¹ This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

¹ Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

Abstract

Canada has been the major prosecutor of this fishery since the implementation of the 200-mile fisheries zone in 1977, frequently taking more than 70% of the total landings. Preliminary information for 1987 indicates a decrease of about 10,000 tons from the 1986 reported landings of 27,000 tons which may be due to incomplete statistics for some countries. Catch rates have generally been declining since 1984 and data from research surveys have not indicated a strong year class since those of the early 1970s. General production models are not appropriate because there are no significant trends in the catch rate series.

Résumé

Le Canada a été le principal exploitant de cette pêche depuis la mise en application de la zone de pêche de 200 milles en 1977; cette pêche représentait souvent plus de 70 % du total des débarquements. D'après les renseignements préliminaires pour l'année 1987, il y aurait une diminution d'environ 10 000 tonnes par rapport aux 27 000 tonnes débarquées en 1986, comme l'indiquent les relevés. Cette différence est peut-être attribuable à des lacunes dans les statistiques concernant certains pays. Les taux de capture ont généralement baissé depuis 1984 et, selon les données de relevé de recherche effectués, il n'y a pas une classe d'âge importante depuis les débuts les années 1970. Les modèles de production généraux n'étaient pas appropriés parce qu'il n'y avait pas de tendances significatives dans les séries des taux de capture.

Introduction

Nominal catches reported from this fishery since 1959 have ranged from a low of 14,519 t in 1980 to a high of 186,837 t in 1959 (Table 1, Figure 1). Catches for Div. 3K have generally been greater than 50% of the total reported landings for this stock and greater than 84% in recent years. Canada has been the major prosecutor of this fishery since the implementation of the 200-mile fisheries zone in 1977, frequently taking more than 70% of the total landings (Table 2). Preliminary data for 1986 and 1987 indicate a drop of about 10,000 tons in 1987 from the 1986 reported catch of 27,047 tons. This may be due to incomplete statistics for some countries at this time. Improved market conditions for redfish were considered responsible for the increase in landings in the 1984-86 period (23,000 tons - 29,000 tons) from a period just prior to this when landings ranged from 14,000 tons to 18,000 tons.

Catches from Div. 2GH have been less than 900 tons since 1977 and have commonly been taken in the July to December period perhaps in part due to ice cover earlier in the year (Table 3a). Catches from Div. 2J have been less than 7000 tons since 1977, except for higher levels in the range of 12,000-16,000 tons in 1978 and 1979, and have been taken throughout the year although mainly in the June to September period (Table 3b). A high parasite load has been noted in Div. 2J. In Div. 3K catches have been greater than 21,000 tons since 1984 and are taken throughout the year (Table 3c).

Sequential population analysis (SPA) of this stock has not been possible to date because of non-convergence in the population matrix.

Methods and Results

A catch and effort database was compiled from ICNAF/NAFO Statistical Bulletins for the 1959-1985 period. In addition, preliminary NAFO data for 1986 (provided by the NAFO Secretariat), preliminary Canadian data for 1986 and 1987 (provided by the Nfld. Region), preliminary Canadian data for 1987 (provided by the Scotia-Fundy Region) and foreign country data for 1987 (provided by the Observer Program, Nfld. Region) were also appended to the database. On the recommendation of CAFSAC at the 1987 meetings, country-gear-tonnage class (CGT) categories were further classified as side or stern trawler which had been combined in previous assessments (cf. Power and Atkinson 1987) for both midwater and bottom trawls. If this information was not readily available, it was gained by reviewing the following: NAFO lists of fishing vessels operating in the convention area, Lloyd's Registry of ships and/or consulting with the Observer Program. Initially selected from this database were observations where redfish comprised more than 50% of the total catch and were therefore considered redfish directed.

A multiplicative model (Gavaris 1980) was again used this year to derive a standardized catch rate series incorporating the previously described database. Within the model all catch and effort observations less than 10 units and any CGT or month category data with less than five samples were deleted. For this assessment the reference categories were Nfld. TC 5 stern trawler, August, Div. 3K and 1959. The CGT reference is different from last year's assessment in which the Poland TC 7 bottom trawler was used.

Residuals from the regression were plotted against predicted values (Figure 3) and expected normal values (Figure 4) and did not reveal any outliers. In order to determine whether the multiplicative model is appropriate for the divisionally aggregated data, yearly residuals for each division were plotted over time (Figs. 5-6). These plots indicate that Div. 2J residuals are more variable both intra- and inter-annually than those for Div. 3K. This is likely an artifact of sample size. However there does not appear to be any violation of the assumption of proportional effect with regard to these two divisions. There are no similar plots for Div. 2G and 2H because after the initial deletions described above there were insufficient data (zero in the case of Div. 2G) for any evaluation of the model assumptions.

The analysis of variance (Table 4) indicates a significant regression that explains only 39% of the variation in the data. All category types were significant but the year effects were only marginally significant. In past assessments when using this multiplicative model, categories with similar parameter estimates derived from the regression were grouped together a posteriori. Since the statistical validity of this practice has been questioned it was decided against doing any groupings within category types. The estimated parameter coefficients for each category are listed in Table 4. The standardized catch rate series (Table 5, Figure 7) shows that over the 1959-1987 period catch rates have generally been in the 1-2 tons/hour range. There was an increase from 1959-1964 followed by a decrease to 1969. Catch rates gradually increased from about 1973 to 1984. They have subsequently declined but are still at relatively high levels. Standardized effort has been in the range of 9000 to 15,000 hours since 1980 (Figure 2). Previously, general production analyses have been carried out on this stock (Power and Atkinson 1987). There must be, however, significant trends in catch rates over time for these analyses to be valid. Since there is little contrast in the standardized catch rates over time from a statistical point of view, it was therefore concluded that general production analyses are not appropriate with these data.

Commercial frequencies available from the 1987 fishery (Figs. 9-13) were combined by the method of Gavaris and Gavaris (1983) as outlined in Fig. 8 and then converted into numbers at age using a single age/length key (Table 6). The weight-length relationships used were:

$$WT(\text{males}) = 0.01659FL^{2.9548}$$

$$WT(\text{females}) = 0.01372FL^{3.0210}$$

The predominant length range is 25-35 cm. (mode often about 28 cm.), corresponding to the relatively strong year-classes of the early 1970s. The catch-at-age and weight-at-age matrices are shown in Tables 7 and 8.

The Newfoundland Region has carried out stratified random surveys to divisions 2J and 3K since 1978 (Tables 9-12). Since coverage was not complete in all years, a multiplicative model (Gavaris 1980) was used to derive estimates for those strata which

were not covered in certain years. The regression results for each dataset were highly significant ($p < .01$) and the smallest r^2 was 0.80. The historical series of mean numbers and weights per standard tow by STRAP are given in Tables 9-12 as well. The estimates from the model compare favorably with strap estimates using the same strata (Tables 9-12, Fig. 14) because there were not too many missing strata to be accounted for. There appears to be a downward trend both in Div. 2J and Div. 3K in stratified mean per tow for numbers and weights (Fig. 14). The very high values for Div. 2J in 1981 and Div. 3K in 1983 were the result of high catches in one set in stratum 228 and 634 respectively. These strata get weighted heavily when calculating the stratified mean per tow. Mean numbers and weights by stratum for Div. 2GH are given in Tables 13 and 14. The time series is not continuous and, therefore, it is not possible to determine if there are any trends in biomass or abundance. It does appear, however, that the density of redfish in these more northern divisions is lower than in Div. 2J and 3K. The geometric mean biomass from surveys in Div. 2J3K during the 1978-87 period is about 265,000 t.

The length frequencies and numbers at age determined from the surveys (Figures 15-19) indicate that no relatively strong year-class(es) has appeared from 1978 to the present.

As mentioned previously SPA was not attempted because of the relatively short time series of catch-at-age coupled with low fishing mortalities. Because of these, the population matrix does not converge.

Conclusions

The catch rates are declining from the high 1984 level. Although the survey results also suggest a decline over this period, the surveys did not show the dramatic increase in biomass that is suggested by the catch rate series from 1981 to 1984.

No significant trends could be detected in either the catch rate series or the survey series because of large variances associated with each.

The present TAC of 35,000 t implies exploitation at about $F_{0.1} = 0.15$, assuming $M=0.1$ and a population biomass at the geometric mean biomass from the surveys. It should be pointed out the large variance associated with the survey estimate implies a large variance for the derived $F_{0.1}$ yield.

There is no evidence of good recruitment to the fishery since the early 1970s based on the research length frequencies and so it is anticipated that catch rates will continue to decline.

NOTE

FOR THE AGES FLAGGED BY * THERE WAS AN AGE LENGTH KEY WITH ONLY ONE AGE DETERMINATION FOR SOME LENGTH, SINCE THE VARIANCE FORMULA HAS $N-1$ IN THE DENOMINATOR IT CANNOT BE EVALUATED FOR THIS LENGTH, CONSEQUENTLY THIS VARIANCE COMPONENT IS NOT INCLUDED IN THE VARIANCE FOR THE FLAGGED AGES, THIS IS GENERALLY NOT A SERIOUS PROBLEM SINCE IT OCCURS WHEN FEW FISH ARE CAUGHT AT THAT LENGTH,

Table 7 : Estimated numbers of redfish caught at age (000's) in
