The Canadian Georges Bank scallop catch for 1987 was $6,800 \mathrm{t}$, a $45 \%$ increase over last year and the highest of the last six years. This continues the recovery from 1984 landings, which were the worst since 1959, and is due to the strong 1982 and good 1981 and 1983 year-classes. The biomass at the end of 1987 is the highest it has been since the peak of 1977-1978. Research data indicates that recent year-classes have not been as strong, and therefore catches will not continue at this level in 1988.

In 1987, the second year for a TAC divided into enterprise allocations, the strong 1982 year-class was of a size that allowed it to be blended with smaller animals. CPUE continued to fall from a peak in mid 1986 as the strong year-class was being depleted, but the annual rate remains well above the average for the past 16 years.

Yield per recruit and resultant stock projections estimated a Fo.l catch level of $6,500 t$ for 1987 which compares well with the estimated 6,800 removals. However, the $F$ level was significantly higher than $\mathrm{F}_{0.1}$. Although quota controls were in place, the higher $F$ is due to an effort increase of about 50\% from 1986 to 1987 combined with a selectivity change in response to the size composition of the stock. Effort was focused more on age 4 and 5 animals, perhaps because older animals were not needed for blending.

The stock projections are performed with starting numbers derived from the cohort analysis, aged forward to January 1988. The F0.1 catch level for 1988 is 4,800 t.

## RESUME

Les prises canadiennes de pétoncles sur le banc Georges sont estimées à 6,800 t en 1987, une augmentation de 45\% comparée a l'année précédente et les prises les plus élevées durant les six dernières années. Les débarquements continuent de s'améliorer depuis 1984 losqu'ils avaient atteint le niveau. le plus bas jamais enregistre (1959). Cette performance est attribuable à la forte classe d'age de 1982 et aux bonnes années de 1981 et de 1983. La biomasse établie à la fin de 1987 est la plus élevée qu'elle a été depuis le plateau de 1977-78. Les données de recherche indiquent que les plus recentes classes d'âge ne sont pas aussi fortes que celle de 1982 et que les prises ne pourront continuer à ce niveau en 1988.

En 1987, la 2 ième année du régime d'allocations par entreprise, l'importante classe d'age de 1982 avait atteint une taille qui permettait de la mélanger avec des animaux plus petits. Les PUE continuèrent à baisser du pic de la mi-1986 à mesure que l'importante classe d'âge diminuait mais le taux annuel demeure au-dessus de la moyenne pour les 16 dernières années.

D'après une analyse de rendement par recrue et une projection de stock on estima un niveau de prises de 6,500 t. à Fo.1 pour 198.7; ce qui se compare bien avec les $6,800 \mathrm{t}$ qu'on suppose débarquées. Cependant, le niveau de F était significativement plus élevé que Fo.1. Même si les prises étaient contrôlées, le $F$ plus grand est da à une augmentation de l'effort d'à peu près 50 \% de 1986 à 1987 en plus d'un changement de la sélectivité suscité par la structure du stock. L'effort était dirige davantage vers des animaux de 4 et 5 ans, peut-être parce que des animaux plus vieux n'étaient pas requis pour renconter le compte de viandes.

Pour les projections de stock, les nombres de depart provenant de l'analyse de cohortes sont agés d'avance à Janvier 1988. Le niveau des prises avec $\mathrm{F}_{0} .1$ pour 1988 est de $4,800 \mathrm{t}$.

## INTRODUCTION

Two strong year-classes, those of 1957 and 1972 , produced major peaks in landings in the last 30 years of the Georges Bank scallop fishery (Figure 1 and Table 1). The more recent peak occurred in 1977 and 1978 with landings of over $17,000 \mathrm{t}$. Landings fell to about $10,000 \mathrm{t}$ in 1980 but increased by almost 6,000 t to $16,000 \mathrm{t}$ in 1981 as a result of increased Canadian and U.S. fishing effort and a relaxation of the enforcement of the meat count regulation on the Canadian fleet. U.S. catch levels have shown an upward trend since the early 1970 's to over $8,000 \mathrm{t}$ in 1981 , representing an increase of $400 \%$ from 1976 to 1981 and a parallel increase in effort. From 1982 on, landings by the Canadian fleet decreased steadily to $1,945 \mathrm{t}$ in 1984 , its lowest level since 1959. Marked improvements in catches and catch-rates characterize the fishery in the last two years, however, as landings reached $4,900 \mathrm{t}$ in 1986, a 250\% increase over 1984 and $6,800 \mathrm{t}$ for 1987. The last two year-classes have not been strong and catches and catch rates are expected to fall in 1988.

In 1987 the deep-sea fleet (vessels over 19.8m L.O.A.) fished under a meat count of 33 per 500 g , which had been implemented on January 1st, 1986, and other management measures as per 1985. 1987 marked the second year of the three year experimental fishing plan based on enterprise allocations. Following the Inshore/Offshore Agreement of 1986 , the Bay of Fundy fleet was entitled to $8 \%$ ( 548 t ) of the Georges Bank allocation for 1987. This fleet fished all of its allotment, but in an orderly fashion compared to 1986. According to the agreement, their entitlement for 1988 will be $4 \%$ of the Georges Bank TAC.

## METHODS

Catch and effort data are compiled from logbooks. Those logs with complete effort data are called Class 1 and are used to determine catch rates (Table 2). The Class 1 data represent more than $90 \%$ of the total. Also, data on size distribution of meats from the commercial fleet are derived from port samples. Canadian port sampling data were applied to the Canadian and U.S. total catch east of the ICJ line. This assumes similar fishing practices for both fleets. The annual changes in fishing practice can be seen in Table 3 , which contains weight distribution in 2 gram intervals for the last seven years. Changes within 1987 are shown in the same manner in Table 4 , which has the monthly distributions. Figure 2 shows the monthly catches and CPUE's for the last four years.

Catch in numbers at age (Table 5) for the cohort analysis are derived from the port sampling data and the sum of U.S. and Canadian catches in the Canadian zone. For more details on the method used to derive catch at age see Roddick and Mohn (1985). The total catch (U.S. and Canadian) from the Canadian zone is decomposed into weight frequencies. The weights were converted to shell heights using the allometric relationship derived from 1982-1985 research and commercial data (Robert et al., 1987). The values expressing meat weight as a function of shell height use the parameters 9.102E-6 for the constant and 3.097 for the exponent of height. These values agree closely with those of Serchuck et al. (1982) for the same stock. Von Bertalanffy growth coefficients relating shell height and age were taken from Brown et al. (1972) as had been done previously.

Traditionally, catch statistics are compiled on an annual basis and recruitment to a fishery is discussed in terms of year-class strength. It is generally accepted that Georges Bank scallops are born in October and the
first annual ring is laid down the following spring. This is typically less than 10 mm and becomes difficult to discern as the animal grows. For this reason the ring, which is approximately 25 mm from the umbo is often referred to as the first annulus (see, for example, Naidu 1970). The convention which we shall adopt is that animals born in the fall of a year will be of that year-class and it will be further assumed that they were born on January 1 of that year. The deposition of the ring less than 10 mm will take place during the first year of life. The date of the deposition will be assumed to take place on April 1. A back calculation is then made to estimate the shell height for January 1. The annual growth rates for weights, given in Table 6, are converted into rates for heights and this results in a $16 \%$ reduction of the ring size being used for the January 1 size. For example, an animal born in the fall of 1978 is of the 1978 year-class and will be approximately 25 mm on its second birthday (January 1, 1980) although the ring would not be deposited for a few months. Table 6 , as well as all other age data, uses this convention, with correction of ring sizes back to January 1. For use in age/weight programs and projections the actual weights used are mid quarter values.

As for recent years, a research survey was carried out on Georges Bank during August 1987. The design of the survey was based on a stratification by commercial effort. The logbooks of the commercial fleet in the preceding 9 months were analyzed to determine areas of high and low fishing intensity. The areas of high intensity were sampled more heavily as they represent the area most important to the fleet (and presumably the areas of greatest abundance). The estimate of abundance was formed by contouring the catch rates at age of the survey tows and expanding the mean by the area enclosed by a given contour (Robert et al. 1986). The average number of animals at age per tow is given in Table 7. The numbers per tow are converted into indices of abundance by weighting them by the appropriate contour areas. The indices are shown in Table 8. The details of the surveys on a per stratum basis are given in Table 9.

A Thompson-Bell type yield per recruit analysis was carried out (Mohn et al. 1987) breaking growth down into quarters and using 1986 selectivity values, corrected to reflect the meat count of 33 meats $/ 500 \mathrm{~g}$. This was done in order to take into account the dynamic growth of the younger age-classes of scallops. This method also takes into account the average quarterly distribution of effort. However, this method cannot include the effects of blending. This analysis is still applicable and was not recalculated herein.

The regulations operant on the offshore fleet are that the catch should average no more than 33 meats per 500 g which corresponds to an average weight of 15 g per meat. Placing a limitation on the average instead of stipulating a minimum means that the fishermen may take small animals and then balance them with larger ones. Such a practice, called blending, renders the use of most yield models inappropriate. If there are not enough larger animals to blend in, then the mortality on the small ones will have to be reduced. Thus, the partial recruitment is a function of abundance at age. In order to take this practice into account, a stock projection program was written in 1984 (Mohn et al. 1984) in which the mortality on the animals beneath the stipulated average is adjusted until the mean weight of the catch is within 1\% of the required average. The only other way in which this program differs from the normal stock projection is that the variables are updated quarterly because of the very rapid growth of the young scallops. The annual growth is divided into quarterly components of $10,35,35$ and $20 \%$ and annual effort is partitioned into quarters by the rates of $19,35,29$ and $17 \%$, which reflects the 1987 fishery. Selectivity for the projections follows the pattern of the
fishery as revealed from the cohort analysis instead of that of the gear (Caddy 1972). Starting numbers at age for the projections were derived by aging ahead the fourth quarter 1987 cohort estimates to Jan. 1988.

Because cohort analyses deal only with the removals from a cohort and not the growth of the animals it is not appropriate to use data collected on an annual basis for a dynamic species like scallops. In the first year of recruitment the animals experience approximately a $300 \%$ increase in weight. In order to reduce the magnitude of the errors caused by ignoring growth effects, the cohort analysis was carried out on a quarterly basis. This required that catch at age be determined on a quarterly basis. Also, the above mentioned quarterly distribution of effort had to be taken into account. Selectivity had to be determined on a quarterly basis also. This was done by adjusting the recent two year's selectivity pattern to reflect the port sampling data for the last quarter of 1987. This pattern, multiplied by the $F$ determined from tuning for the last quarter year, was used as a starting vector for the quarterly cohort analysis. Natural mortality was set at .025 per quarter and no attempt was made to include a seasonal, age or time dependent effect.

Tuning must be applied to both the catch-at-age determination and to the cohort analysis. Because age-length keys are not available for the scallop fishery (actually they would have to be age-meat weight keys) a growth model was developed to convert port sampled weight distributions into numbers caught per quarter (Roddick and Mohn, 1985). The model is tuned against the port sampling data. A matrix of residuals is examined for local patterns and longer term trends. The total residual is also used in the tuning process. Relative year-class strengths and survivorship are adjusted in the tuning process. The catch-at-age is fairly stable to the tuning except in the older ages when year-classes overlap in size. Fortunately there are few animals caught above age 6 and the increased sensitivity does not significantly affect the results. Once a stable catch-at-age matrix is produced, a VPA is carried out in the normal manner. The results of the trial VPA could be used to retune the age determination. Significant discrepancies were not found so retuning was not carried out. The interdependence of the catch-at-age tuning and subsequent VPA tuning are a concern and research is underway to address this problem.

The VPA is tuned against a number of independent, and sometimes contradictory, sets of observations. The most important is the commercial CPUE. Research estimates are also used. $F$ versus effort does not aid in the tuning process. Tuning selectivity is more difficult in scallop data than for most fisheries. This is because the VPA is done on a quarterly basis and the F's on the most recent year affect only the last quarter. Thus one cannot 'dial up' the exact numbers or F's one might want for the most recent year as can be done with annually collated data. The older (6+) animals seem to be experiencing less effort directed against them in the last two years than was previously the case. This may be because the meat count has not been restrictive with the large 1982 year-class becoming fully recruited. $F$ on the oldest animals was found by multiplying the effort pattern by the mean terminal F from the older ages. Because the selectivity is highly domed, these values are not critical and the normal iterative determination was not undertaken. The terminal $F$ (annual rate) ranged from 0.6 to 1.6 for the purposes of tuning. A range of this magnitude was required to drive the residuals in the research vs VPA biomass across the regression line. The residuals of the last two year's data and the correlation coefficient were used as criteria (Table 10). As expected, the correlation coefficient was not very sensitive. The + signs in this table denote that the residual is above
the regression line and the minus sign, below. The cohort biomass vs CPUE tuning was internally consistent in that the residuals came closest to the regression line at the approximate maximum correlation ( $F=0.8$ ) .

The VPA biomass and the research survey biomass are used as a secondary criteria for tuning. Over the range of F's (except the highest value) the last two year's residuals are always positive and the correlation coefficient does not attain a minimum. This relationship is deemed to be less important because of the fleet's concentration in areas of high abundance and on a few age classes when compared to the research surveys broader coverage. Plots of the regressions used in the tuning process. are presented in Figures 3, 4 and 5 at terminal F's of 0.8 and 1.0 . The VPA biomass vs CPUE shows a linear distribution with the last two years being well above the mean (Figure 3). The high agreement between these two gives them a stronger value in the tuning process. The VPA vs research biomass (Figure 4) shows a cluster of points and one outlier (1978) which dominates the regression. The early research results are not considered to be reliable and hence the weighting given to this relationship is subordinate to CPUE. F vs effort is given in Figure 5. The correlation is quite low and decreased as the residuals for 1986 and 1987 approach the regression line. Therefore, these data were not used in the VPA tuning. Both the CPUE and research biomass, the independent data used for tuning, show a fall in abundance from 1986 to 1987 . We could not duplicate this trend in the VPA using reasonable terminal F's. The best estimate for terminal $F$, if one heavily weights the CPUE tuning, is at $F=0.8$. Depending on how much importance one wishes to give to the research biomass based tuning, the terminal $F$ moves increasingly upward. A reasonable upper limit might be an $F$ of 1.0 , which is the upper edge of the CPUE regression minimum (Table 10).

## RESULTS

Survey catch rates (Tables 7 and 8) indicate that stock rebuilding is taking place. For the first time in 4 years, age 7 scallops have appeared in the research survey and a sizeable quantity of age 6 animals were also seen. Survey catch rates indicate a significant reduction in the abundance of age 5's when compared to the 1986 survey results, likely due to fishing activity. Pre-recruits are estimated to have decreased compared to the strong 1982 yearclass, but are still important. Noticeable concentrations of this strong year-class (age 5 in 1987) are still found and the abundance of this age is the strongest seen for 6 years. Survey results are also shown in a graphical representation (Figures 6 and 7) in which darker shading depicts hïgher abundance. These figures show the aggregated nature of the resource in the survey area on Georges Bank. Figure 6 is at a lower resolution and contains the distribution of the numbers of 2,3 and 4 year olds for 1985 to 1987 , as well as the total biomass. Figure 7 is at a higher resolution and shows older animals that have survived form the strong 1982 year-class (age 5) as well as the age 4's.

The cohort analysis results are given in terms of numbers-, $F-$, and biomass-at-age (Tables $11 a, b, 12 a, b$ and $13 a, b$ ) which have been combined into annual values from quarterly analysis for the two terminal $F$ levels under consideration. For either terminal $F$ the 1982 year-class is almost twice the size of those seen since 1981. The annual F's for 1986 and 1987 are the lowest ( $\mathrm{F}_{\text {term }}=0.8$ ) or among the lowest ( $\mathrm{F}_{\mathrm{term}}=1.0$ ) in the 16 year period covered by the VPA. These two years are also the only ones which are under quota control. Effort increased from 1986 to 1987 which is also evidenced in the average $\mathrm{F}^{\prime}$ s. In 1987, in contrast to 1985 and 1986, age 4 animals are the hardest fished. This may reflect high local concentrations of the age 4 's as well as the relative (compared to recent years) abundance of older animals for
blending. The principal effects of the two different terminal F's are in the abundances (and $F^{\prime} s$ ) in the terminal year. The lower terminal $F$ results in a $17 \%$ higher biomass ( 18,420 viz $15,906 \mathrm{t}$ of meats)

The quarterly based yield per recruit analysis used mid quarter meat weights and the quarterly expanded selectivity derived from the cohort analysis. (See Mohn et al. 1987.) The $\mathrm{F}_{\text {max }}$ was estimated to be at an F of 0.630 and $F_{0} .1$ at 0.402 . These values differ from assessments earlier than 1986 as the selectivity pattern has changed with the introduction of a lower meat count. The same selectivity is used in projections which are carried out at $F_{\text {max }}$ and $F_{0.1}$ using each of the two cohort analysis results (Tables 14 and 15). This partial recruitment is not quite as domed as the 1987. VPA result as the 1987 value reflects the specific size distribution and fishing pattern for that year. The annual values for the partial recruitment for ages 3 to 11 are $0.10,0.75,1.0,0.71,0.50,0.37,0.37,0.35,0.32$. The projections are for a three year period and assume a recruitment level of 400 million animals, a level which is low but not extreme. The $\mathrm{F}_{0} .1$ and $\mathrm{F}_{\text {max }}$ catch levels for a terminal $F$ of 0.8 are 4,800 and $6,900 \mathrm{t}$ respectively. The mean weights of catch are projected to be well above the legal limit of 33 meats per 500 g . The biomass is essentially stable under $\mathrm{F}_{\text {max }}$ and increases about 10\% per annum under $\mathrm{F}_{0} .1$ and the assumed recruitment pattern. The catch levels are about $20 \%$ lower when a terminal $F$ of 1.0 is used for the VPA.

Figure 8 shows the apparent lack of a stock recruit relationship as described by traditional models. This may indicate that environmental factors, or dynamics not accounted for in conventional models, determine yearclass strength.

## CONCLUSIONS

A relatively strong recruitment was seen in the 1986 fishery. This is evidenced by the change in the monthly CPUE of 1986 compared to 1985 (Figure 2). Fishing early in the year means a loss of yield, and may affect the cohort analysis. The fishery required less blending as the season progressed and the CPUE, although slightly lower than in 1986 , is still above the long term average. The 1987 research survey indicates that the strong recruiting year-class of 1982 will be followed by less abundant ones which will not support the fishery at the 1987 level. These conclusions are supported by the cohort analysis which is principally tuned to CPUE. At F0.1 the recommended catch level for 1988 is 4,800 t.

The scallop stock on Georges Bank is still undergoing rebuilding. Therefore, it is still strongly dependent on recruiting year-classes. As the pre-recruits are first seen as 2 year olds and are fully recruited two years later, it is not possible to predict stock status with any confidence more than a year into the future.

A cautionary note is appended as a closing comment. There are special problems in applying traditional assessment techniques to scallop stocks. One example is the tuning which is required for both the generation of catch-atage and in the VPA process. This assessment uses techniques which are still under research and being refined.

## ACKNOWLEDGEMENTS

Thanks to G.A.P. Black, Biological Sciences Branch for his contribution in producing the shaded contour plots from the abundance-at-age data.
