<sup>1</sup>This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

<sup>1</sup>Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

## ABSTRACT

The provisional catch of American plaice in NAFO Division 4T in 1989 was 4,987 t. The proportion of the total catch taken by seines was 46%, representing an increase of 8% from 1988. Bottom trawls took 39% of the total catch. Standardized catch rates from multiplicative analyses in the American plaice directed, cod directed and combined fisheries showed stability in the American plaice directed component and a decline in catch rates from the 1970s in the other two indices. None of the indices were considered to accurately reflect stock size because of violations in the assumptions of the multiplicative model. Research vessel (RV) mean numbers per tow in 1989 were the lowest in the series. The average total mortality estimates for fish of age 8-18 from the RV data were 0.36 for 1971-79 and 0.53 for 1980-89. Assuming natural mortality to be 0.2, fishing mortality during the 1980s was therefore above  $F_{0.1}$ . Projections assuming constant recruitment, natural mortality, and growth gave yields between 4,699 and 7454 t. Fifteen per cent of the mature biomass, as determined from RV survey gave a yield of 3,220 t. Therefore, a TAC of between 3,000 t and 8,000 t is considered to be closer to the  $F_{0.1}$  level for this stock than the current TAC of 10,000 t. However, a restrictive quota may result in increased discarding at sea.

## RÉSUMÉ

Les prises de plie canadienne dans la division 4T de l'OPANO en 1989 se sont établies à 4 987 t (chiffre provisoire), dont 46 p. 100 ont été capturées à la senne - huit pour cent de plus qu'en 1988 - et 39 p. 100 au chalut de fond. Les taux de prises normalisés d'après les analyses multiplicatives effectuées dans les pêches directes de la plie canadienne et de la morue ainsi que dans la pêche mixte dénotaient une stabilité dans la pêche directe de la plie canadienne et une baisse par rapport à 1970 dans les deux autres formes de pêche considérées. Aucune des données de référence n'était perçue comme un reflet exact de la grosseur du stock, en raison d'écart par rapport aux hypothèses du modèle multiplicatif. Les résultats moyens par trait obtenus par les navires scientifiques en 1989 étaient les plus bas de la série. D'après ces résultats, la mortalité moyenne totale pour les poissons de 8 à 18 ans se chiffrait à 0,36 pour 1971-1979 et à 0,53 pour 1980-1989. Si l'on se fonde sur une hypothèse de mortalité normale égale à 0,2, il s'avère que la mortalité due à la pêche durant les années 1980 a été supérieure à  $F_{0.1}$ . Les rendements obtenus dans des projections fondées sur une croissance, une mortalité naturelle et un recrutement constants, s'échelonnaient de 4 699 t à 7 454 t. Quinze pour cent de la biomasse à maturité donne un rendement de 3 220 t, d'après les données des navires scientifiques. Par conséquent, on estime qu'un TPA situé entre 3 000 t et 8 000 t serait plus proche du niveau  $F_{0.1}$  que le TPA actuel de 10 000 t. Toutefois, un contingent plus restrictif pourrait aboutir à une hausse des rejets en mer.

## INTRODUCTION

Since 1965 reported landings from the NAFO Division 4T American plaice stock have varied from a high of 11,780 t in 1966 to a current low of 4,987 t in 1989 (Table 1). A precautionary TAC of 10000 t has been imposed on the landings of this fishery since 1977. Average annual landings have been almost 1,500 t less than this. Landings for the last four years have been below 8,000 t.

Historically, the American plaice fishery was primarily a by-catch fishery of the southern Gulf of St. Lawrence cod fishery. Since 1986 a fishery directed for American plaice has taken roughly half the total landings. The stock is exploited both by mobile gears, such as otter trawler, Danish and Scottish seines, and fixed gears including gillnets, longlines and handlines. The composition of gears has changed from mainly longlines from 1937 to 1946 to a mixed fishery of longlines, otter trawl and Danish seine from 1947 to 1963 (Powles 1969). Since 1965 gillnets have been used also (Table 1). Danish seines have taken an increasing proportion of the total landings from 1965 to 1989 and are now the dominant gear type.

### Reported Landings and Description of the Fishery in 1988

Reported landings for 1989 are tabulated from the provisional data supplied by the Statistics Branches of the Scotia-Fundy, Newfoundland, Quebec and Gulf regions of the Department of Fisheries and Oceans. The provisional estimate of landings for 1989 was 4,987 t, down over 1700 t's from 1988 and only 49.9% of the TAC. Reported landings by gear and month are presented in Table 2. Reported landings of flatfish in the entire Gulf of St. Lawrence are shown in Table 3. The total flatfish landings in the Gulf for 1989 are approximately 2800 t lower than the 27 year average.

The proportion of NAFO Division 4T American plaice landed in Quebec decreased from 38% of the total landings in 1988 to 34% in 1989 (Table 4). The Maritimes took virtually all the remaining catch (65.6%). The proportion taken by Danish, Scottish and pair seines increased from 38% of the landings in 1988 to 46% in 1989 (Table 1). Landings by fixed gear decreased substantially from 1,370 t in 1988 to 759 t in 1989 (Figure 1).

There have been no closures of the American plaice fishery in 4T since 1985 (Table 5). The mobile gear (M.G.) (vessel length classes 65-100', 45-65' and <45') fishermen caught substantially less than their allocations. The fixed gear (F.G.) fishermen also caught less than their allocation of 1500 t. Closures in the cod fishery to protect young cod ( G. Chouinard

Canadian Dept. of Fisheries and Oceans, Moncton, N.B., pers. comm.) may have impacted the fishing patterns of American plaice fishermen. The impact may have occurred in two ways: 1) when the cod fishery was closed more vessels would be directed towards American plaice; 2) fishermen complained that they were forced to stop fishing groundfish altogether during the cod fishery closures because they quickly exceeded their by-catch of cod when fishing for American plaice. This latter effect was most severe for the P.E.I. fishermen.

#### Age Determination

The procedures for calibration and age error checking used by the Gulf, MAFD cod program were applied throughout age reading ( Tallman MS 1988 and Chouinard *et al.* 1987). The results of age reader agreement tests reading are shown in Table 6. The overall agreement was 70 to 80 % with no bias.

#### INPUT DATA

##### A) Commercial Fishery Data

###### i) Landings and Weight at Age

Sampling of the commercial fishery in 1989 was comparable to previous years. Samples were taken from April to November when over 99% of the landings were taken. Over 15,800 fish were measured in 1989 ( Table 7), and of these ages were determined for 2,246 fish.

Semi-annual age-length keys, were prepared for the periods before and after July 31. This split provided the best balance for the temporal aspects of the fishery which began in April and closed by the end of November (Table 2). As well, the partition provided the best balance of landings, ages and lengths sampled within the major gear types (Tables 2, 4, 5). We assumed that age at length was unaffected by gear sampled and combined otoliths within each half of the year to make the semi-annual keys.

The length frequencies by gear and semi-annual period weighted by the corresponding landings were used with the appropriate age-length key to obtain the landings at age by gear and half year period (Table 8). Sampled gears were grouped in the following categories: 1) otter trawls and paired bottom trawls (PTB's); 2) seines, Danish and Scottish; 3) gillnets and longlines. Unsampled landings were incorporated by multiplying the landings at age for sampled gears by the ratio the total landings over sampled landings.

All calculations of age-length keys and landings by gear

within semi-annual periods were done for each sex separately. The landings at age for males, females and juveniles were combined to give the overall landings at age for a gear type.

Landings at age and their variances by gear and semi-annual period are presented in Tables 9 and 10. Variances are similar to those recorded in recent years.

Weights at age from 1976 to 1989 were determined using a length-weight relationship calculated from RV survey data for each year. The parameter estimates for the power curve ( $Y=aX^b$ ) for 1976 to 1989 are shown in Table 8. The correlation coefficients for the regressions in 1989 were 0.97, 0.96 for the males and females respectively. The lengths and weights at age for 1989 by sex are shown in Tables 11 and 12.

A decline in the average length at age from the first to second half of 1989 was observed in some age groups of the female American plaice caught by otter trawl. Tallman (1990) suggested that this effect was a result of the movement of the trawler fleet from the south-eastern part of the southern Gulf of St. Lawrence to the north-western Gulf during the course of the fishing season. American plaice in north-western 4T grow more slowly than those of south-eastern 4T. Hence, the fleet may land smaller fish at age during the latter half of the year. An alternative hypothesis (Tallman 1990) is that the larger fish may migrate into a winter refugium in the Laurentian Channel somewhat sooner than the smaller fish. Clay (1990) and Powles (1969) showed that the Channel is utilized by American plaice during the colder months. In 1989, there appeared to be no striking decline in size at age from the first half of the year to the last (Table 12).

The combined landings at age for 1976 to 1989 are shown in Table 13. In 1989 fewer fish over age 13 were caught relative to 1988. The matrix shows some strong year classes apparently recruiting to the fishery in the late 1970's. In the 1980's recruitment appears to be much less. Coefficients of variation of the landings at age from 1976 to 1989 shown in Table 14 are low and thus the landings at age are well estimated.

#### B) Catch at Age

The stratified-random bottom trawl survey carried out by research vessels in NAFO Div. 4T during September of each year since 1971 (Halliday and Koeller 1981) supplied the raw data for the calculations. The survey trawl was equipped with small mesh liners of 32mm in the lengthening piece and 6mm in the codend (Halliday and Koeller 1971). According to Clay (1979) this should retain 50 per cent of the American plaice of 7 cm in length. However, Halliday et al. (1989) noted that survey catches had a modal length of 22 cm suggesting that fish smaller

than this may not have been fully recruited to the gear. Even so, over the size range expected in commercial catches (greater than 20 cm) the survey probably gives an unbiased estimate of the population size structure available to commercial gear.

Length frequency distribution for each sex was calculated from the RV database to provide an estimate of the mean number per tow in each stratum of American plaice of each sex and length category within sex that was available to the fishing fleet in any given year. Between 1984 and 1986 length frequencies for sexes combined were taken. To convert these to sexed length frequencies the proportions of males, females and juveniles were estimated at each length from the RV detailed biological samples. The length frequencies were then divided accordingly.

The spatial and temporal heterogeneities of the proportions at length were examined using a two way anova without interaction (strata by year) using the RV biological data from 1984-1987. Proportions were estimated for 5 cm intervals of length to give reasonable sample sizes. The proportions were transformed using the arcsine transform suggested by Sokal and Rohlf (1981) for this type of data. The model was significant only at length intervals 31-35cm and 36-40cm (Table 15). Within these categories there were no significant year effects. Area effects were significant in both length groups (Table 15). Multiple comparisons using the Tukey-Kramer test (Sokal and Rohlf 1981) showed no significant differences among strata in the 36-40 cm length group. In the 31-35 cm length group stratum 38 was significantly different from strata 415, 431 and 420. When stratum means were ranked relative to stratum 438 a southwestern grouping, composed of strata 403, 432-434, 436-439, was apparent. This pattern is consistent with the hypothesis that there might be two stocks in Division 4T (Tallman 1990, Halliday et al. 1989, Powles 1965, 1969). Therefore, we divided the Division into two regions composed of the above strata and the rest of the area. The percent of each sex was applied to the length frequencies caught for each geographical unit.

The fleet does not fish with uniform intensity in all areas. For each NAFO unit area, the mean number per tow of each stratum in the unit area was multiplied by the proportion of the unit area that the stratum occupied. A total for each unit area was calculated by summing numbers within each. The theoretical population distribution in each unit area was weighted by the percentage of commercial fishery landings.

To summarize mathematically:

for "i" strata and "j" unit areas

Theoretical length

$$\text{frequency distribution} = \sum_{j=1}^J N_i P_{ji} Q_j$$

where:

$N_i$  = mean number per tow in stratum "i"

$P_{ji}$  = proportion of unit area "j" that is made  
up of stratum "i"

$Q_j$  = proportion of catch that is from unit  
area "j"

We will use the terms "theoretical catch" to describe the catch calculated from RV data that is unscaled to landings and "catch" to describe the catch derived from the addition of the discards calculated from the RV data to the commercial landings calculated using AGELEN (Wright 1990).

A theoretical distribution of catch at length for a given mesh size was calculated by applying a selectivity ogive (Table 2) to the sexed length frequency distribution. Ogives varied according to the year to correspond to the mesh size regulation at the time. The standard mesh size limit for mobile gear was 110mm in 1976, 120mm from 1977 to 1980 and 130mm from 1981 to the present (Clay et al. 1984). The ogives used were those calculated by Clay et al. (1984).

The resulting theoretical catch at length distribution was scaled to the landings by the ratio of the area under the curve of landings to that of theoretical catch. The domain of the scaling factor was chosen to reflect lengths above which the research vessel catch and the commercial catch would be unbiased by differential availability of American plaice to the net and the discarding practices. Chouinard and Metuzals (1985) found that less than 5% of the numbers caught were discarded in the 40 cm length group. Halliday et al. (1989) suggested that the majority of fish 35cm and below were discarded. To be as conservative as possible a lower bound of 40 cm was chosen. An upper bound of length was chosen (60 cm) beyond which it was thought that sampling would be sporadic. This figure was used to

scale the length frequency of the theoretical catch to the landings.

The following calculations were made on the lengths below 40 cm of the scaled estimated catch. The landings at length were assumed to be the minimum appropriate estimate of catch. To estimate discards, the landings at length were subtracted from the catch at length. Age-length keys for the new length frequency of the catch (<40 cm) were made for each sex using a program written in the SAS language. The length frequency of the discards of each sex was used with the appropriate age-length key calculated from the RV data to obtain the discards at age by sex. The estimated discarded catch and the landings were summed to give an estimated catch at age.

The discards at age for 1976 to 1989 are shown in Table 16. As one would expect the range of lengths is less than the landings at age but the number of ages where discarding occurs is broad (on average ages 4 to 15).

The catch at age including discards is shown in Table 17. While some of the increases appear rather large the discarding rate of roughly 83.5 per cent in numbers in 1976 corresponds well with the value of 76 per cent given by Halliday et al. (1989) for that year. The estimate of 66 % discarded catch by numbers is close to the 61.8 % recorded by Chouinard and Metuzals (1985) for 1984. The calculated value for 1980 of 59 % may be compared to 45.8 % recorded by Cliche (1981). When I limited the discard estimates to the unit areas surveyed by Cliche (areas 4Tf, 4Tk, 4Tl, 4Tn) the overall rate was 46 %.

The inclusion of discards improves the consistency in the matrix compared to the landings at age. The ages of full recruitment appears to be between ages 7 to 9 compared to 12 or 13 for the landings at age matrix.

#### Commercial Catch Rates

Tallman and Sinclair (1988) used catch rates to judge relative changes in stock size of the American plaice stock in NAFO Division 4T. However, we deem the catch rate series to be unreliable as an indicator of stock size because the fleets participating in both the American plaice directed and cod directed fisheries are thought to change as a function of stock size. Catch rates are calculated here for illustrative purposes. Separate catch rates were calculated for the American plaice directed (1977-1989) and cod directed (1966-1989) fisheries as well as the two groups combined (1966-1989). Gears used were restricted to otter trawls and Danish seiners. The two gears account for over 84% of the reported catch in the fishery and well over 95% of the available catch rate data. The 1984-85 data were revised according to 1984 NAFO statistics and 1985 regional

data respectively. Observations with less than 10 units of effort were removed. Months with less than 10 observations through the series were deleted in the combined run. A multiplicative model was used to calculate a standardized catch rate index for each gear (Gavaris 1980).

Observations were allocated to categories of gear/tonnage class/NAFO country code, month and year in the American plaice directed and cod directed runs. Observations in the combined run were allocated to categories of gear/tonnage class/NAFO country code, American plaice or cod directed fishery, month, and year. In all runs country codes 27 and 28 (Maritimes and Quebec, respectively) were combined into code 2 (the former Maritimes-Quebec code).

The analysis of variance tables and regression coefficient from the three runs are shown in the appendix 2 (Tables A, C, E). For the American plaice directed fishery, the model accounted for 40% of the variation and each category was significant. The model accounted for 63% and 47% of the variation in the cod directed and combined runs and in each case all categories were significant. Plots of the residuals of each run are shown in the appendix 2, Figures A, B and C. In each case the residuals appear to be randomly distributed. The residual distribution did not indicate heteroscedasticity, consequently weighting was not used.

Catch rate in all models declined from 1987 to 1988 and are well below historical catch rates of the late 1970s and 1960s (Appendix 2, Tables B, D, F and Figures D,E and F).

The cod by-catch and combined indices were rejected as useful indices of abundance on the grounds that sampling for American plaice would not cover the same time periods or locations from year to year due to closures in the cod fishery in recent years. Also, these indices might involve different components of the fleet in different years. Similarly, the American plaice directed index was not used in assessment because the vessels participating change depending on the cod fishery and the relative success rate in the American plaice fishery. However, it is interesting that the trend in catch rates is downward and follows the results of the RV survey analysis.

#### Research Survey Data

In 1986, the research vessel E.E. Prince was replaced by the Lady Hammond to conduct the fall groundfish survey in the southern Gulf of St. Lawrence. A comparative fishing experiment between the two vessels had been conducted in the 1985 survey to determine conversion factors. The CAFSAC Statistics, Sampling

and Surveys Sub-committee recommended that the catch per tow of American plaice from the E.E. Prince be multiplied by a factor of 1.8 to be made comparable to the new survey estimates from the Lady Hammond. The numbers at age for 1971 through to 1985 were adjusted by the conversion factor.

In addition to the change of survey vessels, a change was made to the survey design. In 1984 the random Stratified Station design was replaced by a fixed survey with random initial allocation of stations. From this point onward the index was calculated from a consistent set of 61 fixed stations. A constant trawlable unit size was used for both vessels.

From 1984 to 1986 length frequency sampling was conducted on sexes combined. Sexed length frequencies were resumed in 1987.

The sum of the mean numbers per tow at age from 1971-1989 are shown in Figure 3. Mean numbers per tow at age are presented in Table 18. The pattern of the mean numbers per tow reflects the high abundance at the end of the 1970s. The numbers per tow for 1986, 1987, 1988 and 1989 are the lowest in the series.

The mean numbers per tow by strata showed that American plaice occur in abundance in particular strata. The most notable are strata 19, 22, 23, 29, 33, 34. The pattern of distribution is relatively constant.

#### ESTIMATION OF PARAMETERS

##### A) Mortality from the Survey

Total mortality, Z, at age was calculated for the period using catch curve analysis (Ricker 1975) with consecutive ages of a cohort (Table 19). While these were variable from year to year there were generally higher total mortalities in the 1980s than in the 1970s as indicated by averages in Table 20. Also the total mortalities at age increased to about age 8 but were relatively constant to age 18. Estimates of older age abundance were not available at this time because sampling was limited in those age groups. The average age 8-18 values of Z were 0.36 for 1971-79 and 0.56 for 1980-88.  $F_{0,1}$  for this stock is estimated to be 0.2 with M assumed to be 0.2. Thus, fishing mortalities have been above the target in recent years.

The standard errors for the RV survey from 1971 to 1989 are shown Table 21. The coefficients of variation are shown in Table 22.

RV mean number per tow for plus groups are shown in Table 23. Total mortalities using plus groups were calculated to smooth the total mortalities (Table 24).

### B) Fishable Biomass

Total biomass was estimated from the RV survey from 1984 to 1989 by combining the biomass of the males, females, and juvenile American plaice. This period was chosen because there was relative stability in the mean number per tow. Biomass for each sex was estimated by multiplying the weighted average weight at age times the numbers at age.

The biomass of age 10 plus fish for the years 1988 to 1989 was estimated by combining the age 10+ biomass estimates of the males, females and juveniles (Table 25).

### C) Yield per Recruit

Yield per recruit was calculated using the mean weight at age from the RV survey (ages 4 to 20) for 1983 to 1989 and a preliminary estimate of partial recruitment (calculated using the MULTPR function (S. Gavaris, Dept. of Fisheries and Oceans, St. Andrews Biological Station, St. Andrews, N.B. pers comm.) on preliminary estimates of fishing mortality from 1983 to 1987. The 1983 to 1987 time period was chosen because there was a change in mesh size regulations in 1982. The  $F_{0.1}$  level was 0.32 and the  $F_{max}$  was 1.50 (Table 26).

$$F_{0.1} = 0.3183 \quad F_{0.1} \text{ Yield} = 0.075 \text{ kg Ave Wt.} = 0.276 \text{ kg}$$

$$F_{max} = 1.5000 \quad F_{max} \text{ Yield} = 0.105 \text{ kg Ave Wt.} = 0.231 \text{ kg}$$

### D) SPA Calibration Adaptive Framework

SPA was calibrated using the adaptive framework (Gavaris 1988). The parameters estimated were 1) the size of the age classes 4 to 14 in 1989, 2) the slopes of the lines relating RV mean numbers per tow at age 4 to 14 and , 3) the catchability coefficient. Constraints on the parameters were placed on the initial analysis but were removed for the final run. The parameter estimates and their standard errors and the weighted residuals are presented in Table 27. Examination of the correlation matrix of the parameters showed that most correlations were between minus or plus 0.05 to 0.15 (Table 28). However, there were some correlations as high as 0.38. Age by age plots are shown in appendix 2. The residuals are highest in the late 1970s when population numbers were high. In recent years the residuals are close to the line.

#### E) Estimation of Total Allowable Catch

The RV survey has relatively low coefficients of variation (Table 22). Mortality estimates from the survey could be used to calculate biomass and thence a TAC.

The approach using age dis-aggregated total mortality estimates was as follows: The estimated average fishing mortality from age 8 to 18 is approximately 0.33. The abundance indices from both the RV survey and the commercial catch rates indicate relative stability in the population in the 1980s. The average catch over the same period has been 7,454 t. using the catch equations the biomass (B) may be estimated as:

$$B = \frac{C Z}{F (1 - e^{-Z})}$$

$$= 28,503 \text{ t}$$

where,

C = average catch (7,454 t)

Z = current total mortality (0.53)

assuming M = 0.2 then

F = current fishing mortality (0.33)

Therefore one could estimate the  $F_{0.1}$  catch as

$$C = \frac{F_{0.1} B (1 - e^{-Z_{0.1}})}{Z_{0.1}}$$
$$= 4,699 \text{ t}$$

With  $F_{0.1} = 0.2$

$Z_{0.1} = 0.4$

This estimate is made with the assumption that biomass has been relatively stable in the recent past, the age structure is stable, recruitment has been stable and there is no changes in the partial recruitment.

Another estimate using the same method but with age aggregated plus groups gave a yield of 7,454 t ( average total Z from ages

12 and 13 = 0.40, average total F = 0.20 ).

An alternative method which approximates fishing at  $F_{0.1}$  is to multiply the fishable biomass by 0.15 (D. Rivard, DFO, Ottawa, pers. comm.). Using this method with the age 10+ biomass from 1987 and 1988 the projected yield is 3,649 t.

### PROGNOSIS

Catch rates are lower in recent years than during the late 1970s and the survey mean number per tow in 1989 is the lowest recorded. Estimates of F indicate levels in excess of F0.1. The status quo projection suggests that fishing at  $F_{0.1}$  would require a reduction in the TAC to between 5,000 and 7,500 t. Fifteen per cent of the fishable biomass suggests an even lower TAC of approximately 3,650 t. Given the concordance of all the indices a more appropriate TAC for this stock at this time is between 3,000 and 8,000 t. However, discarding continues to be a serious problem with this stock. A TAC that is restrictive to the fishery, such as 4,000 t, may result in more fish being discarded and no conservation gains from the reduction in landings.

### ACKNOWLEDGEMENTS

The authors wish to thank G. Chouinard, D. Clay, S. Courtenay, G. Neilson and D. Swain of the Department of Fisheries and Oceans, Moncton and W. Brodie, Department of Fisheries and Oceans, St. John's for their helpful advice and criticism of the manuscript.

NATURAL MORTALITY RATE : 0.2

F0.1 COMPUTED AS .3183 AT Y/R OF .0750

FMAX COMPUTED AS 1.5000 AT Y/R OF .1054

WARNING: CONVERGENCE CRITERION NOT SATISFIED FOR FMAX.  
 FMAX IS THE VALUE OF F GIVING THE HIGHEST YIELD,  
 FOR ALL F COMPUTED IN THE GIVEN INTERVAL!

### MOBILE GEAR

### FIXED GEAR

### TOTAL CATCH

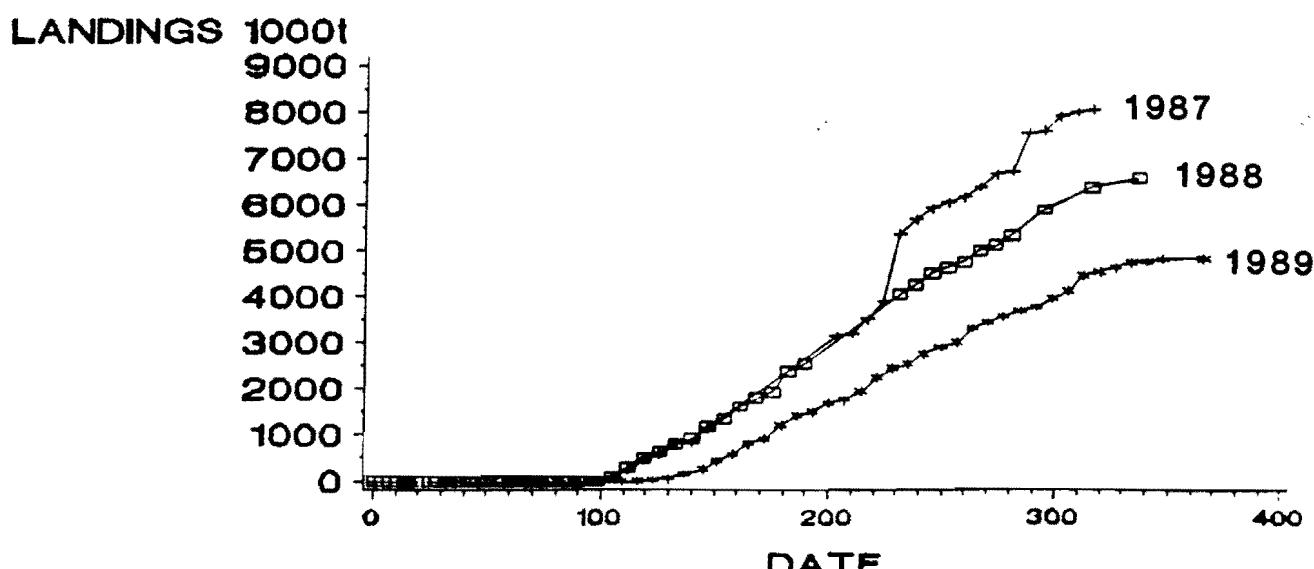

Figure 1 Weekly catches of American plaice

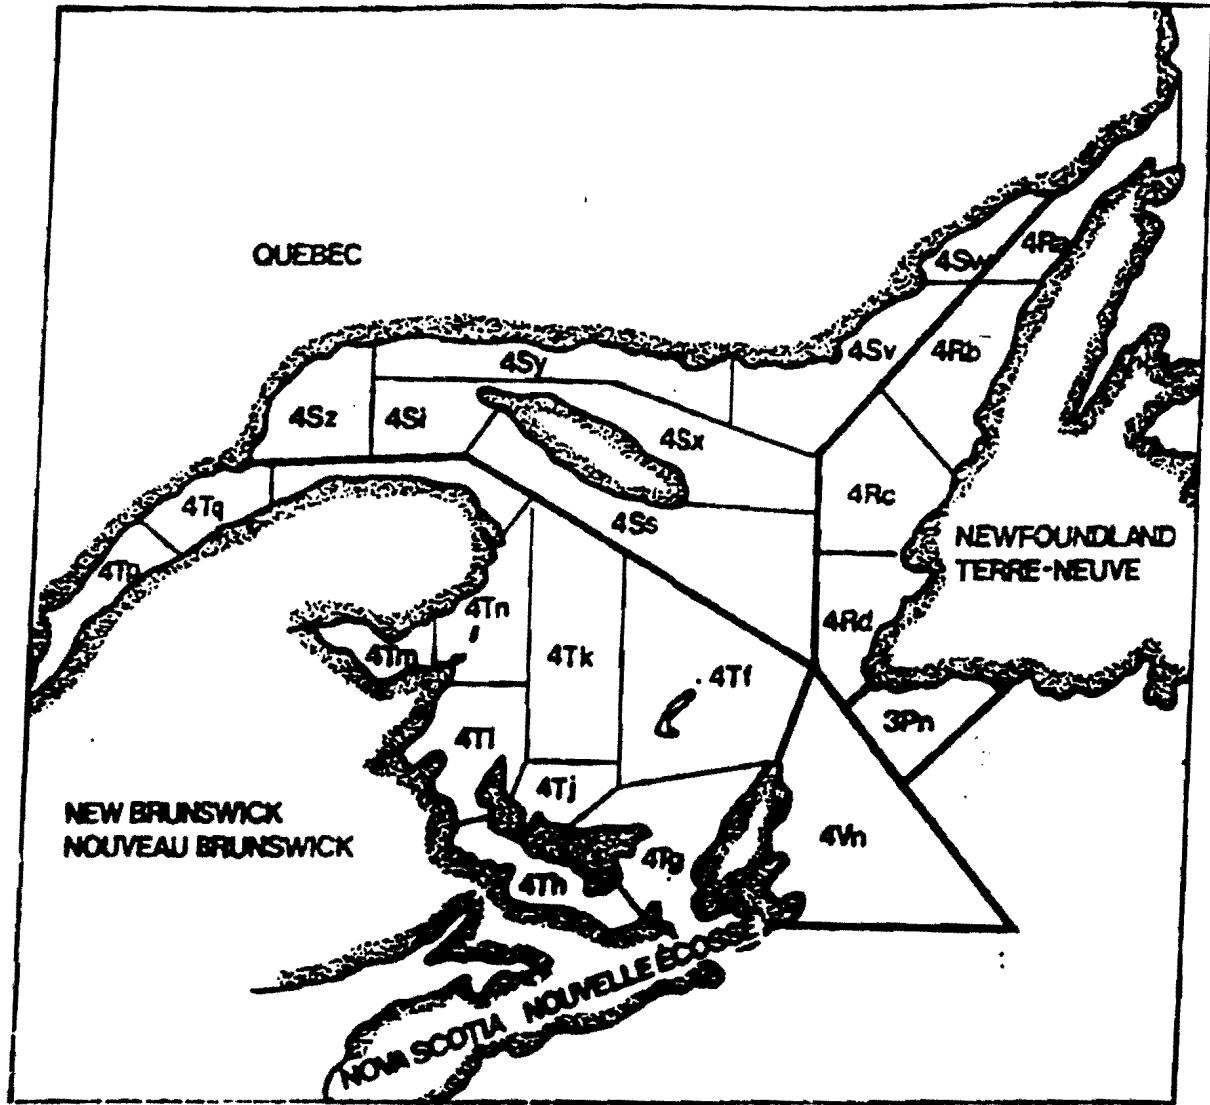

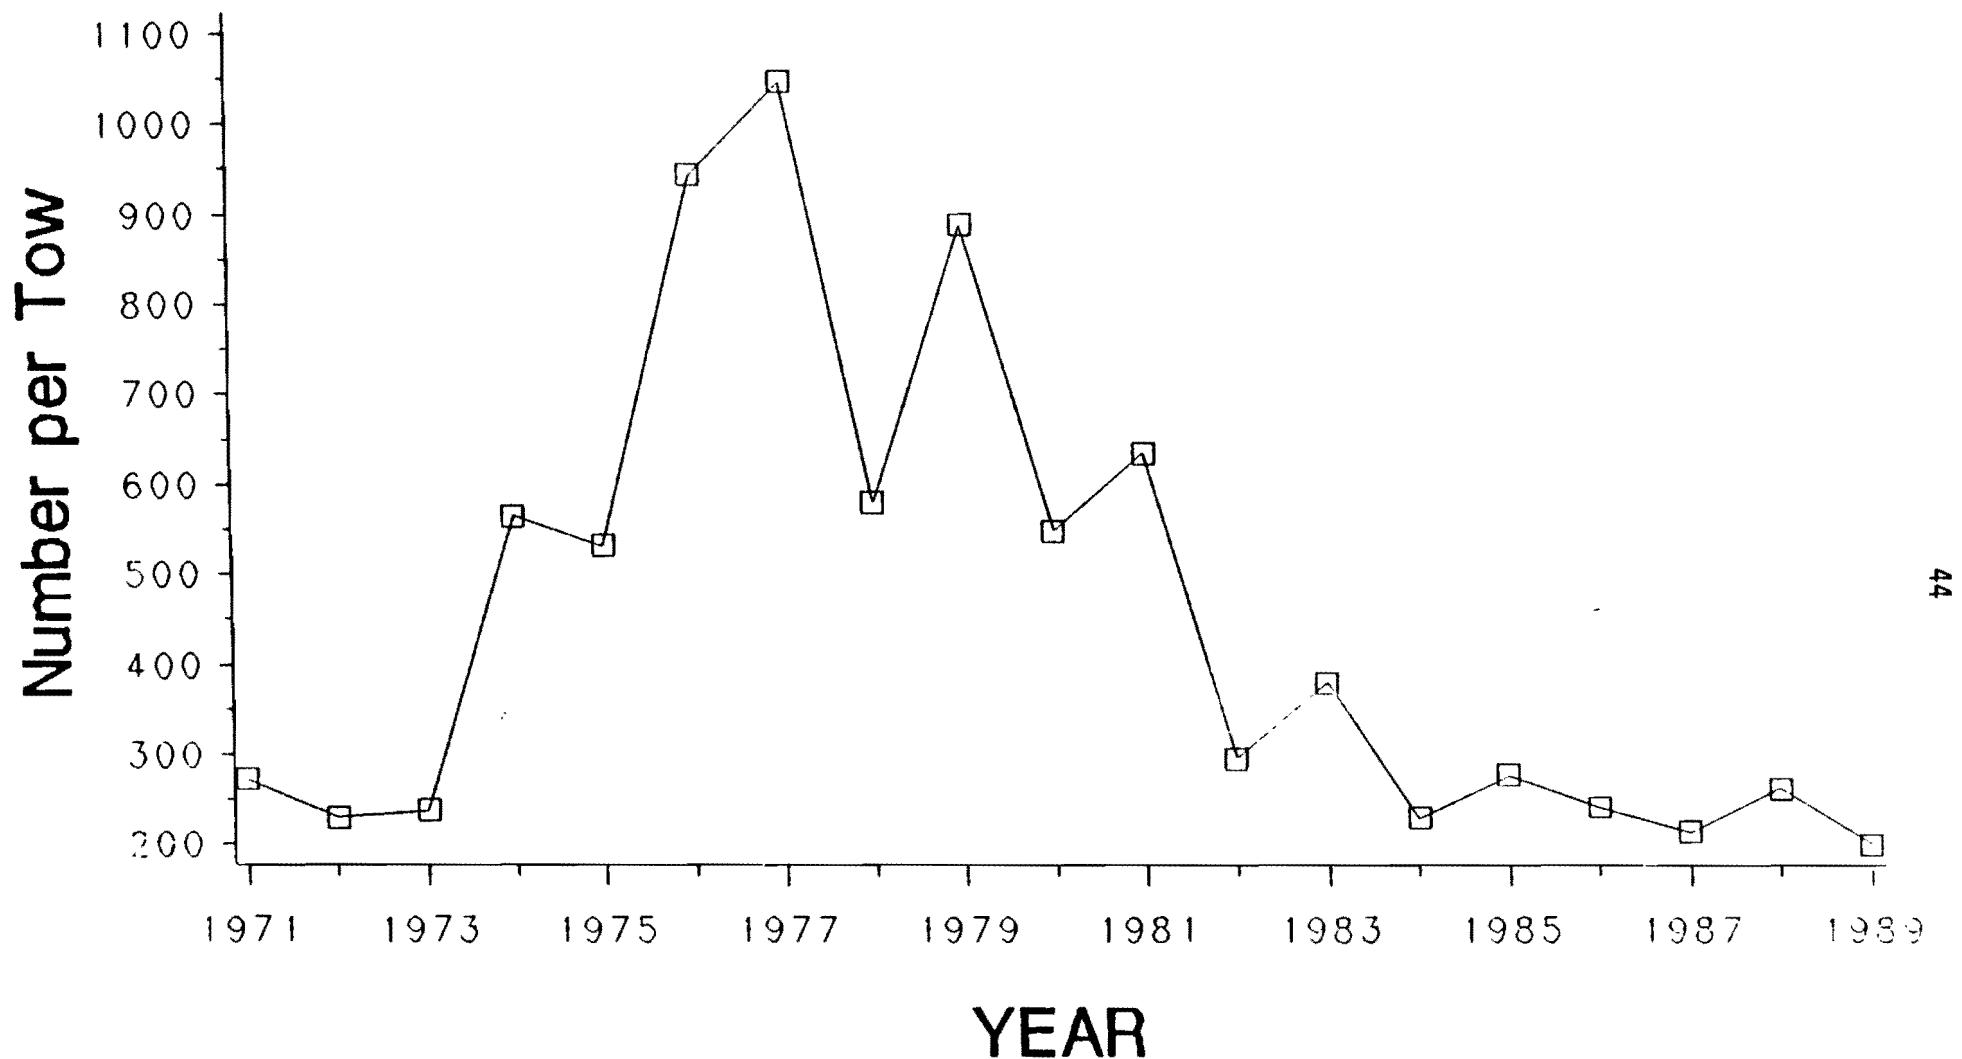

Figure 2 Gulf of St. Lawrence.

**Figure 3. Mean number per tow from research vessel survey.**

## Appendix 1

The formulation used for ADAPT with RV data is as follows:

Parameters:

-Population estimate

$N_{13,1989}$

-Calibration coefficients

$K_2$  for RV survey data, ages 4-15 disaggregated

Structure:

- Error in catch at age assumed to be negligible
- Natural mortality assumed to be 0.2
- F oldest age group set equal to F for ages 15-19
- no PR was assumed for 1989
- Intercepts fitted

Input:

- $C_{i,t}$  i = 4-20 t = 1976-1988
- $RV_{i,t}$  i = 4-14 t = 1976-1989

Objective Function:

- Minimize

$$\sum_t (obs(RV_t) - pred(RV_t))^2$$

An alternative formulation (log model) used for ADAPT with RV data is as follows:

Parameters:

-Population estimate

$N_{13,1989}$

-Calibration coefficients

$K_2$  for RV survey data, ages 4-15 disaggregated

Structure:

- Error in catch at age assumed to be negligible
- Natural mortality assumed to be 0.2
- F oldest age group set equal to F for ages 15-19
- no PR was assumed for 1989
- Intercepts fitted

Input:

- $C_{i,t}$   $i = 4-20$   $t = 1976-1988$
- $RV_{i,t}$   $i = 4-14$   $t = 1976-1989$

Objective Function:

- Minimize

$$\sum_t \ln(\text{obs}(RV_t) - \text{pred}(RV_t))^2$$
