Assessment of the Voisey Unit Arctic Charr Population in 1987
by
J. B. Dempson

Science Branch
Department of Fisheries and Oceans
P. O. Box 5667

St. John's, Newfoundland A1C 5X1

1 This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

1 Cette série documente les bases scientifiques des conseils de gestion des pèches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncēs finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisēe par les auteurs dans le manuscrit envoyé au secrétariat.

## Abstract

Reported landings of Arctic charr from the Voisey assessment unit totaled 21 t in 1987 and exceeded the total allowable catch of 17 t by $25 \%$. This catch represented $22 \%$ of the total catch of Arctic charr from the Nain Fishing Region in 1987. Landings were $28 \%$ higher than in 1986, while effort increased by $23 \%$. Likelihood ratio statistics were used to examine temporal variation in the size composition of the catches from 1980 to 1987. Significant differences were found among years and specific time periods within the fishing season. Mean length is lower in recent years but has not declined consistently over time. The 1977-79 year-classes represented 78\% of the catch in 1987. A sequential population analysis was carried out on catch-at-age data from 1977 to 1987 and suggested a reference level catch in 1988 from 14 to 17 t.

## RESUME

Les débarquements d'omble chevalier enregistrés pour l'unité d'ēvaluation de la Voisey ont totalisé 21 t en 1987 et ont dépassé de $25 \%$ le TPA fixé à 17 t. Ces captures représentaient $22 \%$ du total des prises d'omble chevalier de la région de pēche de la Nain en 1987. Les débarquements étaient de $28 \%$ supērieurs à ceux de 1986, tandis que l'effort a augmenté de $23 \%$. Les statistiques sur le rapport de vraisemblance ont servi à examiner la variation temporelle dans la composition par taille des captures entre 1980 et 1987. Des différences significatives ont étē relevēes d'une annēe à l'autre et entre des périodes particulières à l'intērieur de la saison de pêche. La longueur moyenne est inférieure ces dernières années, mais n'a pas baissé de façon constante avec le temps. Les classes d'âges de 1977-1979 représentaient $78 \%$ des captures en 1987. Une analyse séquentielle de population portant sur les données concernant l'âge à la capture de 1977 à 1987 indiquerait un niveau de rēférence des prises de 14 à 17 t pour 1988.

## Introduction

Catch statistics from the Voisey assessment unit, made up of the Voisey and Antons subareas (Fig. 1), have been available since 1974. It was first assessed as a single unit in 1985. Annual landings have ranged from a low of 4 t in 1975 to 41 t in 1979 with an average of 22 t over the 14 -year period. From 1977 to 1987, landings from this unit have represented $15 \%$ of the total commercial production from the Nain Fishing Region. In 1987, $22 \%$ of the commercial landings came from the Voisey unit. The recommended total allowable catch (TAC) in 1987 was 17 t.

This paper summarizes the results of the 1987 fishery and provides a forecast of available harvest, or reference level catch, for 1988.

## Assessment

## Catch and effort data

Catch and effort data for the Voisey assessment unit are summarized in Table 1 for 1974-87. Landings in 1987 totaled $21 t$, an increase of $28 \%$ from 1986 and exceeded the TAC by $25 \%$. Fifty-nine percent of the catch was taken in the Voisey Bay subarea. Effort increased by $23 \%$ while catch per unit effort was $3 \%$ higher than the previous year. The Voisey unit was closed to commercial fishing July 27, 1987, although $97 \%$ of the TAC had been taken by the week ending July 15, 1987.

## Size distribution of commercial landings

Since 1980, approximately 28,000 fish have been sampled from the Voisey assessment unit to obtain information on the size distribution of the commercial landings. The length-frequency data were examined to determine any heterogeneity of samples which could be related to the effect of commercial exploitation on the stock. Likelihood ratio statistics were used to examine temporal variation in the size distributions.

Arctic charr were measured for fork length and recorded in two-centimeter intervals. The smallest fish measured over the past eight years (1980-87) were in the 32 cm interval ( $32.0-33.9 \mathrm{~cm}$ ), while the largest were from the 74 cm grouping. Analyses, however, were conducted on truncated data which excluded fish less than 42 cm in size and those fish which were in size categories 66 cm or higher. In total, $98.8 \%$ of all fish measured were within the $42-64 \mathrm{~cm}$ length intervals. The truncation also removed the possibility of obtaining any zero values for expected cell counts in the analyses.

There was a highly significant difference in the size distribution of catches among years ( $G=1178, \mathrm{df}=77, \mathrm{P}=0.000, \mathrm{~N}=28,037$ ). As indicated in Table 2, modal size has changed from the 52 and 54 cm intervals in 1980 and 1981 to the 50 cm interval during the past five years. Mean lengths are also summarized in Table 2. Mean length in recent years is lower, but has not decreased consistently. Similar to the analyses for the Nain unit catches
(Dempson 1988), the fishing season was stratified into four time periods: June 15-July 14, July 15-July 31, August 1-15, and August 16 to the end of the fishing season. There is a difference in the size distribution among time period, and within individual time periods the size distribution differs between years (Table 3). There is a tendency for mean length of catches to decrease as the fishing season progresses for this assessment unit also (Table 4).

## Cohort analyses

Numbers at age were available since 1977 and are summarized in Table 5. Data were derived from annual commercial sampling programs. Mean age of the catch has ranged from 8.2 to 9.1 years with no apparent increasing or decreasing trend. On average, $70 \%$ of the catch is made up of three age-classes of fish represented by 8-, $9-$, and 10 -year-olds. In contrast, these age classes represent about $60 \%$ of the catch in the Nain assessment unit (Dempson 1988). The 1977-79 year-classes made up 78\% of the catch in 1987.

Weights at age were calculated from commercial samples obtained from 1977 to 1987. Gutted head-on weights were converted to whole weights using the conversion factor of 1.22 (Dempson 1984). For yield-per-recruit analysis, mean weight at age for the period 1977-79 was used as in past assessments. For stock projections, mean weight at age for the period 1984-87 was used (Table 6).

Total mortality ( $Z$ ) was calculated using the Paloheimo method (Ricker 1975) and the average value for all years (1977-78 to 1986-87) was 0.81 . The average $\nexists$ for the last five years was 0.83 . Assuming a natural mortality rate of 0.2 results in an estimate of fishing mortality of about 0.62 . An estimate of total mortality derived from a catch curve using catch per unit effort at age data from 1985 to 1987 similarly gave a value of $Z$ of 0.81 .

An independent estimate of exploitation and fishing mortality, as derived from tag recaptures, was obtained for the first time for this assessment unit in 1987 where:

$$
\mu=1-e^{-F}(\text { Ricker } 1975)
$$

Assuming a value of $10 \%$ for an estimate of tagging mortality, tag loss, and non-reporting of tags results in a value of $\mu$ of

$$
\mu=\frac{72}{148}=0.486
$$

with a rate of fishing mortality of 0.67 ( $95 \% \mathrm{CL}=0.49-0.95$ ).
An initial cohort analysis was run using partial recruitment values and terminal fishing mortality ( $F_{T}=0.5$ ) from last year's assessment (Dempson and LeDrew 1987). An iterative procedure was used to obtain estimates of fishing mortality for the oldest age group ( $F_{B}$ ) (Rivard 1982). Following this, partial recruitment rates were calculated using the historical averaging method from the matirx of fishing mortality values from 1981 to 1985 . These values were
then applied to the initial terminal fishing mortality rate and the procedure repeated until the partial recruitment values stabilized (Table 6).

Yield per recruit was calculated by the method of Thompson and Bell (Ricker 1975) using partial recruitment rates and mean weight at age. $\mathrm{F}_{0.1}$ was 0.40 at a yield per recruit of 1.08 kg .

Cohort analyses were run using a range of terminal fishing mortality values from 0.3 to 0.85 . In each run, fishing mortality rates for the oldest age group ( $F_{B}$ ) were re-evaluated using the iterative procedure. Regressions of $F$ (weighted mean $F$ for fully-recruited fish) on fishing effort, and mean mid-year population biomass on catch per unit effort of fully-recruited fish were used in tuning the analysis to identify an appropriate value for $F_{T}$ in 1987. Data from 1977 to 1987 were used in the analyses.

Regressions of $F$ on effort produced the highest correlation at $F_{T}=0.8$ (Table 7). The residual from the last point (1987) to the regression line was the smallest when $F_{T}=0.75$ as were the sum of the residuals or the sum of the squares of the residuals for the past three years (1985-87). The intercept value decreased with increasing $F_{T}$ but was 0.14 with $F_{T}=0.75$.

Regressions of average population biomass on catch per unit of effort were not statistically significant up to $F_{T}=0.85$. As a result, regressions of average exploitable biomass for all age groups on catch per unit effort were calculated for the series of terminal fishing mortality values. Average exploitable biomass is calculated by multiplying the average biomass at age in the sequential population analysis (SPA) by the average selectivity coefficients as determined from the fishing mortality matrix. The correlation coefficients increased with increase in the value of $F_{T}$ with the changing increments indicating a peak slightly beyond 0.85 . The residual for the 1 ast year (1987) was the smallest when $F_{T}=0.80$ while the sum of the residuals or the sum of the squares of the residuals was the least when $F_{T}=0.85$ (Table 7). In general, residuals were relatively small for $F_{T}=0.65$ and above (Table 7).

In summary, the regression analyses suggest a value of $F_{T}$ of about 0.75 to 0.85. Estimates derived from the Paloheimo method and catch curves suggest a value of 0.6 while the estimate obtained from tag recaptures was around 0.7 (0.67). These values appear somewhat high but comparable to the average fishing mortality rate for an earlier year with a similar amount of effort (1979 effort $=102, F=0.749$ ).

## Catch projections

Projections were run with $F_{T}$ varying from 0.65 to 0.8 . Recruitment for the projections was estimated from the geometric mean of population numbers for age 6- and 7-year-old fish for the years 1977-85. Weights at age were based on

1984-87 data. Table 8 summarizes the population numbers and fishing mortality rates for the cohort analysis run with $\mathrm{F}_{\mathrm{T}}=0.7$.

Results of the projections are summarized in Table 9. The reference level catch in 1988 ranges from 14 to 17 t with the highest value occurring when $\mathrm{F}_{\mathrm{T}}=$ 0.65 .
