¹This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author(s). ¹Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteur(s) dans le manuscrit envoyé au secrétariat.

ABSTRACT

The Canadian Georges Bank scallop catch for 1986 was 4,900 t., a 29% increase over last year and the highest of the last five years. This continues the recovery from 1984 landings, which were the worst since 1959. This is due to the strong 1982 and good 1981 and 1983 year-classes. The biomass at the end of 1986 is the highest it has been since the peak of 1977-1978. Research data indicate that the 1984 year-class is also good, and therefore catches should continue at this level or higher in 1987.

In 1986, with a TAC divided into enterprise allocations and the 1981 year-class reaching a size that required little or no blending by the middle of the year, effort focussed on this abundant year-class and CPUE more than doubled over last year.

Yield per recruit and stock projections show that the stock is still fished at a level higher than F_{max} .

For the stock projections the starting numbers are from the cohort analysis, aged forward to January 1987.

RÉSUMÉ

Les prises canadiennes de pétoncles sur le banc Georges sont estimées à 4,900 t en 1986, une augmentation de 29% comparée à l'année précédente et les prises les plus élevées durant les cinq dernières années. Les débarquements continuent de s'améliorer depuis 1984 losqu'ils avaient atteint le niveau le plus bas jamais enregistré (1959). Cette performance est attribuable à la forte classe d'âge de 1982 et aux bonnes années de 1981 et de 1983. La biomasse établie à la fin de 1986 est la plus élevée qu'elle a été depuis le plateau de 1977-78.Les données de recherche indiquent que la classe d'âge de 1984 est prometteuse; par conséquent, les prises devraient continuer à ce niveau ou augmenter pour 1987.

En 1986, la pêche opéra sous un système d'allocations par entreprises. Vers le milieu de l'année, la classe d'âge de 1981 atteignait une grosseur de viandes telle qu'il n'était presque plus nécessaire de mélanger pour obtenir le compte de viandes en vigueur. Cette abondante classe d'âge devint le point focal de l'effort et les PUE plus que doublèrent celles de l'année précédente.

L'analyse de rendement par recrue et les projections de stock montrent que le stock est encore exploité à un niveau plus élevé que F_{max} .

Pour les projections de stock, les nombres de départ provenant de l'analyse de cohortes sont âgés d'avance à Janvier 1987.

INTRODUCTION

Two strong year-classes, those of 1957 and 1972, produced major peaks in landings in the last 30 years of the Georges Bank (Fig. 1 and Table 1). scallop fishery The more recent peak occurred in 1977 and 1978 with landings of over 17,000 t. Landings fell to about 10,000 t in 1980 but increased by almost 6,000 t to 16,000 t in 1981 as a result of increased Canadian and U.S. fishing effort and a relaxation of the enforcement of the meat count regulation on the Canadian fleet. U.S. catch levels have shown an upward trend since the early 1970's to over 8,000 t in 1981, representing an increase of 400% from 1976 to 1981 and a parallel increase in effort. From 1982 on, landings by the Canadian fleet decreased steadily to 1,945 t in 1984, its lowest level since 1959. Marked improvement in catches and catch-rates characterize the fishery in the last two years, however, as landings reached 4,900 t in 1986, a 250% increase over 1984. As another moderately good year-class is about to recruit to the fishery, and the biomass is the highest it has been since 1978, this fishery should continue to improve.

In 1986 the deep-sea fleet (vessels over 19.8m L.O.A.) fished under a meat count of 33 per 500g, which had been implemented on January 1st, 1986, and other management measures as per 1985. In addition, an arbitrary upper catch limit of 4,300 t had been agreed to for 1986. This competitive fishery landed trips over 13,608 kg. With the agreement from industry, the fishery closed on May 20th to provoke negotiations toward the implementation of enterprise allocations. Much discussion took place and the fishery resumed on June 9th; every component of the deep-sea fleet having ratified the allocation plan.

The Bay of Fundy fleet was entitled to fish 111 t on Georges Bank in 1986 (2.9% of the previous year's catch of 3,812 t). Depleted stock conditions in the Bay of Fundy waters shifted a great deal of effort from this fleet to Georges Bank stocks. Preliminary figures establish that this fleet's take was well over their allotment.

METHODS

Catch and effort data are compiled from logbooks. Those logs with complete effort data are called Class 1 and are used to determine catch rates (see Table 2). Also, data on size distribution of meats from the commercial fleet are derived from port samples. Canadian port sampling data were applied to the Canadian and U.S. total catch east of the ICJ line. This assumes similar fishing practices for both fleets. The annual changes in fishing practice can be seen in Table 3a, which contains weight distribution in 2 gram intervals for the last seven years. Changes within 1986 are shown in the same manner in Table 3b, which has the monthly distributions.

Catch in numbers at age (Table 4) for the cohort analysis are derived from the port sampling data and the sum of U.S. and Canadian catches in the Canadian zone. For more details on the method used to derive catch at age see Roddick and Mohn (1985). The total catch (U.S. and Canadian) from the Canadian zone is decomposed into weight frequencies. The weights were converted to shell heights using the allometric relationship derived from 1982 -1985 research and commercial data (Robert et al., 1987). The values expressing meat weight as a function of shell height use the parameters 9.012E-6 for the constant and 3.097 for the exponent of height. These values agree closely with those of Serchuck et al. (1982) for the same stock. Von Bertalanffy growth coefficients relating shell height and age were taken from Brown et al. (1972) as had been done previously.

Traditionally, catch statistics are compiled on an annual basis and recruitment to a fishery is discussed in terms of yearclass strength. It is generally accepted that Georges Bank scallops are born in October and the first annual ring is laid down the following spring. This is typically less than 10 mm and becomes difficult to discern as the animal grows. For this reason the ring, which is approximately 25 mm from the umbo is often referred to as the first annulus (see, for example, Naidu 1970). The convention which we shall adopt is that animals born in the fall of a year will be of that year-class and it will be further assumed that they were born on January 1 of that year. The deposition of the ring less than 10 mm will take place during the first year of life. The data of the deposition will be assumed to take place on April 1. A back calculation is then made to estimate the shell height for January 1. The annual growth rates for weights, given in Table 5, are converted into rates for heights and this results in a 16% reduction of the ring size being used for the January 1 size. For example, an animal born in the fall of 1978 is of the 1978 year-class and will be approximately 25 mm on its second birthday (January 1, 1980) although the ring would not be deposited for a few months. Table 5, as well as all other age data, uses this convention, with correction of ring sizes back to January 1. For use in age/weight programs and projections the actual weights used are mid quarter values.

A research survey was carried out on Georges Bank during August 1986. The design of the survey was based on a stratification by commercial effort. The logbooks of the commercial fleet in the preceding 9 months were analyzed to determine areas of high and low fishing intensity. The areas of high intensity were sampled more heavily as they represent the area most important to the fleet (and presumably the areas of greatest abundance). The estimate of abundance was formed by contouring the catch rates at age of the survey tows and expanding the mean by the area enclosed by a given contour (Robert et al. The average number of animals at age per tow is given in 1986). Table 6. The numbers per tow are converted into indices of abundance by weighting them by the appropriate contour areas. The indices are shown in Table 7.

A Thompson-Bell type yield per recruit analysis was carried out breaking growth down into quarters and using 1986 selectivity values, corrected to reflect the meat count of 33 meats/500 grams. This was done in order to take into account the dynamic growth of the younger age-classes of scallops. This method also takes into account the average quarterly distribution of effort. However, this method cannot include the effects of blending.

A more detailed study of yield per recruit as it applies to the Georges Bank scallop stock was carried out, but as it is detailed in a separate paper (Mohn et al., 1987) it will not be repeated here.

The regulations operant on the offshore fleet are that the catch should average no more than 33 meats per 500 grams which corresponds to an average weight of 15 grams per meat. Placing a limitation on the average instead of stipulating a minimum means that the fishermen may take small animals and then balance them with larger ones. Such a practice, called blending, renders the use of most yield models inappropriate. If there are not enough larger animals to blend in, then the mortality on the small ones will have to be reduced. Thus, the partial recruitment is a In order to take this practice function of abundance at age. into account, a stock projection program was written in 1984 (Mohn et al 1984) in which the mortality on the animals beneath the stipulated average is adjusted until the mean weight of the catch is within 1% of the required average. The only other way in which this program differs from the normal stock projection is that the variables are updated quarterly because of the very rapid growth of the young scallops. The annual growth is divided into quarterly components of 10, 35, 35 and 20% and annual effort is partitioned into quarters by the rates of 10, 55, 25 and 10%. Selectivity for the projections follows the pattern of the fishery as revealed from the cohort analysis instead of that of the gear (Caddy 1972). Starting numbers at age for the projections were derived by aging ahead the 1986 cohort estimates to Jan. 1987.

Because cohort analyses deal only with the removals from a cohort and not the growth of the animals it is not appropriate to use this method for a dynamic species like scallops. In the first year of recruitment the animals experience approximately a 300% increase in weight. In order to reduce the magnitude of the errors caused by ignoring growth effects, the cohort analysis was carried out on a quarterly basis. This required that catch at age be determined on a quarterly basis. Also, the above mentioned quarterly distribution of effort had to be taken into account. Selectivity had to be determined on a quarterly basis also. This was done by adjusting last year's selectivity pattern to reflect the port sampling data for the last quarter of 1986. This pattern, multiplied by the F determined from tuning for the last quarter year, was used as a starting vector for the quarterly cohort analysis. Natural mortality was set at .025 per quarter and no attempt was made to include a seasonal or age dependent effect.

RESULTS

Survey catch-rates (Tables 6,7 and 8) indicate that while year-classes older than 5 are depleted, the strength of the stock is improving with relatively abundant age 5 scallops. The 1982 year-class (age 4) which is sizable, has practically not been exploited yet. A lowering of the meat count to 33 per 500g and reduced fishing pressure are starting to show positive results. The prerecruits (1983 year-class) seem more important than the 1985 survey results had shown; the next incoming year-class also appears to be strong. Stock rebuilding is noticed in contour analysis results (Table 7) to follow the trends outlined in survey catch-rates. Recruited abundance, number-wise, has not been that high since the recent survey series started in 1978.

The cohort analysis was tuned by regressing commercial CPUE versus 4+ biomass (Figure 2.) The regression coefficient was 0.94 and it was encouraging to see a good relationship between these The CPUE was from Canadian vessels inside the Canadian variables. Table 9 contains the population estimates for Jan. 1 of ar. Table 10 is the fishing mortalities. The quarterly Zone. each year. estimated mortalities for 1986 are lower than 1985's, especially on older animals, as the strong year-class of 1982 has reached a size that no longer requires the blending of large animals to make the meat count (Table 11). These results suggest that the fishing mortality is of the order of 1.07 for the fully recruited 5-yr olds, which were required for blending at the start of the year. It is still very low on the larger four year old year-class in spite of its making up more than half the catch by numbers, this is due to its magnitude. Although effort focussed on this group, the fact that it is three times the size of its neighbors resulted in a low fishing mortality by the last quarter of 1986.

A comparison of the research survey contouring and cohort biomass can be seen here and in Figure 3.

	1978	1979	1980	1981	1982	1983	1984	1985	1986
Research Cohort									8625 18356

3+ Biomass Estimates From Research Survey And Cohort Analysis.

The quarterly based yield per recruit analysis used midquarter meat weights and the expanded selectivity used both in the cohort analysis and in the projections. (See Figure 4.) The F_{max} was at an F of 0.630 and $F_{0.1}$ at 0.402. These values differ from previous assessments as the selectivity pattern has changed with the meat count.

Figure 5 shows the apparent lack of a stock recruit relationship as described by traditional models. This may indicate that environmental factors, or dynamics not accounted for in conventional models, determine year-class strength.

Two projections were run for a three year period, one at F_{max} , and the other at $F_{0.1}$, using an estimated recruitment of 400 (x10⁶) for 1987 and 300 (x10⁶) for the following two years (Table 11). As expected F_{max} shows a more rapid removal of the incoming ageclasses. The $F_{0.1}$ shows a sustainment of the pulse at a biomass approximately 25% higher after three years. The recommended catch level from this projection, based on $F_{0.1}$, is 6,500 t for 1987. For more details on the setting of catch levels for this stock see Mohn et al 1987.

Figures 6a and 6b show some of the results of a contour analysis of the survey data. These figures show the aggregated nature of the scallop resource, and they are seen to be concentrated on the Northern Edge and NE Peak for 1986. The total number of scallops is shown in the upper left hand contour map of Figure 6a. Figure 6b follows the 1982 and 1983 year-classes from 1984 to 1986, the concentrations along the Northern Edge appear to be less persistent than the concentrations on the Peak. By age five (Figure 6a), the aggregations are well scattered (no change of scale).

CONCLUSIONS

A relatively strong recruitment was seen in the 1986 fishery. This is evidenced by the change in the monthly CPUE of 1986 compared to 1985 (Figure 7). Fishing early in the year means a loss of yield, and may affect the cohort analysis. The fishery required less blending as the season progressed and the CPUE doubled over last year. The 1986 research survey indicates that the strong recruiting year-class of this year will be followed by an above average one which should further bolster the fishery. At $F_{0.1}$ the recommended catch level for 1987 is 6,500 t, at F_{max} the catch level is 9,000 t.

There is a problem relating the research abundance indices and those derived from cohort analysis as is shown in Figure 3; although the most recent 5 years have tracked each other fairly well (Figure 3). The relative magnitude of the recent trends from the cohort and the contouring analysis suggests that the research figures could be corrected by a factor of two.
