1 This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.
${ }^{1}$ Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

#### Abstract

Reported landings of Arctic charr from the Voisey assessment unit totaled 14 t in 1988, about 83\% of the total allowable catch. This catch represented $19 \%$ of the total catch of Arctic charr from the Nain Fishing Region in 1988. Landings were $34 \%$ lower than in 1987 when the total allowable catch was exceeded by $25 \%$. Effort decreased by $49 \%$ relative to the previous year, while catch per unit effort increased by 29\%. Trends in length-frequency distributions and mean weights at age suggest that a selective removal of a particular stock component characterized by large fish may have occurred. Sequential population analyses were carried out on catch-at-age data from 1977 to 1988 and suggested a reference level catch of 12.5 to 15.4 t .

## Résumé

Les débarquements déclarés d'omble chevalier provenant de l'unité d'évaluation de la baie Voisey ont atteint 14 t en 1988 , soit environ $83 \%$ du total des prises admissibles et $19 \%$ des prises totales d'omble chevalier dans la region de la baie Nain en 1988. Les debarquements étaient inférieurs de $34 \%$ à ceux de 1987 , année où ils depassaient de $25 \%$ le total des prises admissibles, et l'effort était inférieur de $49 \%$ à celui de 1'année antérieure, tandis que les prises par unité d'effort augmentaient de $29 \%$. Les tendances dans la distribution des longueurs et les poids moyens selon 1'âge donnent à entendre qu'un retrait sélectif d'une partie donnée du stock, en $l^{\prime}$ 'occurrence des gros poissons, a pu se produire. On a effectué des analyses de séquentielles de population a partir des données sur les prises selon l'ăge de 1977 à 1988. Elles permettent de situer entre 12,5 et $15,4 \mathrm{t}$ le niveau de référence des prises.

## 1. Introduction

Arctic charr catch statistics from the Voisey stock unit, made up of Voisey Bay and Antons subareas (Fig. 1), have been available since 1974. It was first assessed as a single unit in 1985. Annual landings have ranged from 4 to 41 t (mean $=21 \mathrm{t}, 1974-88$ ), and from 1977 to 1988 have represented $16 \%$ of the commercial production from the Nain Fishing Region. In 1988, 19\% of the commercial catch came from the Voisey stock unit. The recommended total allowable catch (TAC) in 1988 was 17 t.

This paper summarizes results of the 1988 fishery and provides a forecast of the reference level catch for 1989.

## 2. Trends in catch and effort

Catch and effort data for the Voisey stock unit are summarized in Table 1 for $1974-88$. The highest catch of 41 t occurred in 1979, the lowest of 4 t was in 1975. The TACs listed in Table 1 for 1979-84 applied only to the Voisey Bay subarea. The quota area catch in Table 1 lists the catch specifically from the Voisey Bay for those years. Since 1985, the TAC has applied to the entire stock unit.

Landings in 1988 totaled 14 t , about $83 \%$ of the TAC but $34 \%$ lower than the 1987 catch which exceeded the recommended TAC by $25 \%$. Effort decreased by 49\% with catch per unit effort (CUE) up by $29 \%$.

## 3. Length distribution of commercial landings

Figure 2 illustrates the length-frequency distribution of commercial catches from the Voisey stock unit from 1980 to 1988. Similar to the Nain unit, there has been a shift from a modal size of 52 and 54 cm in 1980 and 1981 to the 50 cm interval during the past six years. In general, length-frequency distributions have not changed dramatically over these years. As explained in the Nain unit assessment, with the use of 114 and 127 mm mesh gill nets in conjunction with the large overlap in size at age in these Arctic charr populations, major changes in the length distributions resulting from over exploitation of the stock would probably not be expected unless severe recruitment overfishing has occurred. Any consistent changes that do occur would have to be evaluated in relation to trends in catch rates, biomass estimates (if available) and age distribution.

### 4.1 Sequential population analyses (SPA)

Catch at age data are available since 1977 and are summarized in Table 2. Catch at age data, along with the estimated standard error and coefficient of variation (C.V.) for the 1988 data are shown in Table 3. Those ages that contributed to the majority of the catch (ages $7-10,84.4 \%$ of the total) had coefficients of variation less than 15\%. Data were derived from annual commercial sampling programs carried out at the Nain fish plant. Mean age of the catch has ranged from 8.2 years in 1979 to 9.1 years in 1981, with no
apparent increasing or decreasing trend. In 1988, three age-classes, represented by $7-, 8$-, and 9 -year-old fish made up $67 \%$ of the catch. A summary of the percent at age in the catch is provided in Table 4.

Weights at age were derived from commercial samples obtained from 1977 to 1988. Gutted head-on weights were converted to whole weight using the conversion factor 1.22 (Dempson 1984). For the yield-per-recruit analysis, mean weight at age for the period 1977-79 was used, similar to past assessments. For the stock projections, mean weight at age for the period 1987-88 was used. Table 5 summarizes the mean weight at age data for specific time periods.

An estimate of total mortality ( $Z$ ) was calculated using the Paloheimo method (Ricker 1975) and the average value for the last four years was 0.81 , although the data varied considerably. An estimate derived from a catch curve using catch per unit of effort at age data from 1986 to 1988 was 0.83 and refers to an average mortality during the period of time the fish were recruited into the fishery. Natural mortality was assumed to be 0.2.

An initial SPA was run using partial recruitment values and terminal fishing mortality ( $\mathrm{F}_{\mathrm{T}}=0.7$ ) from last year's assessment (Dempson 1988). An iterative procedure was used to obtain estimates of fishing mortality for the oldest age group ( $F_{B}$ ) (Rivard 1982). Following this, partial recruitment rates were calculated using the the historical averaging method from the matrix of fishing mortality rates generated by the SPA using years 1982-86. These values were then applied to the value for terminal $F$ and the procedure repeated until the partial recruitment values stabilized. Final partial recruitment rates and the selectivity coefficients are shown in Tables 5 and 6 respectively.

Yield per recruit was calculated by the method of Thompson and Bell (Rivard 1982) using partial recruitment rates and mean weight at age. $\mathrm{F}_{0.1}$ was 0.40 at a yield per recruit of 1.08 kg .

### 4.2 Calibration

A series of SPAs were run using a range of terminal fishing mortality rates from 0.3 to 0.7 . In each run, fishing mortality rates for the oldest age group were re-evaluated using the iterative procedure. Regressions of $F$ (weighted mean F for fully-recruited fish) on the index of fishing effort and average exploitable biomass on catch per unit effort were used in the calibration process to determine an appropriate value for $\mathrm{F}_{\mathrm{T}}$ in 1988. Data from 1977 to 1988 were used in the analyses.

Regressions of $F$ on effort had the highest correlation coefficient at $\mathrm{F}_{\mathrm{T}}=$ 0.45 . The residual for the 1988 point was also the smallest at $\mathrm{F}_{\mathrm{T}}=0.45$, while the sum of residuals for the last three years (1986-88) or the sum of squares of residuals for the last three years were smallest when $\mathrm{F}_{\mathrm{T}}=0.55$ and 0.5 respectively (Table 7). The intercept value increased with an increasing value of $\mathrm{F}_{\mathrm{T}}$ used, but was not significantly different from zero for any terminal $F$.

Regressions of average exploitable biomass on CUE had the highest correlation when $F_{T}=0.5$. With respect to the residual for the last year (1988), it was lowest when $\mathrm{F}_{\mathrm{T}}=0.35$, while the sum of the residuals for the last three years, or the sum of squares of residuals for the last three years, was smallest when $F_{T}=0.5$ and 0.4 respectively. The intercept value was closest to zero when $F_{T}=0.5$ (Table 7). In summary, the regression analyses suggested terminal fishing mortality could range from 0.35 to 0.55 .

Figure 3 illustrates the trend in population biomass from 1977 to 1988 based on several values for terminal $F$. All cases show a substantial decrease in biomass from the latter 1970s to the early 1980s. There is little evidence, at estimated current values for terminal fishing mortality ( $F_{T} \sim$ 0.45 ), that the population biomass is increasing despite the high catch rates experienced this year. Table 8 summarizes the estimated population numbers, biomass, and fishing mortality for the SPA run with $\mathrm{F}_{\mathrm{T}}=0.45$.

### 4.3 Catch projections

Projections of reference level catches for 1989 were run with $\mathrm{F}_{\mathrm{T}}$ varying from 0.45 to 0.55 . Recruitment for the projections was estimated from the geometric mean population numbers for age 6 -year-old fish for years 1977-86. Weights at age were based on the 1987-88 data. Results of the projections are summarized in Table 9. The 'reference level catch' in 1989 ranges from 12.5 t , with $\mathrm{F}_{\mathrm{T}}=0.55$, to 15.4 t with $\mathrm{FT}=0.45$. The latter value is about $9 \%$ lower than the TAC of 17 t in 1988. It should be noted that the high catches in the 1977-81 period (average $=29 \mathrm{t} \cdot \mathrm{y} \mathrm{-}^{1}$ ) probably had a significant impact on reducing the total stock biomass in subsequent years. The likelihood of increased spawning escapements in recent years, when catches have been lower, will hopefully aid in rebuilding the stock to earlier levels. However, without information on spawning escapements from any index rivers, we do not know in fact what actual spawning escapements are, nor if they are increasing. Assuming that they have been, the impacts will not be apparent in the fishery for a number of years, as fish only begin to be recruited to the commercial fishery at age 6 .

Fishing mortality rates experienced by some of the northern Labrador Arctic charr stocks (F's of 0.4 to 0.7 or annual rates of 33 to 50\%) appear rather high when compared with, for example, some of the cod populations. However, in comparison with values often assumed for our Atlantic salmon stocks, they tend to be much lower. Occasionally an exploitation of $85 \%$ on large salmon and $55 \%$ on small salmon has been used (Pippy 1982). These annual values would relate to instantaneous rates of about 0.8 to 1.9. Salmon have a different reproductive strategy than charr, and a much lower turnover time, and could undoubtedly support higher levels of exploitation. Optimal rates have not been derived for salmon. As additional information on year-classes in the fishery become available, the capacity of Arctic charr populations to tolerate and respond to various levels of exploitation, and the effects of exploitation on population characteristics will slowly become more apparent.
