${ }^{1}$ This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the secretariat by the author.
${ }^{1}$ Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat.

#### Abstract

Since 1970, nominal landings have varied from a minimum of $3,616 \mathrm{t}$ in 1974 to a maximum of $14,039 \mathrm{t}$ in 1981. The provisional nominal landings for 1990 and 1991 ( $4,919 \mathrm{t}$ and $4,106 \mathrm{t}$ respectively) were below the average ( $6,380 \mathrm{t}$ ) for the period 1970-91. The proportion of the landings taken by gillnetters continued to be greatest in 1990 and 1991 but landings by this gear type have been below average since 1985. Eighty to $90 \%$ of the total landings since 1986 have come from unit areas $4 \mathrm{Tg}, 4 \mathrm{Tj}$ and 4 Tl (depths $<200 \mathrm{~m}$ ). As in previous years, the majority of the landings in 1990 and 1991 were taken in July and August. The TAC has been $5,500 t$, since 1988.

The modal age has shifted from age 6 in 1988 and 1989 to age 5 in 1990 and 1991. Since 1986, fewer older fish (age 8-10) have been caught. The fishery is dependent on only 4 year classes and as a result it will be sensitive to annual fluctuations in recruitment.

The research vessel mean catch per tow decreased in 1990 and 1991 and there were fewer 1, 3 and 4 year old's caught than in 1989. The indication is that recruitment is not above average. The mean length and weight of white hake caught during the surveys in 1990 and 1991 were lower than those seen from 1986-88. The estimates of population abundance and biomass for 1990 and 1991 are below average for the series of Lady Hammond surveys of the southern Gulf (1986-91).

An SPA based assessment of this resource has not been conducted since 1989 due to the lack of a reliable index of abundance and because of concerns about stock definition. Instantaneous mortality rates (Paloheimo Z's), calculated from research surveys indicate that the fishing mortality appears to have been high (approximately 1.0) for the past several years.

Anecdotal reports from the Index Fishermen Program suggest that hake tended to be "smaller and scarcer" in 1990 and 1991.

## RÉSUMÉ

Depuis 1970, les prises nominales ont varié, passant de 3616 t en 1974 à 14039 t en 1981. D'après les chiffres provisoires obtenus, les prises nominales de 1990 et de 1991 (4919 t et 4106 t respectivement) étaient inférieures à la moyenne ( 6380 t) de la période allant de 1970 à 1991. Une grande partie de ce manque peut être imputée à la baisse des prises par le secteur de la peche aux filets maillants. De quatre-vingt à quatre-vingt-dix pour cent des prises totales réalisées depuis 1986 provenaient des sous-divisions $4 \mathrm{Tg}, 4 \mathrm{Tj}$ et 4 Tl (à des profondeurs inférieures à 200 m ). Comme par le passé, la majorité des débarquements ont eu lieu en juillet et aoâ. Le TPA est fixé à 5500 t depuis 1988.

En 1988 et 1989, le groupe d'âge modal était celui de 6 ans; il est passé à 5 ans en 1990 et 1991. La pêche est devenue de plus en plus axée sur 3 ou 4 classes uniquement ( 5 à 7 ans).

La moyenne des prises par trait de chalut réalisés par le navire de recherche a baissé en 1990 et 1991, et on a capturé moins de poissons de 1 an, 3 ans et 4 ans qu'en 1989. Cette situation indique que le recrutement n'est pas supérieur à la moyenne. La longueur et le poids moyens des merluches blanches capturées pendant les relevés de 1990 et 1991 étaient inférieurs aux moyennes obtenues au cours des relevés de 1986 à 1988. Les estimations de la biomasse et de l'effectif de la population pour 1990 et 1991 sont également inférieures à la moyenne pour la série de relevés effectués par le navire Lady Hammond dans le sud du golfe (de 1986 à 1991).

Il n'y a eu aucune analyse séquentielle de la population (ASP) de cette ressource depuis 1989, à cause de l'absence d'un indice d'abondance fiable et à cause aussi des inquiétudes à l'égard de la définition du stock. Les taux de mortalité instantanée (Paloheimo Z), calculés à partir des relevés de recherche, indiquent que la mortalité due à la pêche semble avoir été élevée (environ 1,0) depuis quelques années.

D'après les déclarations obtenues des pêcheurs repères au poisson de fond, on suppose que le merlu a tendance à être plus petit et plus rare en 1990 et 1991.

## INTRODUCTION

The fishery for white hake (Urophycis tenuis, Mitchill) in the southern Gulf of St. Lawrence usually does not commence until May when the last of the sea ice has dispersed. Landings peak between July and September and decline through October and November (Table la and b). Since 1970, nominal landings have ranged from a low of 3,616 tonnes in 1974 to a high of 14,039 tonnes in 1981 (Table 2 and Figure 1). This resource was not managed by a TAC (Total Allowable Catch) until the precautionary quota of 12,000 tonnes was placed upon this stock in 1981 for the 1982 season. Recent assessments (Clay et al., 1986; Clay, 1987; Clay and Hurlbut, 1988) suggested long term yields in the range of 5,000 to 6,000 tonnes. The TAC for 1987 was reduced to 9,400 tonnes and for 1988 to 5,500 tonnes. It has remained at 5,500 tonnes since then.

This fishery is carried out mainly by small inshore vessels, and is strongly affected by weather and local market conditions. Winter ice conditions preclude inshore fishing from December through April of most years. Two gear types are used in this fishery: fixed gear (gillnets and longlines); and mobile gear (small otter trawlers (< 20 m ) and larger seiners). The majority of the fishery is conducted in Northumberland Strait, on the western end of P.E.I., and between P.E.I. and Cape Breton Island.

Previously the hake fishery in the Gulf was considered to be a by-catch fishery, however a recent analysis (Clay and Hurlbut, 1990) indicated that it tends to be a directed fishery, traditionally pursued during periods between other, more economically lucrative fisheries (ie. lobster, scallop, etc.). From 1986 to 1989 the directed portion of the Gulf hake fishery was 69 to $75 \%$ of the total landings and 44 to $48 \%$ of the total effort (trips with some hake landed) (Clay and Hurlbut, 1990). The directed fishery is most intense from June to October with gillnets having the highest percentage of directed trips in all months except September.

The combined evidence from a discriminant function analysis of morphometric and meristic characters (Hurlbut and Clay, 1990), seasonal and annual distributional studies (Clay, 1991; Clay and Hurlbut, 1989) and a tagging study (Kohler, 1971) indicate that white hake from NAFO Division $4 T$ may be characterized by two distinct components:
(1) fish from the shallow inshore southern Gulf (depths $<=200 \mathrm{~m}$ ), principally the Northumberland Strait area (the "Strait" component - Figure 2) and
(2) fish from along the Laurentian Channel in depths in excess of 200 m (the "Channel" component - Figure 2).

In terms of the assessment of this resource, several problems need to be addressed, including:
a) the management unit for white hake in NAFO Division 4 T is composed of at least two different stock components with minor biological differences,
b) the research vessel data for these two components are limited and highly variable, and thus of little use in assessment calibration,
c) there are difficulties with the interpretation of trends in commercial catch rate series derived from purchase slips (trip effort) and
d) the white hake fishery often comprises an 'alternate fishery' rather than a 'by-catch fishery'.

Because of these problems, a formal analytical assessment of this resource is difficult. The present document reviews the status of the fishery as well as other information.

## LANDINGS

## Total Landings in NAFO Division $4 T$

The provisional landings in 1990 (Table 1a - Figure 1) were 4,919 tonnes, a decrease of $4 \%$ from the 5,128 tonnes caught in 1989, and a difference of $-21 \%$ from the average landings for the period: 1970-91 (Table 2). In 1991, the provisional landings were 4,106 tonnes (Table 1b - Figure 1), a decrease of 20\% from 1989 and a difference of $-34 \%$ from the average landings for the period: 1970-91 (Table 2).

## Landings by Canadian Statistical Unit Area

In the Gulf of St. Lawrence, white hake are caught mainly by small inshore vessels that are not required to complete log books. Therefore, no estimate of fishing effort by individual vessels is available. Trip landings are, however, recorded on purchase slips for the inshore as well as other components of the fishing fleet. These generally only include $75 \%$ to $95 \%$ of the official landings. The rest of the landings are reported on Supplemental 'A' and 'B' slips.

Eighty to $90 \%$ of the total white hake landings in the past six years have come from that part of the 'Strait' component of the NAFO Division 4 T management unit comprising Unit areas 4 Tg ,

4Tj, and 4Tl (Figures 3 and 4). Over the same period (1986-91), annual landings from the unit areas that encompass the 'Channel' component (ie. $>200 \mathrm{~m}$ depth) (Unit areas $4 \mathrm{Tf}, 4 \mathrm{Tk}$, and 4 To ) have not exceeded 10\% of the total landings, however, these unit areas also include some inshore shallow zones that probably produced the majority of the reported landings in these areas. Landings from unit areas 4 Th and 4 Tm have been minor and constant, while landings from unit area 4Tn have increased since 1988 (Table 3 Figure 5). Thus, since 1986, the majority (approximately 90\%) of the hake landings in the Gulf of St. Lawrence have been from the 'Strait' component of the stock.

## Landings by Gear Type

The gillnetter portion of the landings was still the largest in 1990 and 1991, however, the proportion of the landings attributable to this component has decreased (from 36\% in 1989 to $28 \%$ in 1991) and was only marginally greater than the otter trawl portion (27\%) in 1991 (Tables 1 a and b-Figure 6). Landings by longliners and seiners were not substantially different than in 1989.

## Commercial catch rates

A commercial catch rate series has been used in past assessments of this resource, when it was assumed that each purchase slip represented one unit of fishing effort (day). This approach was not employed this year because the model explained only a small percentage (< 25\%) of the variation in previous years and because of errors encountered in the coding of inshore otter trawlers (Prior to 1984 a certain percentage of the stern trawlers were coded as side trawlers and vice versa).

As a long term solution to this problem, an Index Fishermen Program has been started in the southern Gulf of St. Lawrence. It is directed at cod in particular but is designed to collect data for other species as well. Of the 50 participants in this program, about one quarter are considered to fish at least parttime for white hake.

## AGE DETERMINATION AND COMMERCIAL SAMPLING

In 1990 and 1991, all of the commercial white hake samples from NAFO Division $4 T$ came from fish caught in less than 200 m depth ('Strait' component of the stock). No samples came from Unit Areas 4Tf, 4 Tk , or 4 To (areas incorporating the 200 m contour) (Figure 3).

Commercial port samples of white hake were obtained according to previously established protocols (Clay et al., 1985; Clay and Hurlbut, 1989; Clay and Clay, 1991). Samples were obtained from 2 sources:

1) the P.E.I. Department of Fisheries and Labour provided 9 length frequency samples (1,523 fish measured) in 1991
2) In 1990, the Department of Fisheries and Oceans (DFO) port samplers collected 40 length frequency samples (6,697 fish measured) and 799 otoliths, of which 738 provided acceptable age estimates. In 1991, DFO port samplers collected 34 length frequency samples (6,458 fish measured) and 569 otoliths, of which 541 provided acceptable age estimates.

The commercial port samples and research vessel surveys (741 otolith ages in 1990 and 821 otolith ages in 1991) provided the material for estimates of growth.

After the age of about 3, white hake are sexually dimorphic; females grow faster, to a larger size, and to an older age than males (Clay and Clay, 1991). The protocol on research surveys was changed to permit sexed sampling (length frequencies and otoliths) but low commercial sampling intensity and the tendency for white hake to be landed gutted/head-off have precluded the construction of separate commercial age-length keys for each sex.

The age composition for the research surveys (1990 and 1991), were calculated from sexes combined and sexes separated keys to investigate the impact of not obtaining sexed commercial samples. This analysis indicates that the impact appears to be minimal for both years (1990 and 1991 - Figure 7).

Quality control tests were conducted during the entire period of age determination, after every 200 to 250 otoliths. In 1990, intra-reader agreement ranged from 80 to $91 \%$ with a mean of 84\% when repeat samples were re-aged. In 1991, intra-reader agreement ranged from 78 to $91 \%$ with a mean of $85 \%$. Agreement with the past control (contract) reader in 1990, ranged from 75 to $84 \%$ with a mean of $80 \%$ when reference trays ( 50 previously aged otoliths) were re-aged. In 1991, agreement with the past control reader ranged from 67 to $83 \%$ with a mean of $77 \%$.

Low sampling intensity in 1990 and 1991 allowed for separation of aged samples into only two gear groupings for both years (Table 4 a and b). As with previous assessments of this resource, otter trawls and seines were combined because they were considered comparable as were gillnets and longlines.

Seven combinations of time and gear were chosen for the length frequency data from the available samples for 1990 and 1991 (Tables 4 a and b). The appropriate age-at-length keys were
used to determine the age composition of the length frequencies from the landings.

The catch-at-age, weight-at-age and length-at-age were calculated for each key for 1990 and 1991 (Tables 5, 6 and 7 a and $b$ respectively) using the AGELEN program (ver 3.21) for sexes combined. These data were added together for the final catch numbers at age and a weighted average (by numbers in each age group) was calculated for the weights- and lengths-at-age.

The mean length-at-age in 1990 and 1991 (Table 7 a and b) was compared with the mean length-at-age for 1988 and 1989 (Table 7 c and d). As in the past, larger fish were predominant in the gillnet landings, however the mean length- and weight-at-age of fish caught by longline was considerably smaller, and more similar to the mean length-/weight-at-age for the two mobile gears. This apparent similarity in length- and weight-at-age must be due, in part, to the limited number of samples from this gear component.

When the catch-at-age for 1990 and 1991 is compared with that for 1988 and 1989 (Table 8 and Figure 8), it is evident that fewer older fish (ie, age 8-10) have been caught since 1986. The modal age has shifted from age 6 in 1988 and 1989 to age 5 in 1990 and 1991. One- and two-year-olds, which occurred for the first time in the commercial samples in 1989, were absent in 1990 and 1991. This fishery is dependent on only 4 year-classes (ages 4-7) and, as a result, it will be sensitive to annual fluctuations in recruitment.

## RESOURCE SURVEY DATA

The annual September resource survey in the southern Gulf of St. Lawrence in 1990 and 1991 was a random stratified, 24 hour survey (147 and 192 sets completed).

In previous analyses, the RV abundance has not been successfully used in the calibration of the assessment for this resource.

For this update, the research vessel mean catch per tow, C.V.'s of the mean catch per tow, and weights-at-age (Tables 9 $a, b$ and $c$ ) were estimated using the RVAN analysis programs. From 1971-83, the survey of the southern Gulf was a stratified random survey (E.E. Prince), but approximately twelve fixed stations were surveyed each year. These fixed stations were included in this analysis, as they were in previous assessments (Clay and Hurlbut, 1989, 1990). For the years 1984 - 1987, when the survey of the southern Gulf was a fixed station design (Lady Hammond), the dataset for this analysis was limited to only 61 fixed
stations that were fished each of the four years as was done for the assessment of 4 TVn (Jan.- April) cod (Chouinard and Sinclair, 1988). Since 1988 the survey has been a stratified random survey.

The research vessel mean catch per tow decreased in 1990 and 1991 (Figure 9 - Note: the catch rate for the E.E. Prince was adjusted with the conversion factor (1.2) derived from a comparative fishing experiment conducted in 1985 (Nielsen, 1987)) and there were fewer 1, 3 and 4 year olds caught than in 1989 (Table 9a). The indication is that recruitment is not above average. The mean length and weight of white hake caught during the surveys in 1990 and 1991 was lower than seen from 1986-88 (Figure 10). The estimates of population abundance and biomass for 1990 and 1991 are below average for the series of Lady Hammond surveys of the southern Gulf (1986-91)(Table 10).

An SPA based assessment of this resource has not been conducted since 1989 due to the lack of a reliable index of abundance and because of concerns about stock definition within the 4 T management unit.

Instantaneous mortality rates were calculated for white hake caught on research vessel surveys (1971-91) using Paloheimo's (1961) method (Table 11):

$$
\begin{gathered}
\mathrm{Z}=-\ln \left[(\mathrm{C} / \mathrm{f})_{2} /(\mathrm{C} / \mathrm{f})_{1}\right] \\
\left(\text { where }(\mathrm{C} / \mathrm{f})_{\mathrm{n}}=\right.\text { mean catch per tow at age) }
\end{gathered}
$$

This analysis indicates that the fishing mortality appears to have been high (approx. 1.0) for the past several years.

## ANCILLARY INFORMATION

At industry meetings, in 1988 and 1989, fishermen in Northumberland Strait (eastern PEI - St. Georges Bay) reported catching more small hake than in recent years. In 1990 and 1991, many of the participants in the Index Fishermen Program, that directed for white hake (predominately those fishing fixed gear), reported that hake tended to be "smaller and scarcer".

## SUMMARY

Landings were below average in 1990 and 1991 (21\% and 34\% below those for the period 1970-91). Fewer old white hake were caught and the fishery is dependent on only four age classes. As a result, this fishery will be sensitive to annual fluctuations in recruitment.

The research vessel surveys indicate that recruitment has not been above average and that fishing mortality appears to be high.

The precautionary TAC of $5,500 \mathrm{t}$ appears to represent a high rate of exploitation. However, given the uncertainties about stock definition, there is no firm basis to suggest a modification of the $5,500 \mathrm{t}$ TAC.

## ACRNOWLEDGEMENTS

We would like to thank Ross Claytor, Mark Hanson and Gloria Nielsen for many constructive comments on an earlier draft of this manuscript.
