¹ This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

¹ Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

ABSTRACT

Data analyses are presented from 1987 for the five herring stock complexes within the Newfoundland Region: a) White Bay-Notre Dame Bay, 2) Bonavista Bay-Trinity Bay, 3) Conception Bay-Southern Shore, 4) St. Mary's Bay-Placentia Bay, and 5) Fortune Bay. Commercial landings increased from 4800 t in 1986 to 22600 t in 1987. The 1982 year-class continued to dominate both in the commercial fishery and in the research gillnet program. Biomass estimates were calculated from an acoustic survey using a dual beam hydroacoustic system rather than the sonar-sounder technique of previous years. Advice is provided based upon the acoustic survey, research gillnet catch rates, the dominance off a single year-class and historical fishing patterns.

RESUME

On présente des analyse des données de 1987 sur les cinq zones de stocks de hareng de la région de Terre-Neuve : 1) baie White-baie Norte Dame, 2) baie de Bonavista-baie de Trinité, 3) baie de Conception-côte sud, 4) baie St. Mary's-baie de Placentia et 5) baie de Fortune. Les débarquements commerciaux sont passées de 4 800 t en 1986 à 22 600 t en 1987. La classe d'âge de 1982 est restée prédominante tant dans la pêche commerciale que dans le programme de recherche au filet maillant. Les estimations de biomasse ont été établies à partir d'une étude acoustique réalisée au moyen d'un système hydro-acoustique à double faisceau plutôt qu'à l'aide de sonars et d'échosondeurs comme cela s'était fait précédemment. Les avis formulés sont fondés sur l'étude acoustique, sur les taux de prises obtenus dans le cadre du programme de recherche au filet maillant, sur la prédominance d'une classe d'âge et sur les caractéristiques historiques de la pêche.

INTRODUCTION

DESCRIPTION OF THE FISHERY

As in 1986, the 1987 herring management plan provided an allowance for fixed gear (gillnets and traps) within each stock area (Fig. 1) with allocations to bar seines and purse seines based on TAC residuals and/or market expectations. There was also a limited fixed gear allowance and bar seine allocation along the Labrador coast and south coast (Pass Island to Cinq Cerf Bay) of Newfoundland. The spring fishery opened April 6 in all areas and closed June 7 in St. Mary's Bay-Placentia Bay, and Fortune Bay but was extended to June 21 in the three northern areas. The fall fishery opened August 15 and closed December 31 for all areas.

The management plan provided allowances and allocations for the spring fishery. For the two southeast coast stock areas, the entire TAC was allocated to the spring fishery; however, for the three northern areas, a portion of the TAC was held in reserve. The fall fishery allocations included uncaught portions of the spring fishery allocations plus a portion of the reserves, where necessary. Advised catch levels and allocations by fleet sector and stock area were as follows:

Stock Area	TAC (t)	Fixed gear allowance (t)	Allocation (t)		Reserve (t)
			Bar seine	Purse seine	
White Bay-Notre Dame Bay (WB-NDB)	31500	6000	1000 1900	6000 9700	6900
Bonavista Bay-Trinity Bay (BB-TB)	13700	2500	150 1150	6000 1650	2250
Conception Bay-Southern Shore (CB-SS)	3500	1000	150 100	1000 300	950
St. Mary's Bay-Placentia Bay (SMB-PB)	2550	950	300 300	500 500	0
Fortune Bay (FB)	2400	500	1500	400	0
Labrador Coast	-	500	200	-	-
South coast Newfoundland	-	100	100	-	-

NOMINAL CATCHES

TACs and landings ($\times 10^3$ t) by stock area are listed below for 1980 to 1987.

		1980	1981	1982	1984	1984	1985	1986	1987
WB-NDB	TAC	5.3	5.3	1.2	0.0	1.5	2.0	5.5	32.5
	Catch	6.5	4.7	2.0	0.4	1.5	1.8	2.7*	14.0*
BB-TB	TAC	4.4	4.8	0.7	0.0	0.4	0.8	3.8	13.7
	Catch	5.4	4.0	0.5	0.1	0.2	0.6	1.7*	6.9*
CB-SS	TAC	0.4	0.5	0.2	0.0	0.1	0.2	0.6	3.5
	Catch	0.5	0.2	0.1	≤ 0.1	≤ 0.1	0.1	0.2*	1.3*

ANECDOTAL INFORMATION

The historical development of the Newfoundland herring fishery has been reviewed in previous documents (Wheeler and Chaulk 1987, Wheeler et al. 1986). The fishery reopened in 1986 after several years of closure due to low stock abundance. Quotas were not taken in either 1986 or 1987 due to poor market conditions. However, even given the poor market conditions, 1987 landings from the northern stock areas (Tables 1-3) were in excess of 20,500 t, comparable with the peak years of 1976-79. In these areas, the 1987 fishery was concentrated in the fall when plants could obtain the high fat content product required by the limited market. The fishery in the two southeast coast stock areas, traditionally a winter and spring fishery, did not develop in 1987 (Tables 4 and 5) as markets were poor and plants were preparing for the more lucrative capelin fishery. There were attempts during the spring to supply herring for the roe market; however, the protracted spawning period made it difficult to obtain sufficient roe at the required stage of maturity.

INPUT DATA

BIOLOGICAL SAMPLING

The number of herring sampled in the Newfoundland region in 1987, from the commercial fishery and research programs, was 13,462 (Table 6). This represented a decrease of 15% from 1986, due mainly to a decrease in the number of research samples collected. When apportioned by stock area, month, and gear type (Table 7), samples were available for 89% of the commercial catch; up from 79% in 1986. Samples were collected randomly; all fish sampled were measured and aged.

Mean weights at age for 1987 (Table 8) were derived from commercial and research samples of spring spawning herring collected from January to June.

COMMERCIAL FISHERY DATA

Commercial catch-at-age data (Tables 9-13 and Figs. 2-3) were calculated for spring and autumn spawners for each stock area by applying age compositions and mean fish weights from the appropriate commercial samples to the landings. As in the past, catch-at-age data were generated using research samples collected from commercial mesh size gillnets for those areas where no commercial samples were available. Both 1986 and 1987 catch data are preliminary as final catch statistics are not yet available. Data for autumn spawners, 1970-87, have been included in this assessment as in the three southern areas, autumn spawners have, at times, accounted for greater than 25% of the catch.

As in 1986, the 1982 year-class of spring spawners dominated the fishery (by number) in all areas, accounting for 53% to 80% of the catch. The relative importance of the 1979 year-class declined from previous years especially in the northern areas where the 1983 year-class was the second most abundant. The 1986 year-class represented approximately 10% of the catch in Conception Bay-Southern Shore. This may be anomalous, i.e. a function of the samples chosen to calculate catch at age. Further evidence in 1988 will be required before suggesting the strength of this year-class. The 1985 year-class represented between 2% to 5% of the commercial catch in three of the five stock areas. This is consistent with reports during the fishery of small fish being available in most areas.

The percentage of spring spawners in the catch increased in all areas consistent with the recruitment of the 1982 year-class. As in previous years, the percentage of autumn spawners generally increased from north to south.

Except for Bonavista Bay-Trinity Bay, the percent age composition of the 1987 commercial catch (Fig. 4) is very comparable to that projected from last year's assessment. As was discussed last year, sampling during the 1986 acoustic survey in Bonavista Bay-Trinity Bay from which projections were made, may have been biased toward the 1985 year-class accounting for differences in that area between the projected and observed catch at age (Wheeler and Chaulk 1987).

No commercial catch-rate data were collected in 1987. As gillnet landings represented less than 15% of the total catch, it was decided not to use data from this source to calculate catch rates. Purse seines accounted for 82% of the landings. However, purse seine catch rates have not been used recently as an index of abundance for any Atlantic Canada herring stock and for the North Sea herring it has been determined that commercial catch rates may not be a useful indicator of abundance (Anon. 1988). Therefore, it was decided not to collect such information in the Newfoundland region, but to concentrate research efforts on abundance indices independent of the commercial fishery.

RESEARCH SURVEY DATA

A. Acoustic Survey

Subsequent to CAFSAC deliberations last year, it was decided to conduct a survey in the fall of 1987 along the northeast coast utilizing a dual-beam hydroacoustic system.

The objectives of the survey were as follows:

- 1) To derive unscaled density estimates through echo integration along predetermined coastline transects in each of the stock areas.
- 2) To determine in situ mean backscattering cross-section estimates from as many herring schools as possible in order to scale the integration outputs.
- 3) To derive population numbers and biomass estimates by areal expansion of the density estimates from the coastline transects.
- 4) To compare density estimates between coastline (along shore) transects and zigzag (inshore-offshore) transects in a subsample of randomly selected areas to determine if herring densities were greater nearshore (0-50 m) or offshore (50-90 m) within the stock boundaries.
- 5) To determine herring distribution patterns within the stock areas to aid in future survey design.

Prior to the survey, each of the two northern stock areas, White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay was divided into grids or strata of approximately 100 km² surface area (Appendices 1-4). As in previous surveys, the outer stock boundary was determined by the 90 m contour. However, in areas with extensive offshore shoal water, the outer boundary was determined as the point four nautical miles from shore. Grids with equal surface area were chosen to allow intra-stock density differences to be accounted for in stock biomass estimation. A coastline transect (i.e. parallel to shore) through each grid was chosen. As these transects were not chosen randomly within grids, results based upon areal expansions, may be biased. However, the objective was to make the transects and survey design comparable with previous years. Survey coverage was included in each grid throughout the entire stock area to avoid the problem of extrapolation from surveyed to non-surveyed areas experienced in previous surveys. A more detailed zigzag transect, from shore to the outer stock boundary, was included in addition to the coastline transect in seven randomly selected grids. The purpose was to provide replicate coverage and to compare herring density estimates nearshore and offshore within the stock area. It was impossible due to time constraints to include replicate transects in all grids.

The survey commenced October 11, 1987, off Cape Bauld at the northern extreme of White Bay and proceeded southward, terminating December 10, 1987, off Grates Point at the southern extreme of Trinity Bay. Approximately 2900 km of transect were surveyed in 63 of the 82 predetermined grids. The remaining 19 grids were not surveyed due to inclement weather conditions and insufficient survey time. Most of the non-surveyed grids (70%) were in eastern Notre Dame Bay. Biomass estimates calculated for adjacent grids were small (<20 t) suggesting that exclusion of these non-surveyed grids would not affect overall results. A BIOSONICS dual beam hydroacoustic system was deployed from the R. V. MARINUS during the entire survey. A commercial purse seine vessel was chartered from October 11 to November 20 to collect biological samples. No vessel was available from November 21 to December 10. During this time, samples were obtained from commercial vessels fishing in the survey area.

The age structure and spawning affinity of herring was derived from samples taken from 19 locations in 13 grids (Table 14). Sampling was adequate in Notre Dame Bay, Bonavista Bay, and Trinity Bay where samples were obtained from grids which accounted for at least 29% of the total fish numbers. However, in White Bay, samples were obtained from one grid only which accounted for 1.5% of the total estimated numbers. As in the commercial fishery, age distributions from the acoustic survey samples, weighted to account for density differences between grids (Fig. 5) showed the dominance of the 1982 year-class in both stock areas. In White Bay-Notre Dame Bay, the 1982 year-class represented 52% of the population (by number), in Bonavista Bay-Trinity Bay 66%. The 1983 year-class was second most dominant, and represented 19% and 17% of the population in each area. The 1985 year-class accounted for approximately 4% of the population in both areas and the 1987 year-class 11% in White Bay-Notre Dame Bay. As in the past, spring spawners dominated, representing in excess of 90% of the population in both areas.

B. Research Gillnet Program

The research gillnet program was continued for the eighth consecutive year during the spring and fall along the northeast coast and for the sixth year during the spring along the southeast coast. In 1987, 22 fishermen were each contracted to fish a fleet of five gillnets, mesh sizes 2", 2 1/4", 2 1/2", 2 3/4", and 3" for one month, to maintain an accurate daily log record of catches and to collect and freeze samples of their catch. Catch at age (Tables 15-21) and age distributions (Figs. 6 and 7) were calculated by applying age distributions of samples taken during the month, normally at four-day intervals, to catches during that interval and then combining these interval age distributions to obtain one for the entire month. The 1982 year-class dominated in all areas, representing 50-70% of the catch, by number. No other year-class, except for fish ages 11+ in White Bay-Notre Dame Bay, accounted for more than 10% of the catch. The 1985 year-class represented 5% of the catch in Bonavista Bay-Trinity Bay. In comparison, in 1984, the 1982 year-class represented 10% of the catch in the same area. The percentage of spring-spawners has remained consistent from last year in the two northern stock areas but has continued to increase in the southern areas. Catch rates (Tables 22-27 and Fig. 8) have increased from 1986 to 1987 for three of the four stock areas for which there are data available. For Notre Dame Bay, catch rates are the second highest on record. For St. Mary's Bay-Placentia Bay and Fortune Bay, catch rates are the highest on record. However, for Bonavista Bay-Trinity Bay, they are the lowest yet recorded. Logbooks for all fishermen from 1980-87 were reviewed to determine if catch rate fluctuations could be better explained. For White Bay-Notre Dame Bay, catch rates have increased from 1986 to 1987 due to substantial increases in catches for two of the five fishermen. However, catch rates for two of the fishermen declined substantially from 1986 to 1987. One fisherman suggested it was due to prevailing offshore winds in 1987. Examination of his logbook showed little difference in wind direction and speed between 1986 and 1987. Catch rates for all fishermen in Bonavista Bay-Trinity Bay declined from 1986 to 1987. This is impossible to explain given the recruitment of the 1982 year-class to the stock. One fisherman in Bonavista Bay suggested that conditions were good for herring in the fall of 1987; however, the fish remained too deep for the nets. This was also apparent during the acoustic survey as purse seine sampling was more difficult due to the depth distribution of the fish. Another fisherman in Trinity Bay noted that there were no herring netted anywhere in Trinity Bay during the fall of 1987. He had kept nets in the water until December with no success. However, fishermen in the same area are presently (April 1988) experiencing very large catch rates. There were no data collected

from Conception Bay-Southern Shore in the fall of 1987 due to a misunderstanding with the fishermen involved. However, catch rates of two new fishermen during the spring were consistent with results from 1986. Catch rates of the five fishermen in St. Mary's Bay-Placentia Bay have remained very consistent over the last three years. In 1987, the catch rate of the 2" nets decreased; whereas, the catch rates of the 2 1/4" and 2 1/2" nets increased (Fig. 7) consistent with the recruitment of a single (1982) year-class. In Fortune Bay, catch rates have increased steadily from 1982 with the exception of 1986. Similar to St. Mary's Bay-Placentia Bay, the catch rates were higher in the larger mesh sized nets in 1987. Catch rates for the two southeast coast stock areas appear to better reflect stock conditions than do those of the three northern areas. This may be a function of both migratory patterns and possibly market conditions. The research gillnet program is conducted during the fall for the three northern areas at a time when herring are migrating back into the bays to overwinter. Catch rates are therefore dependent both upon the temporal and spatial patterns of migration. Along the southeast coast, the program is conducted during the spring on overwintering fish which are preparing to spawn. Market conditions for herring have been poor and variable during the 1980s. The degree to which a fisherman maintains his nets along the northeast coast during the fall may depend upon the availability of markets for the fish. This is less of a problem along the southeast coast during the spring as most fishermen consistently either use or sell their herring for lobster bait. Research gillnet data from 1980-87 will be reviewed in detail prior to the next assessment to determine if data should be collected during the fall when fish are still migrating or only in the spring on overwintering concentrations.

ASSESSMENT RESULTS

BIOMASS CALCULATION FROM THE ACOUSTIC SURVEY

During the acoustic survey, integration was conducted in real time along the transects and dual beam data, necessary to calculate target strengths, were collected and stored for later analysis by back-tracking over previously integrated fish concentrations.

The water column was divided into ten meter depth strata for integration. Mean squared voltages per depth strata were output every five minutes along the transect. These were then averaged along the entire transect within a grid to provide an unscaled density estimate for that grid.

For the 28 schools from which dual beam data were collected, 1255 single targets were distinguished with a mean backscattering cross section of $0.0003642 \text{ m}^2/\text{fish}$. This single value was used in the scaling factor to convert mean squared voltages to fish densities for all areas surveyed. However, a subsequent and more detailed examination of the frequency distribution of mean backscattering cross sections (Table 28) by bay indicated a broad range of values. These were converted to target strengths and fish lengths according to the following equations given by Foote (1987)

$$\begin{aligned} T.S. &= 10 \log \theta b.s. / 4\pi \\ T.S. &= 20 \log L - 71.9 \end{aligned}$$

where $\theta b.s.$ =mean backscattering cross section (m^2)

L=fish length (cm)

Of the 1255 targets, 610 were from a single school in White Bay. These were eliminated from further analysis as notes in the acoustic log suggested that, based upon voltage amplitudes (1.0-1.5 mv), this school may have been mackerel. A mean back scattering cross section was then calculated for only those targets within the length range for herring ($5.6 \text{ cm} < L < 44.2 \text{ cm}$). This eliminated those observations at each end of the frequency distribution which represented either noise or multiple targets. The value, $0.0003217 \text{ M}^2/\text{fish}$, provided population estimates 12% larger than the original in situ estimate which included all 1255 targets. However, when this was weighted to account for abundance differences between bays, the revised value, $0.0003718 \text{ M}^2/\text{fish}$, provided population estimates within 2% of the original.

Fish density per depth stratum was multiplied by the acoustically sampled water volume per depth stratum to determine fish numbers per depth stratum. Population numbers within the grid were determined by areal extrapolation from the estimate of fish numbers along the transect within the grid. Population estimates were compared for those grids which included both coastline and zigzag transects (Table 29). For five of the seven grids, population estimates derived from the zigzag transect were larger than those derived from the coastline transect. In examining the reason for this, it was determined that fish densities were randomly distributed by depth (Fig. 9). Therefore, population estimates derived from the zigzag transects should be larger as the zigzag transects included deeper water and hence a greater ensonified volume. Fish densities were then extrapolated by grid volume rather than surface area to account for this distribution pattern. Population estimates derived from zigzag transects were greater for three of the seven grids when volumetric extrapolation was used. For three, the shoreline transects gave greater estimates and for one there was very little difference. However, extrapolation by volume also assumes a linear relationship between fish biomass and water depth. Data from the seven zigzag transects were re-analyzed to calculate fish numbers (which are proportional to biomass) by water depth (10 meter intervals) adjusted for searching time (Fig. 10). Although the relationship is dome-shaped and not linear, the assumption of linearity is not severely violated over most of the depth range surveyed, as fish numbers by depth increase in near linear fashion from 0 to 65 M. Any positive bias introduced by assuming a linear relationship would be more than countered by the exclusion of fish outside the 90 m contour. The relationship suggests that the outer stock boundary should be approximately 120 M and that population estimates are biased downward by surveying to 90 M only.

The mean fish weights from samples collected during the survey (Table 14) were applied to the volumetrically derived estimates of population numbers (Tables 30 and 31) to obtain biomass estimates. Population numbers were apportioned by spawning type based upon percentages of spring and autumn spawners in samples collected during the survey (Table 32). Population numbers at age (Tables 33 and 34) were then calculated from age composition of the samples.

Biomass estimates for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay from the 1987 and previous surveys are presented in Table 35. Last year, only those surveyed or core grids in Notre Dame Bay were considered. However, upon the recommendation of CAFSAC, a proration factor of 1.66 was used to estimate total biomass for White Bay-Notre Dame Bay. For both stock areas, biomass estimates peaked in 1985 and have subsequently declined.

Population numbers at age projected to January 1988 have similarly been compared (Table 36) from the 1987 survey, the 1986 survey and from an average of the 1983-86 surveys as used last year for projections. For White Bay-Notre Dame Bay, year-classes exhibit similar trends between the surveys. The differences for Bonavista Bay-Trinity Bay may be highly dependent on sampling. As stated last year (Wheeler and Chaulk 1987), sampling during the 1986 survey may have been biased toward the 1985 year-class in Bonavista Bay-Trinity Bay. In both areas, the relative size of the 1983 year-class compared to the 1982 year-class is smaller in the most recent survey. The combined population estimate for the two stock areas (525.9×10^6) is much more comparable to that from the 1986 survey (519.7×10^6) than to the average estimate from the 1983-86 surveys (996.7×10^6) used last year for projections.

PROGNOSIS

Catch Projections

Projections were run for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay based upon the population numbers at age from the 1987 survey. These vectors were projected to January 1988 accounting for the commercial catch subsequent to the 1987 survey and assuming a natural mortality rate of 0.20.

As in previous years, the following partial recruitment pattern, based upon a historical combined purse seine and gillnet fishery (Winters and Moores 1977) was used for both stock areas:

Age	2	3	4	5	6	7	8	9	10	11+
P.R.	0.10	0.35	0.60	1.00	1.00	1.00	1.00	1.00	1.00	1.00

Mean weights at age were those derived from samples collected during January-June 1987 (Table 9). Natural mortality was assumed to be 0.20. Recruitment at age 2 in 1989 was assumed to be zero. F_{0+1} was assumed to be 0.30.

Three options were used in projections: a) assuming the recommended catches in 1988 and $F = 0.30$ in 1989, 2) assuming $F = 0.30$ in 1988 and 1989, and 3) assuming 1987 catch levels in 1988 and $F = 0.30$ in 1989. The projected biomass and catch levels ($\times 10^3$ t) are summarized in the following text table:

		WB-NDB		BB-TB	
		1988	1989	1988	1989
Option 1	2+ Biomass	94.2	54.3	30.9	12.4
	Catch	34.7	11.9	16.2	2.9
Option 2	2+ Biomass	94.2	67.0	30.9	21.3
	Catch	21.8	14.9	7.2	5.0
Option 3	2+ Biomass	94.2	74.6	30.9	21.6
	Catch	14.0	16.7	6.9	5.0

F_{0.1} projections based upon the 1987 survey (Option 2) suggest that projections made last year, based upon an average population vector from the 1983-86 surveys (Option 1), were overly optimistic. In retrospect, it may have been better last year to project from the 1986 survey estimates rather than from average population estimates of the 1983-86 surveys.

Given problems with the acoustic survey design and certain data treatments, CAFSAC felt that advice could not be provided based upon the survey alone. Advice was therefore provided based upon the acoustic survey, research gillnet catch rates, the dominance of a single year-class and historical fishing patterns. All five of the stocks are dominated by a single large year-class, comparable to the situation during the 1970's. Catch levels, in particular in the north, approximated maximum levels during the 1970's. There is no evidence of strong recruitment since 1983 and insufficient information available to estimate the strength of the 1985 year-class. Therefore, until more information becomes available next year, it is advised that 1988 and 1989 catches for all stock areas be maintained at 1987 levels. However for St. Mary's Bay-Placentia Bay and Fortune Bay, where 1987 catch levels were very low, precautionary TAC's of 1500 t are advised to allow for monitoring of the stocks.

Management Implications

Advised catch levels both for the current year and 1989 are much lower than those advised last year as population estimates from the 1987 acoustic survey are lower than the average estimates from the 1983-86 surveys used for projections last year. However, populations estimates from the 1986 and 1987 surveys are very comparable. Also, for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay, the only stock areas surveyed in 1987, population trends have been similar over the past five years, peaking in 1985 and declining since then. This is consistent with advice provided last year which suggested that yields from these stocks will decrease unless there is adequate recruitment of younger year-classes. Recruitment appears to be generally weak since the 1982 and 1983 year-classes. However, there is limited evidence from both the research gillnet catches and the commercial fishery that the 1985 year-class may be of moderate strength. Until further evidence of the strength of this year-class becomes available within the next year, it is not possible to predict the long-term (3 to 5 year) potential of these stocks.

There are divergent views concerning the ability to calculate absolute population estimates from acoustic surveys. The major concern is in the determination of target strength. ICES scientists in their most recent assessment of the North Sea herring stocks acknowledged that the question of precision, mostly around target strength, remains unchanged. However, they point out that acoustic surveys are proving very valuable as they have the advantage of providing estimates of absolute abundance and age composition, are efficient in terms of data acquisition per unit survey time and are useful for several species simultaneously. Major changes will be made prior to the next acoustic survey, primarily in survey design. However, until a superior methodology is developed, acoustic surveys will continue to be employed to assess herring stocks within the Newfoundland Region.

ACKNOWLEDGMENTS

We would like to thank Dr. Bill Leggett of McGill University for the lease of the hydroacoustic system and Bob Johnson of Canadian BioSonics Ltd. for his expertise and guidance in setting up the hydroacoustic equipment aboard the MARINUS.

We would like to thank M. F. Dawson for administering the research gillnet program, P. J. Williams for administering the sampling program and all other technical staff who were in any way associated with the collection of data used in this assessment. Special thanks are also extended to our typist, M. Y. Hynes.
