

From 1966 to 1971, Goose Island Gully CPUE dropped very rapidly and this seems to be attributable to relatively high combined domestic and foreign catches during 1966-68 (Fig. 14). Because of the uncertainty which attends the estimates of foreign removals, future analysts should not overlook the fact that North American catches were relatively high from 1965 to 1970 (cf. Fig. 12, 14) and the possibility that the foreign fishery had less impact on the stock of ocean perch available to the North American fleet than is here supposed.

A final note of caution about interpreting changes in Goose Island Gully CPUE concerns events subsequent to 1975. In those years U.S. participation declined appreciably and became negligible in 1978 as the result of a Canada-U.S. dispute over an interim fisheries agreement. During

1976-79, fishing effort was down to the level which prevailed in the early 1950s. While a recovery of stock size is to be expected under such circumstances, the modest (and irregular) improvement in CPUE in this period (Fig. 13) may have been due in part to increased catchability, in the sense that schools of ocean perch are more likely to remain intact in the presence of low fishing pressure than under the dispersing effects of high fishing pressure.

Regarding the Mitchell's Gully fishery (Fig. 15), we are faced with a much more complicated situation than that in Goose Island Gully, even if attention is restricted to the North American fishery alone. There were two periods of relatively high catch and high CPUE, 1967-69 and 1973-74. The first may be identified with the then newly developed U.S. fishery associated with the SW edge of Goose Island Bank (Fig. 2) and possibly the foreign fishery to the west of the SW edge in Mitchell's Gully proper. The second reflects the sudden development of a Canadian fishery (followed by the U.S. fishery as news spread) resulting from discovery of trawlable bottom in the outer reaches of Mitchell's Gully during the course of exploratory fishing by the R/V G.B. REED in 1972.

The two-phase history of the Mitchell's Gully fishery, together with the lack of a complete series of data on age composition, makes interpretation of CPUE rather difficult. During and after each of the two periods of relatively heavy removals, CPUE trended downwards, as would be expected (Fig. 15). Perhaps it is only since 1973 that we have a picture representative of changes in the Mitchell's Gully stock as a whole, for by that time both the inner and outer reaches of the gully were being fished by the North American fleet. However, one cannot ignore the possibility that the bimodal CPUE pattern was in part a reflection of variations in recruitment.

The sharp upward turn in CPUE in 1978 deserves the same cautious treatment recommended in regard to recent data for Goose Island Gully. Indeed, it can be stated as a generality that, because of the large number of age groups in the catch and slow rate of recruitment, any sharp upturns in CPUE observed between one year and the next must be attributed to changes in availability. On the other hand, a sharp downward turn could reflect reduced availability, and/or a sudden change in abundance if it were preceded by an abrupt increase in catch. Since availability variations alone do not explain short-term variations in CPUE, it follows that added complications would arise if one were to attempt to minimize the effects of variations in availability by using running averages of CPUEs.

In any event, several more years of data may be required to confirm that, as a result of greatly reduced effort since 1975, the ocean perch stocks in both gullies are undergoing a recovery in abundance.

In regard to uncertainties concerning catches made by foreign trawlers, it is beyond the scope of this report to determine which of the several estimates (minimum, intermediate or maximum) most accurately reflects the actual removals from the two gullies. This is reserved for a later study.

Finally, and once again for the guidance of future analysts, the possibility should not be overlooked that ocean perch inhabiting Goose Island and Mitchell's gullies are in fact inseparable parts of a single stock, despite the available evidence supporting a two-stock concept. More direct and quantitative studies may be required before this question can be fully resolved.

CONCLUSIONS

The new CPUE index of abundance of Pacific ocean perch appears to be reliable in broad terms (not necessarily always year by year) on grounds that it is (1) positively correlated with an earlier U.S. index and (2) compatible with independent but provisional estimates of available biomass. Conclusions on the state of stocks are beyond the scope of the present analysis. Yet it has already been indicated elsewhere (Gunderson et al. 1976) that heavy removals in the mid to late 1960s resulted in a sharp reduction in CPUE. Such is confirmed by the present analysis at least with respect to the Goose Island Gully stock, but interpretation of events before and after that time requires further study in company with an analysis of changes in age structure of the stocks--the subject of a subsequent report.

SUMMARY

The objective of this report was to develop a Canadian standard from which to measure changes in relative abundance (from CPUE data) of Pacific ocean perch (Sebastes alutus) in Queen Charlotte Sound. Because of suspected changes in fishing power of the Canadian fleet during the past decade it was necessary to develop a standard unit of fishing effort. This was done by using Class 7 trawlers (150-199 gross tons) as the standard and equating the effort of all other significantly participating classes to this particular class.

Standardized CPUE estimates for the ocean perch stock in Goose Island Gully for 1965-77 were found to be correlated with provisional estimates of available biomass. They were also correlated with CPUE estimates derived from the U.S. fishery during the same period and the resulting equation was used to obtain CPUE estimates expressed in terms of the Canadian standard for the years 1959-61, a period when the Canadian production was but a small fraction of that of the U.S. fishery. A similar procedure was used to determine a standardized CPUE for the early years of the fishery on the Mitchell's Gully stock.

Using the Canadian index and estimates of total catch by domestic and foreign fleets, total fishing effort (expressed in terms of the Canadian

Class 7 trawler standard) was then computed for each of the two major fisheries in Queen Charlotte Sound.

Pitfalls in the use of these statistics in future stock assessment models are discussed.

ACKNOWLEDGMENTS

The writer is indebted to B. M. Leaman and S. J. Westrheim for their advice and guidance during the preparation of this report and to the former for his subsequent constructive criticism of the manuscript.

^aThere may have been occasions between 1959 and 1964 when some fishing occurred, but significant catches were not made before 1967 (Gunderson et al. 1976). Records for the Canadian fishery prior to 1964 were not coded to distinguish one gully from the other.

^bFigures estimated by Ketchen (1980b) are "intermediate" values. For "minimum" and "maximum" estimates see Ketchen's Table 17.

^cFor 1959-74 figures are from Gunderson et al. (1976), based on performance of the Washington trawl fleet; 1975-79 data provided by Wash. State Dept. Fisheries.

^dNorth American totals for the two gullies differ slightly from those in Gunderson et al. (1976) as a result of re-analysis of Canadian data.

^eEstimated from 1977 ratio in this table.

Table 4. Numbers of trawlers making more than one interviewed landing of Pacific ocean perch per year from Queen Charlotte Sound.

| Year | Vessel class | | | | | | | |
|------|--------------|---|---|---|---|---|---|----|

Fig. 14. Estimated total catch, standardized catch per unit of effort and calculated total fishing effort in the fishery for Pacific ocean perch on grounds associated with Goose Island Gully.

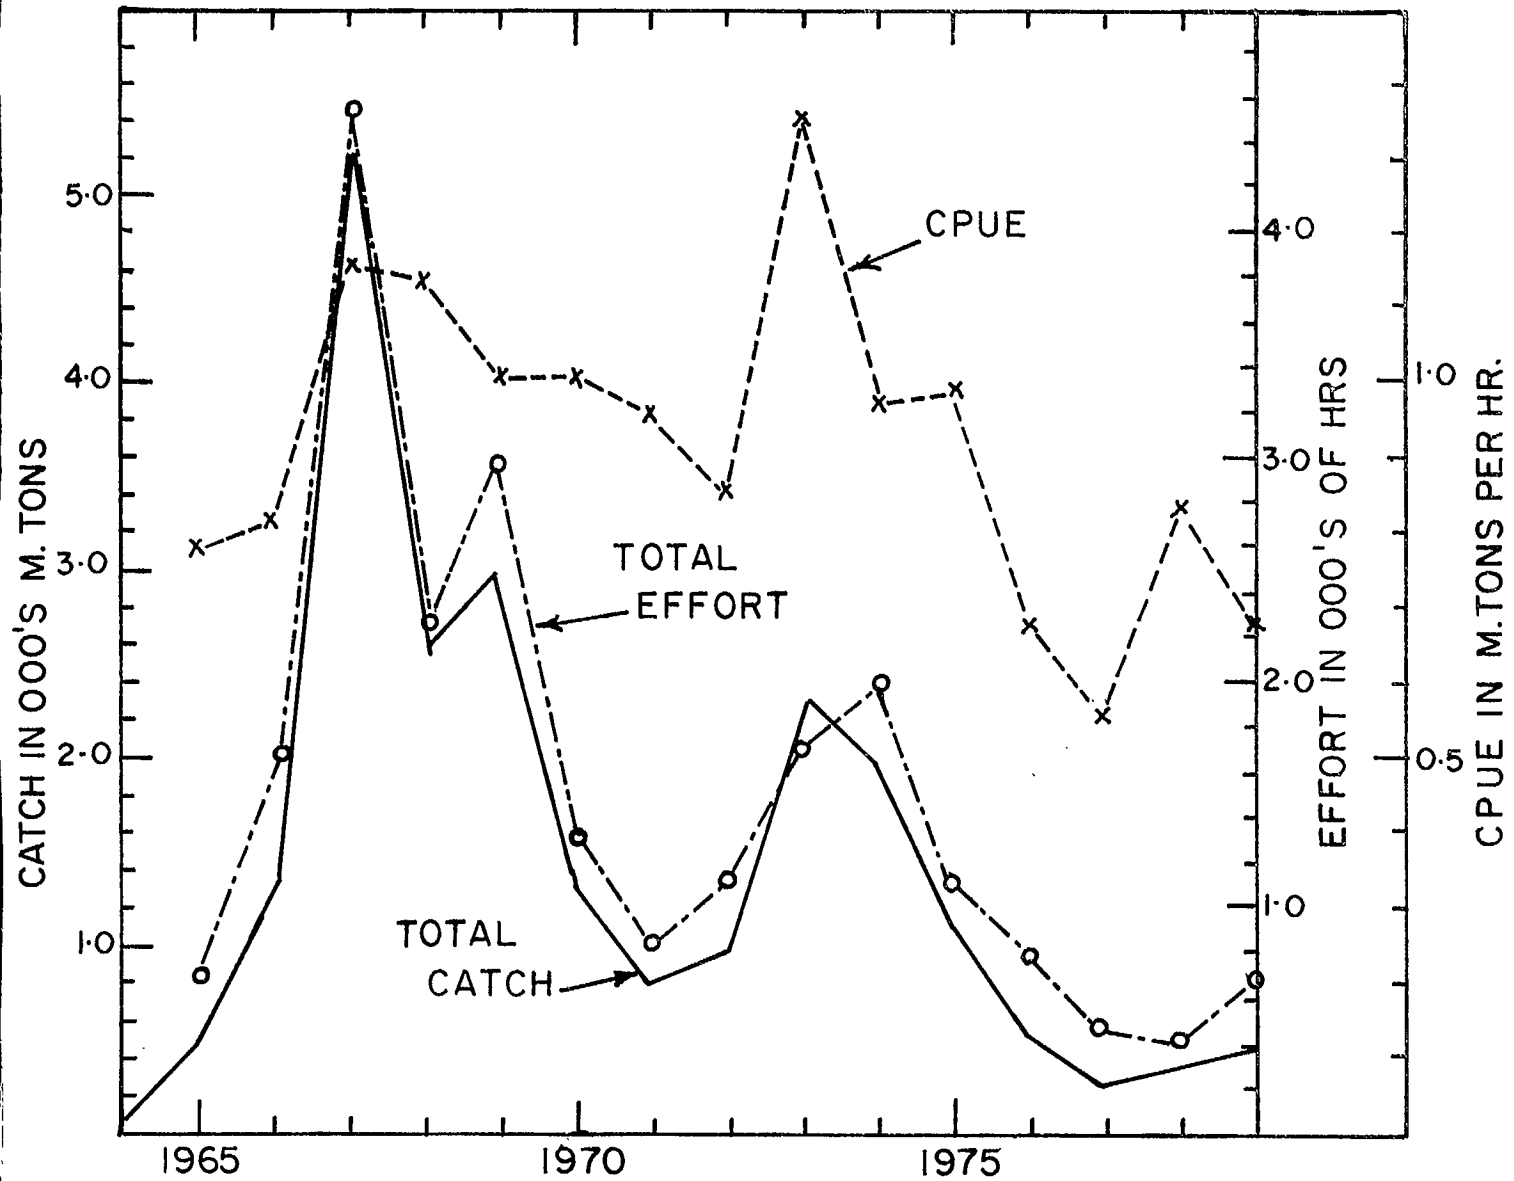

Fig. 15. Estimated total catch, standardized catch per unit of effort and calculated total fishing effort in the fishery for Pacific ocean perch on grounds associated with Mitchell's Gully.

Fig. 16. Evidence of an increase in the efficiency of the Canadian fleet fishing for Pacific Ocean perch in Queen Charlotte Sound (numbers next to dots refer to vessel classes).

Appendix I. An example of the procedure for determining the fishing power (PF) factor of Class 8 trawlers relative to those of Class 7 (CPUE in tons and effort in h).

| Year and month | CPUE | | Effort | | Sum of efforts E8 + E7 | Product of efforts E8 · E7 | $\frac{E8 \cdot E7}{E8+E7}$ (=A) | Axlog $\left[\frac{U8}{U7} \right]$ (=B) | Antilog |
|----------------|---------------|---------------|---------------|---------------|---------------------------|-------------------------------|-------------------------------------|--|------------------------|
| | Class 8 U8 | Class 7 U7 | Class 8 E8 | Class 7 E7 | | | | | $\frac{A}{B}$ (=PF) |
