# Assessment of Atlantic Salmon, (Salmo salar), in the Margaree River, 1987 

## by

R.R. Claytor, G.J. Chaput, and T.G. Lutzac<br>Department of Fisheries \& Oceans<br>Science Branch, Gulf Region<br>P.O. Box 5030,Moncton, NB E1C 9B6

${ }^{1}$ This series documents the
scientific basis for fisheries
management advice in Atlantic
Canada. As such, it addresses the
issues of the day in the time
frames required and the Research
documents it contains are not
intended as definitive statements
on the subjects addressed but
rather as progress reports on
ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat by the author.

1Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

#### Abstract

Sport catch of 1 SW salmon in 1987 as estimated by DFO fisheries officers and Nova Scotia license stub returns exceeded 1986. The DFO estimate of 1 SW salmon sport catch was the greatest since 1947, with the exceptions of 1979, 1981, and 1982. MSW salmon sport catch in 1987 as estimated by DFO and stub returns was $50 \%$ of 1986, but otherwise the DFO estimate was the highest since 1962. A creel survey at Forks Pool suggested that DFO underestimated 15 W salmon fall catch by a factor of 1.2 and MSW salmon fall catch by a factor of 2.0 . Voluntary angling logbooks suggested that Nova Scotia license stubs overestimated MSW salmon fall catch by a factor of 2.0. Using exploitation rates of $20.6 \%$ and $37.9 \%$, both non-adjusted and adjusted estimates of DFO sport catch suggest that spawning requirements were met in 1987. Recovery of tags applied at an estuarine trapnet suggest an angling exploitation rate of $15.5 \%$ for $15 W$ and MSW salmon combined. Considering all of the above factors, we conclude that spawning requirements were met in 1987.

The contribution of 15 W salmon hatchery returns to the summer portion of the run exceeded $60 \%$. but was $30 \%$ for the fall. MSW salmon hatchery returns were $40 \%$ of the summer and $4 \%$ of the fall runs. Assessment of hatchery smolts released to the Margaree River indicate that the Rocky Brook stock has a return rate 2.5 times higher than Margaree origin smolts. Sampling from sport fishery, trapinet, and brookstock collections indicate that 13\% of the MSW returns are either repeat spawning 2 SW or virgin $3 S W$ salmon and that these are primarily female.

MSW salmon returns similar to 1987 are forecast for 1988.

## RESUME

Selon les estimations des agents des pêches du MPO et les talons de permis de pêche de la Nouvelle-Ecosse qui ont été retournés, les prises sportives de saumons unibermarins de 1987 ont dépassé celles de l'année antérieure. En fait, les évaluations du MPO sont les plus élevées depuis 1947, si l'on fait exception de 1979, 1981 et 1982. Par ailleurs, d'après les estimations du MPO et les talons de permis de pêche de la Nouvelle-Ecosse retournés, les prises sportives de saumons redibermarins se sont établies à la moitié des prises de 1986; l'estimation du MPO était la plus élevée depuis 1962. Selon les résultats d'un sondage des pêcheurs, effectué au fosse Forks, il apparait que le MPO a sous-estimé les prises automnales de saumons unibermarins par un facteur de 1,2 et les prises automnales de redibermarins par un facteur de 2,0. Les relevés volontaires des pêcheurs à la ligne semblent indiquer que les chiffres fondés sur les talons des permis de pêche de la Nouvelle-Ecosse surestimaient les prises automnales de redibermarins par un facteur de 2,0 . Si l'on se fonde sur des taux respectifs d'exploitation de 20,6\% et $37,9 \%$, les estimations, révisées et non révisées, de prises sportives établies par le MPO indiquent que les besoins de reproducteurs ont été satisfaits en 1987. Compte tenu
des récupérations d'étiquettes posées à un parc en filet estuarien, on peut chiffrer à $15,5 \%$ le taux d'exploitation combiné de la pêche à la ligne des unibermarins et des redibermarins. Tous ces facteurs permettent de conclure que les besoins de reproducteurs ont été satisfaits en 1987.

La proportion des retours d'unibermarins d'élevage dans la migration d'été a dépassé les $60 \%$. Elle s'établissait à $30 \%$ pour l'automne. Les retours de redibermarins d'élevage ont été de $40 \%$ et de $4 \%$ respectivement dans les migrations d'été et d'hiver. Les évaluations de saumoneaux d'élevage lâchés dans la rivière Margaree indiquent que le stock du ruisseau Rocky a un taux de retour 2,5 fois supérieur à celui des saumoneaux originaires de la rivière. Des échantillons de prises sportives, de saumons captés dans le parc en filet et de spécimens du stock reproducteur permettent d'établir que $13 \%$ des redibermarins qui retournent à la frayère sont soit des dibermarins à pontes antérieures, soit des tribermarins vierges et qu'il s'agit essentiellement de femelles.

On s'attend à ce que les retours de saumon de 1988 soient sensiblement les mêmes qu'en 1987.

## INTRODUCTION

## OBJECTIVES

The purpose of this paper is to provide an assessment of the Margaree River Atlantic salmon stock in 1987. Past assessments have relied exclusively on DFO angling statistics and fixed exploitation rates to determine spawning escapement and forecast returns (Claytor and Chadwick 1985; Claytor and Léger 1986). As a result, these assessments have raised several issues requiring additional information to resolve. These issues include, resolving the difference between angling catch statistics collected by DFO fisheries officers and those from Nova Scotia license stub returns, ensuring that hook-and-release estimates of MSW salmon can be interpreted relative to historical catch-kill records, evaluating the relative contribution of hatchery released salmon to -river returns, and finding a reliable method of forecasting returns. In addition, recent information on size-at-age and previous spawners has been deficient for the Margaree River.

In 1987, three programs were initiated to address the above concerns. Firstly, a creel survey at Forks Pool, the major angling pool, and secondly, voluntary angling logbooks provided a means of resolving the discrepancy between DFO fisheries officers and Nova Scotia license stub returns.

Thirdly, the feasibility of a mark-recapture program to estimate population size, exploitation rate and determine biological characteristics was examined using an estuarine trapnet to capture salmon. The development of these programs and their use in resolving the above issues are described in the following sections.

## BACKGROUND

The Margaree River is located on Cape Breton Island, Inverness County, Nova Scotia. Two principal branches, the Northeast Margaree and Southwest Margaree, meet at Margaree Forks to form the Main Margaree which flows into the Gulf of St. Lawrence. Most of the Atlantic salmon angling occurs in the Main Margaree and Northeast Margaree rivers. Margaree River salmon stocks are composed of two runs: the summer run enters the river up to the end of August; and the fall run, after September 1.

Since 1979, efforts to increase the summer component of the Atlantic salmon stock have consisted of regulatory restrictions and introduction of hatchery-reared progeny from early-run fish. Anglers have been required to release MSW salmon during the early-run (before September 1) since 1979. From 1985-1987, all MSW salmon were released regardless of date caught. In 1984, there was a reduction in the zone 6 commercial fishery from eight to three weeks. There was no zone 6 commercial fishery from 1985-1987.

## METHODS

## LANDINGS

Angling records from 1947-1987 were provided by fishery officers, Department of Fisheries and Oceans, Margaree Forks, Nova Scotia. These records are subsequently referred to as DFO statistics. Sport catches for 1984-1986 were also obtained from Nova Scotia license stub returns ( 0 'Neil et al. 1985, 1986, 1987). Preliminary 1987, as of November 12, Nova Scotia license stub returns were obtained from S. D'Neil, DFO Halifax, Nova Scotia. Commercial landings for zone 6 (1967-1984) are also reported (Claytor and Chadwick 1985).

## FORKS POOL CREEL SURVEY

A creel survey was conducted at Forks Pool (Fig. 1) from September 1 October 15 to estimate catch and effort for this portion of the sports fishery. Creel periods were stratified into AM (0600-1330) and PM (1330-2100) and weekday and weekend (including holidays) periods. It was decided to cover $23 / 30$ ( $75 \%$ ) of the available weekdays and $7 / 14$ ( $50 \%$ ) of the weekend days. Each day within a weekday-weekend stratum was assigned a consecutive number and was selected for the creel using a random number table. Once these days were selected, a random number table was used to determine whether a day would be an AM or PM creel. An odd number selected AM and even PM. Days and time periods are given in Table 1.

During the creel period numbers of $15 W$ salmon kept, and $15 W$ and $M S W$ salmon hooked and released, as well as method of release were noted. (Fig. 2). The release methods were defined as:

1) remove hook $(R H)$, fish was handled by angler and hook removed' by hand;
2) cut line (CL), fish was not handled but leader was intentionally cut or broken by angler;
3) lost (LO), fish took fly, but dislodged hook before it could be intentionally released.

As anglers left the pool they were interviewed to obtain the time they started and completed fishing, numbers and types of fish kept or released, and method of release. Forms used for interview are provided in Fig. 3. Sampling from all 1 SW kept and as many 1 SW and MSW salmon released as possible included fork length (nearest cm), scales, sex, and presence or absence of adipose clips and wire nose tags. Sex was determined internally from kept and externally from released fish.

The observed catch and effort data from each stratum was used to estimate total catch and effort at Forks Pool from September 1 - October 15 in the following manner. Total effort at Forks Pool was estimated by calculating mean effort in hours/day and rod-days/day (rod-day is one angler fishing for any portion of one day) and multiplying by the number of available days in each stratum. These estimates of effort were then multiplied by observed catch/effort to determine estimated catch in each stratum. Estimated catches were divided into $15 W$ and MSW salmon on a proportional basis within each stratum. The estimated catches and efforts were then summed to determine the overall estimated catch/effort. Estimates of fall $15 W$ and MSW salmon catches for the entire Margaree River were calculated using the percentage of total fall 1 SW and MSW salmon catch taken at Forks Pool as an adjustment factor.

The Forks Pool creel provides three comparisons to DFO sport catch statistics, 1) estimates from creel days to DFO counts for the same days, 2) estimates of total Forks Pool catch by creel and DFO, and 3) estimates of total river catch based on Forks Pool creel and DFO. It has been assumed (Claytor and Léger 1986) that DFO underestimates sport catch. Comparing these estimates provides a test of this assumption.

## VOLUNTEER LOGBOOKS

Nineteen members of the Margaree Salmon Association were asked to keep a logbook of each fishing trip on the Margaree River. As of Nov. 3, 1987, eleven of these anglers had returned their logbooks. Anglers were requested to note the start and finish times for each fishing trip, pools fished, numbers kept, hooked and released, and method of release (Fig. 4). In addition, they collected scale samples, determined sex, and collected noses or heads from all hatchery fish kept for wire nose tag detection.

It has been suggested that Nova Scotia license stub returns may be overestimating sport catch (Claytor and Léger 1986). MSW salmon catch, in particular, may be overestimated by the inclusion of lost fish in hook and release reports. Anglers returning voluntary logbooks report method of release and numbers of lost fish. Thus fish which would have been landed (RH, CL) may be separated from those lost. The proportion of 1SW: MSW salmon in logbook catches may be assumed to be identical to all anglers on the Margaree River. By considering only RH or CL releases, these proportions may be used to adjust license stub MSW salmon hook and releases relative to catch/kill reports for 1 SW salmon. Comparing the stub adjustments by this method to creel estimates provides a test of whether or not Nova Scotia license stub returns are overestimating sport catch.

## TRAPNET

A trapnet was used to monitor $15 W$ and MSW salmon returns to the Margaree River for seven, one week periods from June 23 - October 17 (Table 2). The trapnet was located approximately 1 km above the Margaree Harbour Bridge (Fig. 1) and was the same design as the recapture traps on the Northwest and Southwest Miramichi, a commercial Miramichi box trapnet (Dunfield 1974). The trap was made from 5.72 cm ( $2 \frac{1}{4}{ }^{\prime \prime}$ ) knotless nylon mesh, was 4.3 m (14') deep, $3.7 \mathrm{~m}\left(12^{\prime}\right)$ wide, and 18.9 m (62') long. The trap portions at each end were 7.9 m (26') long. The leader extended 90 m (300') to shore and consisted of 14 and 15.25 cm ( $5 \frac{1}{2}$ " and $6^{\prime \prime}$ ) mesh. In the fall a 45 m (150') section of 5 cm (2") mesh was substituted at the shore end of the leader to prevent meshing of salmon. A larger mesh was used in the summer because of the debris in the river that would otherwise be caught in the leader. Even with the larger mesh this debris tended to block the leader and prevent salmon from meshing in the leader. In the fall this debris was not present in large quantities. Hence, it was felt that salmon may have meshed in the leader unless a smaller mesh size were used.

A numbered carlin tag was attached to all fish captured in the trap. Fork length (nearest cm) was measured and a scale sample removed from all fish captured. Sex was determined externally. All hatchery released fish have the adipose fin removed. Wild were distinguished from hatchery returns by the presence of the adipose fin.

An exploitation rate was calculated using tag returns from the sports fishery. As for the LaHave River, tag loss, non-reporting and mortality were assumed to be $30 \%$ overall (Cutting and Jefferson 1986). Twelve tags have been returned to date. We expect an additional return of $17 \%$ during the winter, as is the case for the Miramichi (R. Randall, DFO, Moncton, N.B.) for a total tag return of 14 . This number of tags was used to provide a preliminary estimate of exploitation rate and population size using trapnet data.

## HATCHERY RETURNS

In 1986 smolts of Rocky Brook, Miramichi, parentage released into the Margaree were wire nose tagged, while those of Margaree parentage were not.

All hatchery released smolts were adipose fin clipped. Heads or noses collected from adipose fin clipped 1 SW salmon caught by volunteer logbook anglers, Forks Pool creel, and spot checks at various pools were checked for wire nose tags using a Northwest Marine Technology, Inc. field sampling dectector.

Proportions of hatchery and wild fish returning to the Margaree River were determined from angler logbooks, Forks Pool creel, angler spot checks, broodstock collections (Hatchery and McKenzie pools, Fig. 1), and trapnet captures.

## SPAWNING REQUIREMENTS

The required number of spawners was calculated using the method (Method 2) recommended by Randall (1985) for the Miramichi River. The number of spawners required to meet egg deposition requirements was calculated presuming that all egg deposition came from MSW salmon. The numbers of 1 SW salmon required were calculated assuming that at least one male spawner was needed for each female MSW salmon.

The characteristics used to determine the spawning requirements were essentially those given by Gray and Chadwick (1984) and are repeated below:

| Egg deposition rate | $=$ | 2.4 eggs/m2 (Elson 1975) |
| :---: | :---: | :---: |
| Rearing area | = | 2,797,600 m2 (Marshall 1982) |
| Fecundity MSW | $=$ | 1,764 eggs/kg (Elson 1975) |
| 1SW | = | 1,764 eggs/kg (Elson 1975) |
| Mean weight MSW | = | 4.9 kg (Marshall 1982) |
| 15W | = | 1.7 kg (Marshall 1982) |
| Sex ratio male/female MSW | = | 25:75 (Marshall 1982) |
| 1SW | $=$ | 89:11 (Marshall 1982) |
| Eggs per MSW | $=$ | 6,482 eggs $=1,764 \times 4.9 \times .75$ |
| 1SW | $=$ | 330 eggs $=1,764 \times 1.7 \times .11$ |

## EGG DEPOSITION

Total egg deposition from 1 SW and MSW salmon was calculated as described below:

Sport catch (SC)

| $\frac{\text { Sport catch (SC) + Spawners }}{}$ | $=$ Exploitat |
| ---: | :--- |
| $\frac{S C(1-E R)}{E R}$ | $=$ Spawners |

Exploitation rates for $1 S W$ and MSW salmon 20.6 and $37.9 \%$, were those determined by Hayes (1949).

For years in which there were hook-and-release regulations, 1979-1987, the MSW salmon caught and released were added to the number of spawners calculated as above. This factor assumes there is no mortality as a result of hook and release.

For all years, egg deposition was calculated as the number of $15 W$ or MSW spawners times the eggs per 1SW or MSW fish (see above). The eggs obtained from broodstock collections were subtracted from the above egg deposition values.

## FORECAST

The number of $15 W$ and MSW salmon, both hatchery and wild, caught in the summer and fall segments of the season since 1983 were used in an attempt to forecast returns in 1988. A regression of $15 W$ year (i) against MSW year (i+1) for each part of the run was attempted for this purpose. Considering years since 1983 has the advantage of using only data collected after the implementation of hook and release requirements to calculate forecasts.

## RESULTS AND DISCUSSION

## LANDINGS

Commercial landings for zone 6 (1967-1984) are presented in Table 3, DFO Sport catch statistics from (1947-1987) in Table 4, and Nova Scotia license stubs (1984-1987) in Table 5. 1SW salmon sport catch based on license stub estimates was 1.5-2.5 times DFO statistics from 1984-1987. MSW salmon sport catch based on license stub estimates was 2.5-3.5 times DFO statistics from 1984-1987 (Tables 4, 5). 1SW salmon sport catch in 1987 (DFO) was the greatest since 1947, with the exceptions of 1979, 1981, and 1982. MSW salmon sport catch in 1987 (DFO) was $50 \%$ of 1986 , but otherwise was the highest since 1962 (Table 4).

Most (70\%) of the MSW salmon in 1987 were caught in the fall. Since 1947 the percentage of MSW salmon caught in the fall has ranged between 54-78\%, with the exception of 1980 (99\%) (Table 6). In contrast, the percentage of $15 W$ salmon caught in the summer (76\%) was the highest ever except for 1979, 1981, and 1982. Previous percentages for 1SW caught in the summer have ranged from 51-66\% (Table 6).

The fishing effort and catch observed during the September 1-October 15 Forks Pool creel are presented in Table 7. Estimates of effort and catch for this period are presented in Table 8.

From 1947-1983 Forks Pool accounted on average for 18.7\% of the 1SW and 14.3\% of the MSW salmon catches (DFO) on the Margaree River from September 1

- October 15. Since 1984, Forks Pool has accounted on average for 5.3\% of the 1 SW and $6.6 \%$ of the MSW catches (Table 9). Because of a possible change in catch pattern, only the value for 1987 was used to provide a total estimate of fall 1SW and MSW salmon catches for the Margaree River.

Estimates of $15 W$ salmon retained at Forks Pool by the creel method are similar to those counted by DFO for days corresponding to creel and total time period. DFO accounted for six 1 SW salmon on the days corresponding to the creel. Three 1 SW salmon were observed by the clerk during AM and PM creel periods (Table 1). Using the observed catch and effort from the creel, six 1 SW salmon were estimated to have been caught for all time periods during the 30 creel days. For the entire fall period, DFO accounted for seven 1 SW salmon, while eight 1 SW salmon were estimated to have been caught for the 45 day fall period using creel data (Table 10). This difference suggests that DFO may underestimate 1 SW salmon catch by a factor of $8 / 7$ or 1.1 if only catch at Forks Pool is considered. Using the 1987 proportion of Forks Pool catch (Table 9) to estimate total river catch suggests the actual 15 W salmon catch is 1.2 times (98/85) the DFO estimate (Table 10).

Estimates of MSW salmon, considering only those released by removing the hook by hand, using the creel method are twice those counted by DFO for days corresponding to creel and total time period. DFO accounted for 24 MSW salmon hooked and released on the days corresponding to the creel. Twenty MSW salmon were observed by the clerk during AM and PM creel periods (Table 1). Using the observed catch and effort from the creel, 42 MSW salmon were estimated to have been caught for all time periods during the 30 creel days. For the entire fall period at Forks Pool, DFO accounted for 32 MSW salmon hooked and released, while 63 MSW salmon were estimated to have been caught for the 45 day fall period using creel data. This difference suggests that DFO may underestimate MSW salmon catch by $63 / 32$ or 2.0 (Table 10). Using the Forks Pool proportion method of estimating total river catch suggests that MSW salmon catch may be 2.0 times (563/285) the DFO estimate (Table 10).

Preliminary Nova Scotia license stub returns provides an estimate of 693 1SW kept and 1,540 MSW salmon hooked and released on the Margaree River this year (Table 5). Using the summer:fall (76:24) ratio for 1 SW salmon caught in 1987 (Table 6) an estimate of 166 fish caught in the fall and 527 in the summer is obtained (Table 10). Using the summer:fall (30:70) ratio for MSW salmon catch in 1987 (Table 6) an estimate of 1,078 fish caught in the fall and 462 in the summer is obtained (Table 10).

The proportion of 1SW:MSW salmon in the fall logbook angler catch was 1:4 (Table 7). Assuming the stub estimate of 1 SW salmon is accurate this logbook ratio suggests that catch of MSW salmon should have been 664. This is much closer to DFO statistics. However, stub returns are similar to creel estimates which include lost fish (Table 10).

The general agreement for $15 W$ salmon retained between creel and DFO methods suggests that DFO statistics more closely reflect numbers retained than hook and release figures. This discrepancy could result from the
difficulty of recording or interpreting releases from angler interviews during patrols. Hence, regarding the relationship between hook and release and catch/kill records, it is suggested that with the above correction, removing the hook by hand and cutting the line are appropriate criteria for equivalence between release and catch/kill records for the Margaree River.

These comparisons suggest that DFD statistics underestimate 1SW and MSW salmon catch, while stub returns overestimate MSW salmon catch because lost fish are included in hook and release reports. When DFO catch statistics are adjusted by creel correction factors, 1.2 for $15 W$ and 2.0 for MSW salmon, and lost fish are removed from stub return MSW salmon reports, reasonable agreement occurs between these two statistics.

A summer creel comparable to the fall was not conducted. Hence, determining a correction factor for resolving differences between DFO and stub return statistics unique to this period was not possible. Therefore, the creel correction factors determined in the fall were used to adjust DFO angling catch over the whole season for purposes of determining spawning escapement. Including a summer creel and expansion of the voluntary logbook system will assist in a further resolution of the discrepancy between these two reporting systems.

## SPAWNING REQUIREMENTS

Spawning requirements for the Margaree River were found to be 1,036 MSW and 579 1SW salmon. These figures were derived as given below:
(1) egg requirements $=2.4$ eggs $\mathrm{m}-2 \times 2,797,600 \mathrm{~m} 2$

$$
=6,714,600 \text { eggs }
$$

(2) eggs/MSW salmon $=8,643$ eggs/MSW X. 75 (females)

$$
=6,482
$$

(3) required number of MSW $=6,714,600+6,482$

$$
=1,036
$$

number of female MSW $=1,036 \times .75$

$$
=776
$$

number of male MSW $=260=1,036-776$
number of male $1 \mathrm{SW}=516=776-260$
number of $15 \mathrm{~W}=579=516+.89$
Using these values, MSW salmon account for $100 \%$ of the eg deposition requirements and $97 \%$ of the total egg deposition.

## SPAWNING ESCAPEMENT, EGG DEPOSITION, AND EXPLOITATION RATE

Exploitation rates of 20.6 and $37.9 \%$ applied to non-adjusted DFO counts as in previous assessments (Claytor and Léger 1986) provide estimates of spawning escapement indicating that spawning requirements were met in 1987 (Table 11). Assessments using non-adjusted DFO sport catch suggest that spawning requirements were rarely achieved on the Margaree River since 1947 (Table 12). However, when the DFO sport catch statistics are adjusted as suggested above (by creel survey results), spawning requirements have been met each year since 1985, provided exploitation rate has not exceeded 37.9\% (Table 11). Recapture of tags indicates an exploitation rate of $15.5 \%$. This rate would indicate a population size of 5,265 for MSW and 2,311 for 1SW salmon based on adjusted DFO statistics. These fish would provide 561\% of egg requirements. Considering all of the above factors, we conclude that spawning requirements have been met in 1987.

An exploitation rate of $15.5 \%$ is lower than estimates used in previous assessments. This lower rate could reflect changes in catch patterns resulting from the implementation of hook and release of MSW salmon and/or the prohibition on angling in the sanctuary area above McKenzie Pool (Fig.1). In addition, low water levels during the summer of 1987 may have reduced catchability. As a result, at least another year of tag return data is required to determine which exploitation rates reflect current catch patterns.

## HATCHERY CONTRIBUTION

The proportion of hatchery versus wild 1 SW and MSW salmon in the Margaree River are indicated in Table 13. Applying these proportions to the sport catch (DFO) since 1983 produces the numbers of hatchery and wild salmon caught on the Margaree River in this period (Table 14).

Detector results of 41 angled hatchery return 15 W salmon indicated that 27 or 66\% had wire nose tags and were from the $2^{+}$smolts of Rocky Brook parentage released in 1986. These nose tagged smolts made up $41 \%$ of the hatchery released parr and smolts available to return to the Margaree River as 1 SW salmon in 1987 (Table 15).

Of the 268 1SW salmon caught in the summer of 1987, 169 were of hatchery origin (Table 14). Therefore, 112 of these were from Rocky Brook $2^{+}$smolt releases. From the 26 hatchery returns caught in the fall, 17 would be from this group for a total of 129 1SW salmon of Rocky Brook parentage in the angling catch. Applying the 20.6 and $37.9 \%$ exploitation rates to the hatchery released fish caught in 1987 provides the following return rates for Rocky Brook $2^{+}$smolts and all others available for return as $15 W$ salmon (Table 15).

Exploitation rate

| Origin | Angled | Exploitation rate |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | 20.6\% |  | 37.9\% |  |
|  |  | Total returns | Return Rate | Total returns | Return Rate |
| Rocky Broak $2^{+}$ | 129 | 626 | 6.46 | 340 | 3.51 |
| Others | 66 | 320 | 2.25 | 174 | 1.23 |

Hence, Rocky Brook fish are more than twice as likely to return as 1SW salmon than those of Margaree origin.

The years 1979, 1981, and 1982 are the only other years corresponding to those following releases of Rocky Brook smolts (Table 15). These years provided very high returns of 1 SW salmon (Table 4). Earlier conclusions (Gray and Chadwick 1984) regarding the importance of this stock for increasing the summer 1SW salmon run to the Margaree River appear to be validated by the results of this tagging experiment.

## BIOLOGICAL CHARACTERISTICS

The length-frequency histogram of all sampled fish clearly separates 1SW from MSW salmon and suggests two components to the MSW salmon population. The first component consists of MSW salmon from 62.5-87.5 cm ( $87 \%$ ), and likely includes repeat spawning $1 S W$ and virgin $2 S W$ salmon, while those $>87.5 \mathrm{~cm}$ (13\%) likely include repeat spawning $2 S W$ or virgin $3 S W$ salmon (Fig. 5).

Mean fork lengths of 1 SW salmon sampled in the fall exceeded those in the summer by 1.5 cm (Table 16), while fall exceeded summer MSW salmon by 1.7 cm (Table 17). These differences were significant for 15 W but not for MSW salmon, $p<0.05$.

There was no difference in fork length between male and female 1SW salmon over the entire season (Table 16). Fork length of female MSW salmon sampled in the fall exceeded male MSW salmon by 2.7 cm (Table 17). These differences were significant, $p<0.05$, but only because all salmon over 84 cm were females, suggesting that repeat $2 S \mathrm{~W}$ spawners and virgin 3SW salmon are primarily females.

The sex ratios male/female were 84:16 for 1 SW and 37:63 for MSW salmon. The proportions of males are slightly lower than previous assessment values for 1 SW but higher for MSW salmon. However, they are not sufficiently different to warrant a change in calculation of spawning requirements.

## FORECAST

The fall MSW salmon angling catch (DFO) was predicted using fall 1SW salmon angling catch (DFO) from the previous year since 1983 (Table 14,

Fig. 6). This relationship predicts a fall MSW salmon catch (DFO) of 273 for 1988. This catch would be similar to 1987 (Table 14) and suggests that spawning requirements will be met in 1988 if the fall again accounts for 54 - 78\% for the MSW salmon catch as it has done since 1947 (Table 6). If 273 represents $78 \%$ of the MSW salmon catch, the total number of hook and releases would be 350, this number would provide $89 \%$ of egg deposition requirements if exploitation rate is $37.9 \%$ and $164 \%$ if it is $20.6 \%$. These figures would be doubled if the adjustment to DFO figures suggested above is made. This forecast should be interpreted with caution as it is based on only four points.

The unpredictable nature of summer returns appears to be the reason previous attempts to forecast returns were not reliable. There is no apparent relationship between $15 W$ salmon (year i) and MSW salmon (year i+1) even for wild fish during the summer period (Table 14).

1 One MSW salmon was caught and released twice in sports fishery.
2 Fish tagged during this period were not considered available to sports fishery.

Table 11. Estimated Atantic salmon egg deposition in the Margaree River from 1984-1987 using non-adjusted and adjusted DFO catch statistics. Exploitation rates (20.6 and $37.9 \%$ ) used in past assessments have been used to estimate potential $15 W$ and MSW salmon spawners. Fecundity rates used to calculate egg deposition were 6,482 eggs/MSW and 330 eggs/1SW. Egg deposition requirements are 6,714,600 eggs. * indicates years in which spawning requirements have been met.

| Total season | 60 | 80 | 185 | 40 |
| :--- | :--- | :--- | :--- | :--- |

1 Table 13 should be interpreted with the following cautionary notes. Broodstock collections occur at sites of hatchery releases and may be biased towards them. Trapnet counts would have missed 1SW and MSW salmon which were observed in the sanctuary in early June and may be biased toward wild fish during the summer if most hatchery fish returned during that period.

Table 14. Estimated numbers of summer and fall, wild and hatchery, salmon caught on the Margaree River from 1983-1987 using DFO Statistics from Table 6 and proportions from Table 13.

| Year | Summer |  |  |  |  |  | Fall |  |  |  |  |  |
