## Review of abundance indices for the 4WX herring assessment

by<br>R.L. Stephenson, M.J. Power, U. Buerkle<br>D.J. Gordon, J.B. Sochasky and W.H. Dougherty<br>Marine Fish Division<br>Department of Fisheries and Oceans<br>Biological Station<br>St. Andrews, New Brunswick EOG 2X0

${ }^{1}$ This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.
${ }^{1}$ Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

#### Abstract

Early analytical assessments of 4WX herring (1974-82) were calibrated using catch/effort indices from weir and purse seine fisheries. These were replaced in 1983 by use of a larval abundance index (autumn larval abundance related to VPA derived estimates of spawning stock biomass). Recently, biomass estimates from an acoustic survey of overwintering herring has been used as well. This paper presents the results of a re-evaluation of these and other potential abundance indices which may be of use for either calibration of the VPA or predicting recruitment. The most useful approach to tuning in the short term would appear to be use of a combination of acoustic, larval and research ground trawl survey indices. There is no obvious way of providing a recruitment index in the near future.

## RÉSUMÉ

Les premières évaluations analytiques du hareng de 4WX (1974-1982) étaient étalonnées à l'aide des indices prises/effort caractérisant les pêcheries fixes et la péche à la senne coulissante. Ces évaluations ont été remplacées en 1983 par l'utilisation de l'indice d'abondance larvaire (estimations dérivées de l'abondance larvaire automnale reliés à l'APV de la biomasse du stock de reproducteurs). Récemment, on a également utilisé des éstimations de la biomasse à partir de relevés acoustiques du hareng hivernant. Dans le présent article, on présente les résultats d'une réévaluation de ces estimations et d'autres indices d'abondance possibles qui peuvent être utilisés soit pour étalonner l'APV soit pour prévoir le recrutement. L'approche la plus utile pour l'étalonnage à court terme serait l'utilisation d'une combinaison d'indices des relevés acoustiques, des relevés larvaires et des relevés de recherche par chalutage sur le fond. Il n'y a pas de façon absolument évidente de fournir un indice de recrutement dans un avenir rapproché.

## INTRODUCTION

Calibration of 4WX herring assessments since 1983 has relied primarily on the relationship between an index of autumn larval abundance (LAI) and VPA derived estimates of the spawning stock biomass (SSB). In recent years, tuning has become increasingly difficult. The LAl/SSB relationship seems to have been poorer, and this has raised concerns over the validity of the relationship, its method of calculation, and use in tuning.

In addition, there has been an increasing need for an estimate of the size of pre- and partially recruited age groups, which have been estimated to comprise the major portion of the population and therefore to have a large impact on forecast ability. In 1988, the Pelagic Subcommittee of CAFSAC recommended a reevaluation of existing data including acoustic, logbook, and larval survey series to provide more information on abundance and consideration of development of another abundance estimate - preferably one of relevance to recruiting ages which are a major portion of this fishery.

In this paper we document the history of tuning in this assessment and summarize the recent re-evaluation of existing indices and consideration of potential indices for 4WX herring.

## HISTORY OF TUNING IN THE 4WX ASSESSMENT

A number of tuning methods have been used since 1974 (Tables 1, 2).
Initially, weir catch rates were used to indicate relatively large incoming year-classes, and to modify $F$ values on those year-classes in uncalibrated cohort analyses. From 1978-80, cohort analyses were calibrated, primarily using regressions, with standardized purse seine catch/effort series. This index was rejected, however, in 1981 due to the suspected impact of misreporting and market constraints on purse seine catch rates.

A larval abundance index based upon annual autumn surveys since 1972 was used in 1981, but was rejected in 1982 as a result of an apparent sharp decline in the 1981 point. For that year (1982 assessment), gillnet and N.B. weir CPUE series were used, but these were rejected in 1983 and 1984 in favor of the larval abundance index which has been used since.

Other potential abundance indices have been considered from time to time (Table 2), but have not been used in tuning.

## POTENTIAL ABUNDANCE INDICATORS

A review of tuning in other herring assessments at CAFSAC, at ICES (South of $62^{\circ} \mathrm{N}$ Working Group; Anon. 1988) and in the USA (Fogarty 1990) yields the following list of indices which have been used (or at least considered) within the last 5 years:

Larval abundance index
Laval production estimate
Acoustic abundance of adults
Acoustic recruitment index
Young fish survey (IKMT) recruitment index
Commercial effort (days fished)
Commercial gillnet catch rates
Index fishermen gillnet catch rates
Bycatch in groundfish research surveys
Egg bed surveys

## A REVIEW OF ABUNDANCE INDICES FOR THE 4WX ASSESSMENT

## 1) LARVAL ABUNDANCE

Rationale
Indices based upon larval abundance have several potential advantages including:
i) independent of commercial fishery
ii) efficiently and relatively inexpensively surveyed, using conventional plankton techniques
iii) allow evaluation of a life-history stage at which year-class strength may be determined and, if used to forecast, allow the maximum advance knowledge of recruitment to the fishery.

Additional rationale for herring comes from the persistence or "retention" of larvae in well defined, discrete stock aggregations for considerable lengths of time (lles and Sinclair 1982; Sinclair and Tremblay 1984; Sinclair and lles 1985).

Lavval abundance estimates or indices may be used in two ways: to forecast recruitment and to hindcast spawning stock size (Fig. 1a).

Hindcasting spawning stock size requires assumptions about hatching rates from deposited spawn, and mortality to the time of survey. Absolute estimates of spawning stock size require an estimate of fecundity to translate egg production into
spawning biomass. Such estimates would be used to calibrate the mature age groups of the VPA.

Recruitment forecasting assumes that year-class strength has already been determined at the time of survey or, alternatively, that subsequent mortality factors are constant from year to year. It would be used in assessment as a direct estimate of abundance of the youngest year-class.

Figure 1b illustrates the relative constraints placed on the timing of the surveys as a result of the assumptions involved in forecasting and hindcasting. Surveys used for recruitment forecasting should become more reliable later in the larval stage because of the assumptions of year-class determination; surveys used to hindcast spawning stock size are best undertaken early in the larval stage to minimize the effect of larval mortality. In both cases, the relative value of the survey decreases at metamorphosis due to changes in fish distribution, gear avoidance, etc.

Larval surveys for hindcasting are of two kinds. The first is designed to cover the whole spawning area and spawning period by a temporal series of collections in order to integrate larval production during a relatively early stage (usually up to a larval length of 10 mm , e.g. ICES Herring Working Group, Anon. 1988). The second is designed to cover the entire area of larval distribution at a single time, subsequent to the end of hatching, but close enough to the mean time of spawning to minimize the affect of variable mortality after hatching (as has been used in this assessment, e.g. lles et al. 1985). Both methods assume constant hatching rates from deposited spawn. The first type (temporal series) is potentially better, but is impractical and expensive in large areas.

Data available
Comprehensive surveys of the Bay of Fundy began in 1969 and standard surveys of 116-163 stations (Fig. 2) have been undertaken annually, during late October and early November, since 1972 (Table 3a). A second spring series was undertaken during March from 1975-84 (Table 3b). Sawtooth oblique tows have been made using paired $61-\mathrm{cm}$ bongo nets (. 505 mm mesh) equipped with digital flowmeters. Tows were made to a depth of 5 m off bottom. Set and haul rates were 50 and $20 \mathrm{~m} \mathrm{~min}^{-1}$, respectively, while the vessel was proceeding at 3.5 knots. If initial retrieval time was less than 10 min , the gear was payed out again for successive hauls until a minimum total retrieval time of 10 min was obtained. Samples have been stored in $5 \%$ buffered formalin and sorted for all herring and herring-like (includes Clupeidae and Osmeridae) larvae to a minimum sorting precision of $10 \%$. Larval numbers are expressed volumetrically on the basis of the measured volume filtered by the net and are converted to numbers beneath a square metre ( $\mathrm{no} . \mathrm{m}^{-2}$ ) based on the mean depth during the occupation of each station.

## Indices

## i) Traditional larval abundance index (LAI)

The traditional larval index has been calculated as the mean of the larval density ( $\mathrm{no} . \mathrm{m}^{-2}$ ) for all stations sampled in autumn surveys (see, for example, lles et al. 1985). Both geometric and arithmetic means have been used. In the 1988 assessment (Stephenson and Power 1988), the index was recalculated on the basis of fewer stations in order to exclude those which had not been sampled in some years or which were outside of the stock area (i.e. coastal Maine). This index included a number of stations outside of the larval retention area and, until 1988, included a few stations in what is now known to be part of the 5 Y stock area (see Chenoweth et al. 1989).

In 1989, two additional series were analyzed:
ii) Total larval abundance (TLA)

Total lavval abundance (TLA) was estimated for each year by contouring survey data. Larval density (number per $\mathrm{m}^{2}$; aggregated by $1-\mathrm{mi}^{2}$ grid) was contoured at five levels using ACON (GAP Black, pers. comm.). The program creates a response surface using triangulation. Areas were digitized and multiplied by median density per stratum to estimate total number of larvae. Two indices were calculated: TLA-1 based on an area covered in all surveys in the series; and TLA-2 from a shorter time series of surveys (since 1980) which were extended to the southeast to cover the entire lavval distribution.
iii) Larval retention area (LRA)

The area of larval occupation was digitized as outlined above for the area occupied by greater than $5 \mathrm{~m}^{-2}$ (fall) and $0.5 \mathrm{~m}^{-2}$ (spring). Areas of the two aggregations of lavvae (upper and lower Bay of Fundy) were calculated separately.

The resulting larval series are presented in Table 4 and Fig. 3. It was concluded that modifications to the larval abundance index (total abundance TLA-1 and TLA-2) offer little, if any, improvement over the traditional index.

1989 larval survey
The 1989 Bay of Fundy larval herring survey was conducted between Oct. 23 and Nov. 9 (E. E. PRINCE 391). Coverage included additional stations to the south and east (to define the extent of the larval aggregation) (Fig. 4a) and duplicate coverage of a $7885 \mathrm{~km}^{2}$ area off SW Nova Scotia using random station locations (Fig. 5) (Sochasky, MS). All 79 of the traditional index stations (Fig. 4b) were sampled. The LAI from this survey was 54.5 - a considerable decrease from the 1988 value, but the second highest of the 18 -yr time series (Table 3a).

Random vs fixed station design
In 1988 and 1989 surveys, a comparison was made of the performance of fixed vs random station sampling within a reference area or stratum which contained the traditional patch of high larval density ( $43^{\circ} 10^{\prime}$ to $44^{\circ} 30^{\prime} \mathrm{N}$ and $66^{\circ} 10^{\prime}$ to $66^{\circ} 50^{\prime} \mathrm{W}$ ). For each year, the results of fixed stations have been compared with results from a similar number of randomly placed stations in the same area (Fig. 5).

|  | 1988 |  | 1989 |  |
| :---: | :---: | :---: | :---: | :---: |
| random | fixed | random | fixed |  |
| $n$ | 52 | 47 | 51 | 42 |
| arith. mean | 300.81 | 235.53 | 150.08 | 156.03 |
| SE | 72.10 | 38.62 | 25.13 | 23.33 |

Backcalculation of spawning stock biomass from larval abundance
We have attempted to work back from larval abundance to spawning population biomass as follows:
i) Calculate number of larvae $\left(N_{t}\right)$
a) using digitized areas of lanval abundance $x$ mean abundance
or b) using mean (and variance) of entire survey $x$ survey area.
ii) Calculate number of larvae at hatching ( $\mathrm{N}_{0}$ ) assuming an instantaneous mortality rate $(Z)=0.06$ (from Chenoweth et al. 1989) by:
a) assuming a mid-date of hatching prior to mid-September (i.e. $t \geq 45$ )
or b) calculating time ( $t$ ) since hatching dates from length structure of larvae assuming a growth rate of $.24 \mathrm{~mm} \mathrm{~d}^{-1}$ and a hatching size of 5 mm (Chenoweth et al. 1989).
iii) Calculate spawning females, assuming a fecundity relationship from Messieh (1976) for SW Nova Scotia (In fecundity $=-22.71+4.75$ In length), then total spawners assuming a sex ratio of $50 \%$.

Backcalculation of this type is very sensitive to errors in mortality rate, and does not include any mortality prior to hatching. We consider it premature to attempt backcalculation until laval mortality is better understood.

## 2) WEIR CATCH RATES

The 4WX fishery contains two weir components. Approximately 240 weirs are located on the shore and islands west of Saint John on the New Brunswick side of the Bay of Fundy. Approximately 15 others are located between Yarmouth and Digby in southwest Nova Scotia.

The New Brunswick weir fishery has averaged $23,500 \mathrm{t}$ in recent years (since 1970). Fish are predominantly 2 -year-olds and are marketed mostly as sardines. The N.B. weir fishery is thought to rely on fish from several populations, including coastal USA (5Y) and, historically, Georges Bank (5Z). For this reason, N.B. weir landings have been excluded from 4WX stock totals and have recently been considered inappropriate for use in tuning the 4WX assessment. There is some rationale for reconsideration of its use in that there is a definite synchrony in strong and weak year-classes among populations (e.g. Anthony and Fogarty 1985). In addition, the weir fishery has appealing features including:

- long time series
- free of gear changes
- relatively stable effort
- lack of misreporting.

The Nova Scotia weir fishery has had landings averaging 5750 t (since 1970) comprised mostly of age 2-3 fish. Historical criticism of an index based on this fishery has focused on the strong influence of market demand producing variable landings. In addition, both weir series may suffer from potential variability in availability (behavior) of fish.

We have re-examined weir indices in relation to stock size, and in terms of their use in predicting year-class size (see section on recruitment indices).

Catch-per-unit effort has been calculated as numbers per weir for ages 1-3 in the N.B. weir fishery (Table 5a) and for ages 1-3 and all ages in the Nova Scotia weir fishery (Table 5b) (Fig. 6).
3) ACOUSTIC SURVEY

## Background

Early attempts to survey juvenile and summer aggregations of 4WX herring acoustically were unsuccessful due to:

1) inconsistent distribution of fish
2) large survey area
3) interference with an intense commercial fishery on spawning grounds.

By contrast, surveys of overwintering aggregations were able to find and survey herring, particularly in Chedabucto Bay, N.S. (summarized by Buerkle 1987). Surveys in 1981 and 1982 were designed to cover the area of the historical winter purse seine fishery as estimated from catch reports since 1971. This area extended about 160 km along the shore of N.S. from Liscomb Island to Forchu Head and offshore about 50 km .

1981-83. The 1981 survey covered the area but found the herring concentrated in one small ( $30 \mathrm{~km}^{2}$ ) area. The 1982 attempt failed completely; the boat was unable to survey because of windy weather. The 1983 survey was a more weather-resistant survey track and again covered the area but found negligible quantities of fish. The fishery, however, was making good catches at night in an area where the survey found no fish during the day. The 1981 and 1983 results led to the conclusion that herring are concentrated in small areas and are not reliably available for acoustic detection during the day.

1984-85. In 1984, the emphasis was changed from surveying the whole area to replicate night time surveys in the areas of fish concentration as identified by the commercial fishing effort. The 1984 and 1985 surveys were successful in producing nightly replicate estimates of fish abundance in the areas of fish concentration. They also surveyed the larger area of the historical fishery but found no significant quantities of herring outside the areas of major concentration. This supported the conclusion that surveying the area is ineffective and that the surveying effort should be focused on the known areas of fish concentration.

1986-87. The 1986 and 1987 surveys produced replicate estimates of herring abundance in the areas of commercial fishing in Chedabucto Bay and surrounding areas but did not survey the whole area of the historical winter fishery.
1988. A survey in January 1988 was hampered by equipment failure, and no abundance estimate was made.
1989. A successful acoustic survey of Chedabucto Bay was undertaken in January 1989 (Buerkle 1989). That survey employed a random parallel design recommended by CAFSAC and improvements in processing, particularly with respect to bottom echo detection.

An extension of the survey to Sydney Bight gave no indication of herring east of Chedabucto Bay. An additional experimental survey in February documented three aggregations in the Grand Manan area of the Bay of Fundy and estimated a total of approximately $100,000 \mathrm{t}$. Biomass of the Chedabucto Bay aggregation was estimated to be 450,000 t (Table 6).
1990. The annual Chedabucto Bay survey undertaken between January 4 and 26 (Buerkle 1990; Table 6, Fig. 7) indicated a biomass of approximately
$194,000 \mathrm{t}$, compared with $450,000 \mathrm{t}$ in 1989. This may have been the result of unusual distribution of the fish (fishermen report higher abundance in December), and brings into question the validity of Chedabucto Bay as an index area.

Possible improvements to the acoustic survey
The acoustic survey has become one of the most valuable abundance indicators. Work on acoustic techniques and on application to 4WX herring has resulted in improvements in survey design and protocol which have increased the validity of the surveys.

The winter survey may be missing a portion of the population, and should be expanded if herring distribution varies. Alternatively, it may be possible to survey spawning grounds. Earlier attempts were hampered by incomplete knowledge of the distribution of spawning aggregations and by the high density of vessels on spawning grounds during the survey. However, the situation has changed in the last 5 yr in that 1) spawning areas have been documented using the new purse seine logbook (Power and Stephenson 1990) and 2) there have been fewer vessels fishing on the spawning grounds with the recent inactivity of the gillnet fleet (Stephenson and Power 1989). A survey of spawning grounds would be valuable too in providing information on individual components of the 4 WX stock complex, which would be useful in management of spawning units.

## 4) PURSE SEINE CATCH/EFFORT DATA

The purse seine segment dominates the 4 WX herring fishery and, in recent years, has taken more than $80 \%$ of the stock catch.

While a considerable amount of data has been collected routinely from the 4WX purse seine fishery, the quality and quantity of this information has not always been adequate. Previous assessments of this stock (e.g. Stephenson et al. 1985) discussed the high degree of misreporting that has at times occurred in the purse seine fishery. In some years, statistical information was incomplete, as was information from logbooks. As part of an effort to improve the quality of biological information, a new purse seine logbook was designed and implemented for the 1985 4X summer fishery (Power and Stephenson 1986). At the same time, several operational initiatives were put into effect, including submission of logs on a weekly basis as a condition of license, which reduced misreporting and improved logbook return. The result was a significant improvement in the amount of catch information from the purse seine fishery (Power and Stephenson 1986, 1987).

Several logbook formats had been in use in the 4WX fishery prior to 1985. These formats lacked places for information on a number of important activities for the herring purse seiners, especially searching time. The revised log had several improvements, including fields for search time, markets sought and set specifics laid out on one page for each trip or fishing night.

The historical data series allowed only rough CPUE calculations of catch per night or catch per set, and these were in some areas based upon a small portion of the total fishery (i.e. incomplete logbook information; Table 7). Since 1985, we have been calculating what we hope may be more relevant and useful indices: catch per hour of search time and sets per hour searched (Table 7). These are available by fishing ground and month in other documents (Power and Stephenson 1986, 1987, 1990; Stephenson and Power 1988).

## 5) GROUNDFISH SURVEY BYCATCH

Fogarty et al. (1990: SAW 9) used a US (NEFC) bottom trawl survey abundance index (mean weight of herring (kg)/tow) to tune the most recent US herring assessment.

Bottom trawl surveys of the Scotian Shelf and Bay of Fundy have been conducted in spring, summer and fall for a number of years:

| Survey | Target dates | Years |  |
| :--- | :--- | ---: | :--- |
|  | March | 1979-84 |  |
| Spring | July | $1978-89$ |  |
| Fall | October | $1979-84$ |  |

Standard protocol involves tows of standard length with a Western IIA bottom trawl at random stations within consistent strata (as summarized by Doubleday 1981) and often results in a herring bycatch. Indices based on number of herring per standardized tow (from STRAP) have been calculated for the entire area (4VWX) and strata 80-95 of $4 X$ (Table 8, Fig. 8). Concern regarding this index has been expressed because of the low numbers of herring taken in some years, over possible set, vessel and strata effects and that the peak years in groundfish survey results were offset from those of the larval index.

Relative performance indices
Of the available indices, larval survey, acoustic survey and ground trawl survey are considered to be most useful. These are compared in Fig. 9.

## RECRUITMENT INDICES

There is no established recruitment index for the 4WX assessment. This is a major deficiency, particularly as the fishery relies so heavily on incoming yearclasses. Herring of age 2 form a significant portion of the 4WX fishery and ages 3 or 4 often dominate the catch. Therefore, an early recruitment prediction is required.

As outlined in Fig. 1, recruitment prediction from young stages (early larvae, for example) may be poor because of the potential for variable mortality during larval
and juvenile stages. Late stages, however, have proven to be hard to survey in comparison with early larvae.

The following is an assessment of the existing and potential surveys as recruitment indicates:

1) Larval survey - spring

The existing series of spring larval survey data (1975-84) does not appear to forecast recruitment (as VPA-derived age 1 or 2; Fig. 10). There are two possible explanations:

1) year-class strength has not been determined by the late larval stage (i.e. not during the juvenile stage, after metamorphosis);
2) there was a problem with sampling or coverage in the spring survey such that the results do not reflect actual larval abundance. This could have been the result of

- inefficiency of the gear (bongo)
- incomplete coverage of larval area
- partial metamorphosis prior to survey.

Plots of spring distribution of larvae indicate that larvae are still aggregated in the areas off southwest Nova Scotia and Digby and it seems that coverage should have been adequate. Metamorphosis of fall-spawned larvae does not normally occur prior to late April (Sinclair and Tremblay 1984) so the timing should have been valid. By the time of the survey, these larvae are large, however, and results may have been affected by gear avoidance.

Given the apparently predictable spring distribution of larvae, an improved late larval survey should be considered for a potential recruitment index. This survey should use gear that is appropriate for large lavae (possible Tucker trawl or fine IKMT) and should address related issues of fine-scale distribution (vertical movement, patchiness, etc.) and condition of lanvae as well as hydrographic correlates.

## 2. Juvenile "brit" survey

Previous attempts to survey juvenile herring in the Bay of Fundy have been considered unsuccessful and there is no time series of data. Occasional cruises undertaken with midwater (Boris) trawls and acoustics have concluded that juvenile herring are elusive and unpredictable in distribution.

A recent series of collaborative DFO/Dept. of Manine Resources (Maine) surveys along the coast of eastern Maine and southwestern N.B. has documented some consistency in distribution of early juveniles ("brit") - but relatively few have been seen, they have been hard to catch quantitatively, and are presumed to be of 5 Y stock origin.

## 3. Weir index

Weir catches have been dominated by age 2 fish, which are suitable for the sardine market. We have investigated the question of whether weir catches predict what will happen in the "adult" fisheries. Table 9a, b summarize the catches (in number) of ages 1-3 and the cumulative catches of cohorts over their first 3 yr in both the N.B. and N.S. weir fisheries. Figure 11 shows that catches of adult fish (e.g. age 5) only generally reflect the catches of age 2 fish 3 yr earlier.

Cohort with assumed F's. N.B. weir catch at age 2 used to indicate strong year-classes.

Cohort with assumed F's. Catches of 1973 year-class in both N.B. and N.S. weirs used to modify F for that year-class.

Cohort analysis with assumed F's.

Cohort analysis calibrated with a CPUE index based upon both the N.S. purse seine and weir fisheries. Terminal F's and F's on older age groups adjusted to improve regression with standardized effort.

Cohort analysis calibrated with two purse seine CPUE indices (one incorporating a learning factor) and supported by N.S. weir CPUE.

Cohort analysis calibrated with purse seine CPUE (three indices, with and without learning factor). Recruitment indices based upon environmental conditions (wind and sea level) and weir catches considered).

Problems with purse seine CPUE index cohort analysis calibrated in relation to autumn larval survey index (G mean of 15 stations) and N.B. weir catch rate index.

Sharp decline in larval abundance index. Gillnet and N.B. weir catch rates chosen to tune VPA.

SPA tuned by combination of larval adundance index (G mean vs $5+$ biomass) and N.B. weir catch rates.

SPA tuned with autumn larval abundance (Geom. mean larval abundance in year $N$ regressed with both mature and $5+$ biomass estimates for Jan. 1 of year $N+1$ ).

As above.

As above; tuning based upon the best combination of high correlation, low intercept and minimum residuals.

As above.

1988 CAFSAC Res. Doc. 88/69 As above using arithmetic mean of reduced number of (Stephenson and Power, 1988) stations in "Adaptive Framework."

Fig. 1a. Potential estimates of stock abundance from larval herring surveys (from Stephenson 1988).

Fig. 1b. Schematic representation of the effect of larval survey timing on the relative ability to hindcast spawning stock size and to forecast recruitment to the fishery (from lles et al. 1985).

Fig. 2. Standard survey stations; Bay of Fundy larval herring cruises 1972-88.

Fall Larval Abundance Indices

Spring Larval Abundance

Fig. 3. Time series of larval abundance (total numbers and traditional index) and of area of lavval distribution from fall and spring surveys of the Bay of Fundy.

P391 (NOV. 1989) - All Stations in Survey

Fig. 4a. Abundance (no. larvae $\mathrm{m}^{-2}$ to bottom) for all stations in the November 1989 Bay of Fundy larval herring survey (E.E. PRINCE 391).

P391 Standard 79 Stations Only

Fig. 4b. Abundance (no. larvae $\mathrm{m}^{-2}$ to bottom) at 79 "index" stations on the 1989 survey (P391).

P377 (NOV. 1988) - Standard Stations

P391 (NOV. 1989) - Standard Stations

P377 (NOV. 1988) - Random Grid Stations

Fig. 5. Distribution of stations and larval abundance ( $\mathrm{no} \cdot \mathrm{m}^{-2}$ ) in fixed (left) and random (right) surveys of the larval herring concentration off southwest Nova Scotia in 1988 (upper) and 1989 (lower).

Fig. 6. Catch (numbers $\times 10^{-3}$ ) per weir in Nova Scotia and New Brunswick weir fisheries.

Fig. 7. Herring biomass ( $\pm 95 \% \mathrm{Cl}$ ) from Chedabucto Bay January surveys 1984-90 (from Buerkle 1990).

Fig. 8. Occurrence of herring (number) per set $(A)$ in Canadian trawl surveys of the Bay of Fundy and Scotian Shelf.

Fig. 9. Comparison of time series of potential abundance indices for 4 WX herring.

Fig. 10. Spring larval abundance compared with year-class strength as VPA age 1 or age 2 (from 1988 assessment).

Fig. 11a. Catch at age 2 in New Brunswick weirs vs the contribution of that yearclass of the 4 WX fishery as age 5 ( 3 yr later).

Fig. 11b. Catch at age 2 in Nova Scotia weirs vs the contribution of that year-class to the 4 WX fishery as age 5 ( 3 yr later).
