#### Abstract

${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte atlantique du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

## Abstract

Results obtained from a fish counting fence provided the basis for the assessment of the Conne River Atlantic salmon stock in 1993. Returns to home waters (river and estuary) were 2703 salmon $<63 \mathrm{~cm}$ in length and 100 salmon $\geq 63 \mathrm{~cm}$ in size. This represented an increase of $7 \%$ for small salmon but a $37 \%$ decline for large salmon from 1992. Sea survival was estimated to be only 4.0\% (3.64.4\%), higher than in the previous year but still among the lower values recorded. Estimated egg deposition from small salmon was $4.428 \times 10^{6}$ eggs; $57 \%$ of the target requirement. The contribution from large salmon was $0.332 \times 10^{6}$ eggs and thus $61 \%$ of the required target egg deposition was achieved. Higher sea survival may be associated with years in which smolt condition values were greater. A mark-recapture study suggested a smolt run in 1993 of 55765 (51666-59864). Assuming a sea survival that approximates the average recorded during the past three years (4\%), then no more than 2400 fish would be expected to return in 1994. A sea survival of about $7 \%$ will be needed in order for total returns to homewaters to meet or exceed 4000 adult salmon. It is also cautioned that low spawning escapements from 1991-93 may result in lower smolt production in 1995-97. This, should it occur, could then result in low adult salmon returns, probably below target levels, in 1996-98.

## Resume

L'évaluation de la population de saumon de l'Atlantique dans la rivière Conne (T.-N.) en 1993 est fondée sur les résultats obtenus à un barrage de dénombrement du poisson. Quelque 2703 saumons $<63 \mathrm{~cm}$ et 100 saumons $\geq 63 \mathrm{~cm}$ sont revenus dans leurs eaux d'origine (rivière et estuaire), ce qui représentait un accroissement de $7 \%$ pour le petit saumon et un recul de $37 \%$ pour le grand saumon par rapport à 1992. Le taux estimé de survie en mer n'était que de $4 \%(3,6-4,4 \%)$, soit un taux supérieur à celui de l'année antérieure, mais néanmoins parmi les plus bas enregistrés jusqu'ici. La ponte des petits saumons était estimée a $4,428 \times 10^{6}$ oeufs, soit $57 \%$ de la cible. Celle des grands saumons s'établissait a $0,332 \times 10^{6}$ oeufs, soit 61 \% de la cible. Le taux plus élevé de survie en mer peut être associé aux années où les coefficients de condition des saumoneaux sont plus grands. D'après une expérience de marquage-recapture, 55765 saumoneaux (51 666-59 864) auraient remonté la rivière en 1993. En tablant sur un taux de survie correspondant approximativement à la moyenne des trois dernières années ( $4 \%$ ), les remontées devraient être de 2400 saumons au maximum en 1994. Il faudra parvenir à un taux de survie en mer d'environ 7 \% pour que les remontées totales de saumon adulte dans les eaux d'origine soient égales ou supérieures à 4000 . Il est également à craindre que les faibles échappées de reproducteurs connues de 1991 à 1993 ne se traduisent pas une baisse de la production de saumoneaux de 1995 à 1997, phenomene qui, s'il se confirme, pourrait aboutir à de faibles remontées de saumon adulte, probablement inférieures à la cible, en 1996-1998.

## Introduction

Conne River, SFA 11 (Fig. 1) flows into Bay D'Espoir on the south coast of insular Newfoundland. It is a sixth-order river with a drainage area of $602 \mathrm{~km}^{2}$ and a total length of 193 km . Since 1986, a fish counting fence has been operated to enumerate the upstream migrating population of Atlantic salmon. Markrecapture studies were initiated in 1987 to survey the number of migrating smolts. Both of these operations continued in 1993. Previous estimates of the total return of small salmon have ranged from a low of 2411 in 1991 to 10155 in 1987; lower returns have occurred in more recent years. Target spawning requirements were met or exceeded from 1986-90, but only $50 \%$ of the target was achieved in 1991 and 1992 (Dempson 1993). Smolt production has varied from about 57000 to 75000 fish but for the most part has been relatively stable (coefficient of variation 10.1\%).

This paper summarizes returns of adult salmon to Conne River in 1993 and provides a forecast of one-sea-winter (1SW) returns for 1994. Biological characteristic data are updated and summary information on rainbow trout occurring in Conne River are provided for the first time.

## Noteworthy events or changes in 1993

The following summarizes noteworthy changes to fishery regulations and other observations/events occurring in 1993:

- recreational fishery closed for the entire season;
- food fishery quota reduced from 1200 to 500 fish;
- river age $1+$ salmon sampled from food fishery catch; first indication suggestive of an escaped hatchery origin Atlantic salmon;
- evidence of rainbow trout feeding on salmon parr in Conne River;
- continued evidence for an association between smolt condition and subsequent sea survival;
- video camera system used for the first time at Conne River to enumerate upstream migrating salmon;
- estimated egg deposition increased by $20 \%$ from 1992 with 61\% of the current target spawning requirement met;
- three (3) dynamite blasting caps found along a short stretch of the Bernard Brook tributary; no legitimate reasons were identified to account for the presence of these caps.

## Background

A major change in the management of the Conne River Atlantic salmon stock for 1993 was the complete closure of the recreational fishery and an initial quota of only 500 fish for the Conne River Indian Band Council's food fishery. A forecast of low returns in 1993 prompted the closure of the sport fishery and the reduction in the food fishery quota which had been 1200 fish in previous
years. The food fishery season was from May 31 - July 31, 1993, with other proposed regulations as follows: 1) fishing was restricted to the Conne River estuary and the use of two trap nets; 2) if gillnets were used, mesh size was restricted to 127 mm or larger; 3) maximum weekly harvest levels were 200 fish from May 31June 6 and June 7-13, and 100 fish from June 14-20. As in past years, it was prohibited to retain salmon $\geq 63 \mathrm{~cm}$, although salmon of this size found dead in the food fishery gear could be retained and counted against the quota.

## Methods

1. Landings in 1993

Data on landings from the native food fishery were obtained from the Conne River Native Band Council.

## 2. Biological characteristics

Biological characteristic information on adult salmon, including fork length, whole weight, age and sex, was obtained from limited sampling of salmon caught at the fish counting fence ( $\mathrm{N}=$ 48). The Conne River Indian Band Council provided length, weight, and sex data along with representative scale samples from 255 adult salmon caught in the food fishery. Biological data from Atlantic salmon smolts $(N=246)$ were obtained from specimens sampled at the downstream counting fence trap.

Rainbow trout, which stray into the Conne River as a result of incidental escapements from local fish farming activities in Bay d' Espoir, were also sampled ( $\mathrm{N}=9$ ). The Conne River Indian Band also provided biological characteristic information along with stomachs from five rainbow trout captured in the native food fishery traps.

## 3. Physical measurements

Normally, water temperature information is obtained from continuous recording Hugrun thermographs. In addition, air and water temperatures are also recorded periodically throughout the day at each fish trap check. Water level is determined from a bench-mark pin established in 1986. Information on air temperature, precipitation, and discharge can also be obtained from the Environment Canada, Atmospheric and Environment Service monitoring facility located on the main stem of Conne River, below Conne Pond. Generally, over the course of season, the bench mark water level readings (summarized in Table 6) provide an accurate index of river discharge (Fig. 2).

## 4. Estimated returns and spawning escapement

Adult Atlantic salmon migrants were enumerated at a fish counting fence, located about 1 km upstream from the mouth of the Conne River (Fig. 1), which operated from May 28 to July 31, 1993 (Table 1).

During 1993, adult salmon were counted either as they: 1) passed through monitored openings in the fish counting fence; 2) entered the trap directly; or 3) passed through the video camera tunnel. The video camera system utilized a positive image horizontally directed camera (Panasonic model WV-BD400) housed in a $1.2 \times 1.8 \mathrm{~m}$ wooden box. The fish passage tunnel was approximately 0.5 m square and was incorporated within the above box. The video system was generally operated each day from early evening until about 0900 hours from June 16 - July 29. A Panasonic Time Lapse Video Recorder (Model AG 6040) was used to record the video signal from the camera and could also superimpose the time and date thus providing a summary of actual fish passage times.

Total returns (TR) of adult salmon were estimated from:

$$
T R=F C+M b+C n
$$

where, $\quad$ Fc is the count of fish at the counting fence Mb is the known mortalities below the counting fence, and Cn is the estimated number of Conne River origin salmon caught in the native food fishery.

Spawning escapement (SE) was estimated as:

$$
\mathrm{SE}=\mathrm{Fr}-\mathrm{Ma}
$$

where, $\quad \operatorname{Fr}$ is the number of fish released at the counting fence Ma is the known number of mortalities above the fence

Consistent with the practise established in 1991, estimated egg deposition refers to the 'potential' deposition relative to the current target. That is, no additional adjustments have been made to account for any unknown or assumed mortality of fish up to the time of spawning and thus the potential egg deposition probably overestimates the actual egg deposition.

As in past years, egg deposition was calculated separately for salmon $<63 \mathrm{~cm}$ and salmon $\geq 63 \mathrm{~cm}$ and then totaled.

Egg deposition $=$\begin{tabular}{l}
number of <br>
spawners

$x \%$ female $x$ fecundity 

at size.
\end{tabular}

An estimate of fecundity was obtained from the relationship derived in 1987 (October 27-30) from ripe salmon (Dempson et al. 1987):

Fecundity $=0.1988$ (fork length, cm$)^{2.3942} \quad\left(\mathrm{r}^{2}=0.48, \mathrm{P}<0.001\right.$ )
where for this year, because of small sample sizes, fork length was the mean length of female salmon $<63 \mathrm{~cm}$ in size sampled over all years ( $\mathrm{N}=1013, \bar{X}=508 \mathrm{~mm}$ ).

An estimate of the egg deposition from salmon $\geq 63 \mathrm{~cm}$ in size was obtained using the same length-fecundity relationship for salmon $<63 \mathrm{~cm}$, with the same data for mean length ( 67.8 cm ) and percent females (71\%) as used in past years (Dempson 1989, 1990).

The target spawning requirements were the same as in past years at 7.8 million eggs, equivalent to about 4000 salmon $<63 \mathrm{~cm}$ in size.

## 5. Forecast of 1994 returns

A mark-recapture study was carried out to estimate the smolt production in 1993. The study was similar to those carried out in 1987-92, the design of which is summarized in Dempson and Stansbury (1991) and uses the estimator described in Schwarz and Dempson (1994).

During 1993, 2456 smolts were tagged and released at the upstream partial counting fence site (Fig. 1). At the downstream recapture site, 15992 smolts were caught including 735 tagged smolts. In past years, a simulation approach was used to derive an estimate of returning numbers of adult salmon. The method incorporated into the forecast the uncertainty in the number of smolts migrating in a given year (i.e. mark-recapture estimate) and the variation in smolt to adult survival rates as derived during all of the previous years. Sea survival, however, has declined over time (Fig. 8) and cannot as yet be predicted. Thus, for 1994, the pre-season forecast used the rounded average sea survival recorded during the past three years only. This value was $4 \%$.

## Results and Discussion

1. Landings in 1993

Landings in the recreational fishery are summarized in Table 2 and Figure 3. As indicated above, no recreational fishing was allowed in 1993. In past years, angling exploitation rates, adjusted in some years for the period that the fishery was open, were estimated and yielded the following:

| Year | Exploitation rate |
| :---: | :---: |
| 1986 | 0.275 |
| 1987 | 0.181 |
| 1988 | 0.217 |
| 1989 | 0.223 |
| 1990 | 0.285 |
| 1991 | 0.245 |
| 1992 | 0.268 |

In general, these results indicate that, on average, about one of every four fish that had returned to the river during the period of time the recreational fishery was open was removed by the sport fishery.

Native food fishery catches are also summarized in Table 2. A total of 417 small salmon ( $83 \%$ of the reduced quota) and 3 large salmon were reportedly caught in the 1993 fishery before it closed on July 9 ( $67 \%$ females, $N=255$ ). Of the small salmon caught, 347 ( $83.3 \%$ ) were estimated to be of Conne River origin. The food fishery removed $12.8 \%$ of the estimated total number of small salmon returns to home waters in 1993.

## 2. Biological characteristics

Biological characteristic information was obtained from 246 smolts and 39 1SW fish during 1993. Additional samples of 'large' salmon were also obtained from the counting fence trap ( $\mathrm{N}=9$ ). Small salmon caught in the food fishery in $1993(\mathrm{~N}=253)$ averaged 504 mm in fork length and 1347 g in weight.

Tables 3 and 4 summarize annual biological characteristic data for salmon sampled from the river (1986-93) or for the past two years from the native food fishery (1992-93), respectively. Repeat spawning fish are characterized as consecutive or alternate year spawners. Consecutive spawners sampled from the river are typically less than 63 cm in fork length ( $\bar{x}=544 \mathrm{~mm}, \mathrm{~N}=61$ and $1438 \mathrm{~g}, \mathrm{~N}=44$ ) while alternate spawners average $680 \mathrm{~mm}(\mathrm{~N}=30)$ and $3033 \mathrm{~g}(\mathrm{~N}=3)$ (Table 3) (Fig. 4). Not all size classes of fish can be sampled representatively in that any large salmon angled had to have been released. However, with respect to fish less than 63 cm in size, only 59 ( $3.9 \%$ ) fish out of 1525 samples were either consecutive $(\mathrm{N}=58)$ or alternate spawners ( $\mathrm{N}=1$ ). clearly at conne River, few salmon appear to survive to return and spawn repeatedly.

One freshwater (river) age $1+$ fish was sampled from the native food fishery catch in 1993. This is the first incidence of river age $1+$ fish from this area and is believed to have been an escaped salmon from the local fish farming operations. However, it is noted that this fish could also have escaped from farming operations in other regions.

Figure 5 illustrates the run timing of smolt and adult small salmon at Conne River. Variability in run timing is apparent for both groups with up to a 15 day difference in the 25 th percentile of the run of either life stage. Median dates are typically later during the past three years (1991-93) in comparison with the pre1990 period.

An analysis of the condition of Conne River smolts (Dempson et al. 1994) indicated significant differences in smolt condition among years (Fig. 6). Years in which smolts had a higher condition were those that were typically associated with warmer spring temperatures (Fig. 6). In addition, there is also a suggestion that smolt condition may be subsequently related to sea survival as higher survival of smolts occurred in years where condition was greater (Fig. 6). Last year it was noted (Dempson 1993) that the condition of smolts migrating in 1992 was low and that this could result in lower than expected returns for 1993. This appears to have occurred. Condition of smolts in 1993 was higher than that estimated for 1990-92, and similar to 1987; the year in which sea survival was the highest.

### 2.1 Rainbow trout

Records have been kept on the numbers of rainbow trout that have been encountered at Conne River during the course of field activities (Table 5). This was because of the increased production of rainbow trout at sea farming sites in the Bay d'Espoir area, and the potential impact this could have on wild Atlantic salmon stocks in the vicinity. During the past four years (1990-93), various size classes of trout have been observed. Only small fish were captured in 1993, primarily during the downstream migration of salmon smolts (Table 5).

Twenty-five (25) rainbow trout stomachs have been examined for gross feeding characteristics; 16 (2 empty) from the river and 9 ( 3 empty) from fish captured in the estuary. A qualitative summary follows:

| River | Estuary |
| :---: | :---: |
| Aquatic insects: Ephemeroptera <br> (larval form) Plecoptera Trichoptera | Terrestrial <br> \& Aerial insects: Hymenoptera Coleoptera Odonata Araneida |
| Fish: Threespine sticklebacks <br> Atlantic salmon parr | Fish: Capelin Winter flounder Sticklebacks |
|  | Mollusks: Bivalvia (Mytilidae) |

To date, only one salmon parr was positively identified in a rainbow trout stomach sampled from a fish caught in the river. No salmon were found in the nine rainbow trout samples obtained from the estuary.

## 3. Physical measurements

Average water temperatures and water levels are summarized in Table 6 for the years 1989-93. Temperatures for 1993 were obtained from readings taken during various trap checks as the Hugrun thermograph was rendered inoperable following a flood that resulted from a storm, on July 31-August 1. This storm also resulted in a fence washout on August 1. Sixty-five (65) mm of rain fell and increased the discharge, measured at the outlet of conne Pond on the main river stem of the river (above the Bernard and Twillick Brook tributaries), from a monthly July average of $1.99 \mathrm{~m}^{3} \cdot \mathrm{~s}^{-1}$ to a peak of $46.9 \mathrm{~m}^{3} \cdot \mathrm{~s}^{-1}$ on August 1. The fence was scheduled to have been removed on August 2. Only five salmon in total were counted on the last three days of fence operation, while during the previous 5 days (July 27 - July 31) counts of salmon were averaging 7 fish per day (range 1-15).

## 4. Estimated returns and spawning escapement

There were 2355 salmon $<63 \mathrm{~cm}$ and 98 salmon $\geq 63 \mathrm{~cm}$ counted at the fish counting fence on Conne River in 1993 (Table 7) up to and including July 31. This represents an increase of $19 \%$ in the number of small salmon but a decrease of $36 \%$ in the number of large salmon in comparison with 1992. Peak run of salmon was in standard week 26 (June 25 -July 1) although the single largest daily run occurred on June 23 (192 fish; Fig. 7). Partitioning the count of salmon among the various ways fish were enumerated is as follows:

|  | Small Salmon |  | Large Salmon |  |
| :--- | :---: | :---: | :---: | :---: |
|  | N |  | $\%$ | N |
| Fence opening | 322 | 14 | 21 | 21 |
| Counting fence trap | 926 | 39 | 46 | 47 |
| Video camera chamber | 1007 | 47 | 31 | 32 |
| Total | 2355 | 100 | 98 | 100 |

With respect to the video camera system, salmon generally passed through the chamber all night long. The period from 2230 to 0229 hours accounted for almost $50 \%$ of the total. This pattern of movement is generally consistent with that observed at Biscay Bay River, SFA 9 (M. F. O'Connell, personal communication). A total of 577 fish were associated with time of fish passage as follows:

| Time (hours) | Number of fish | $\%$ |
| :---: | :---: | :---: |
| $2030-2229$ | 116 | 20.1 |
| $2230-0029$ | 139 | 24.1 |
| $0030-0229$ | 145 | 25.1 |
| $0230-0429$ | 113 | 19.6 |
| $0430-0900$ | 64 | 11.1 |

Total returns of adult salmon to Conne River (and estuary) in 1993 are summarized in Tables 8 and 9. The forecast of returns to Conne River in 1993 was higher than in 1992. However, this forecast did not consider the low condition of 1992 smolts and the observed, but preliminary relationship between condition and survival.

Total returns of small salmon (2703) were $7 \%$ higher than in 1992 while large salmon returns (100) declined by $37 \%$. For small salmon, this was consistent with the 1992 forecast in terms of direction, that is 1993 returns showing an improvement over the previous year. However, the magnitude of the increase was wrong and relates to another year of low sea survival. Sea survival of smolts increased from 3.4\% (2.9-4.1\%) in the previous year (1992) to $4.0 \%$ in $1993(3.6-4.4 \%$ ) (Table 10). A comparison of sea survival of smolts at Northeast Brook, Trepassey, SFA 9, with Conne River is illustrated in Fig. 8 (Northeast Brook data from M. o'Connell, personnel communication). On a broad scale, similar patterns are observed; survival declined from 1986-87 (smolt migration year) to 1988-89, followed by the lowest value in 1991 with a small increase in 1992.

Low sea water temperature has been cited as a factor influencing survival of Atlantic salmon. Sigholt and Finstad (1990) found that in cultured Norwegian salmon, low temperature contributed to osmoregulatory failure and poor survival of smolts transferred from freshwater to sea water. Mortality was most pronounced at temperatures below $6^{\circ} \mathrm{C}$. Lega et al. (1992) also found that low sea temperature affects water balance in salmon resulting in a decrease in body moisture content and an increase in plasma osmolarity. The most dramatic changes occurred at temperatures below $4^{\circ} \mathrm{C}$ (Lega et al. 1992). Other studies have established that low temperature or rapid change in salinity alone may not impact on survival; however, when interacting together, decreased survival in Atlantic salmon and rainbow trout occurs (Byrne et al. 1972; Finstad et al. 1988).

Potential spawning escapement in 1993 was estimated to be 2353 small salmon and 97 large salmon (Tables 8 and 9). Mean number of eggs per female is 2357 (based on overall mean size of female salmon). With $82 \%$ of the run made up of female salmon, the number of eggs per fish is 1933. Estimated total number of eggs deposited was:

$$
\begin{aligned}
& \text { small salmon }=4.429 \text { million eggs } \\
& \text { large salmon }=0.332 \text { million eggs }
\end{aligned}
$$

for a total egg deposition of 4.760 million, $61 \%$ of the current target egg requirement and about a $20 \%$ increase in egg deposition from 1992.

The finding of three dynamite blasting caps along a short stretch of the Bernard Brook tributary is of concern. A check with both Federal and Provincial agencies responsible for authorizing permits for blasting indicated that permits had not been issued, nor had there been any specific work in the area to warrant blasting. Thus no legitimate reasons were identified to account for the presence of these caps. It is also noted, however, that no other evidence was found to suggest illegal poaching of salmon by this means had occurred.

Relationships between estimated egg deposition and subsequent smolt output, and estimated smolt output with adult returns are based on limited data and as such, are not conclusive (Fig. 9). At best, higher egg depositions produced more smolt but smolt output from low egg depositions will not be apparent for several more years. Moderate to high numbers of returning adults corresponded with moderate to higher numbers of migrating smolts in the previous year (Fig. 9). Low returns of adults were obtained over the entire range of smolt migrants. We caution, however, that it is premature to draw any conclusions from these limited data.

Estimates of egg-to-smolt survival are now available for three year-classes (1986 to 1988; the 1988 year-class complete only to age 4 smolts in 1993). These values, by year-class, are:

1986 - 0.50; 1987 - 0.46; 1988 - 0.52. Estimates differ slightly from those recorded in $0^{\prime}$ Connell et al. (1992) owing to updated smolt estimates by age class.

## 5. Forecast of 1994 returns

The estimated number of smolts in 1993 was 55765 (95\% confidence limit $=51666-59864$ ) (Table 11); about 18\% lower than the previous year. The percentage of smolts at each river age and the estimated number of smolts in each age group are summarized in Tables 11 and 12, respectively. Part of the decline in the 1993 smolt run could be associated with an egg deposition in 1989 that was $40 \%$ lower than the previous three-year average (1986-88).

At $4 \%$ survival, the approximate average recorded during the past three years, no more than 2400 fish would be expected to return to home waters in 1994. A sea survival of $7 \%$ would be required in order for total returns to meet or exceed the target of 4000 fish. Sea survivals of $7-10 \%$ have been recorded at conne River in past years but it is again stressed that sea survival cannot be predicted. Assuming that the association between condition of smolts and higher survival holds, then returns in 1994 could be greater than that indicated above since the 1993 condition index was similar to that in 1987 when a high survival was recorded.

The need to carry out in-season evaluations cannot be emphasized enough in order to ensure conservation targets are achieved. It is also cautioned that low spawning escapements from 1991-93 may result in lower smolt production in 1995-97. This, should it occur, could then result in low adult salmon returns, probably below target levels, in 1996-98.

## Acknowledgements

Appreciation is extended to Ross Hinks and other members of the Conne River Indian Band who ensured that representative biological characteristic data were obtained from Atlantic salmon captured during the native food fishery.

Figure 1. Conne River, Newfoundland, SFA 11, illustrating the location of the fish counting fences used for the mark-recapture survey. Recapture site is also the location of the upstream adult counting facility.

Water Level

Figure 2. Relationship between relative water level in the lower section of Conne River, as measured at a stationary bench-mark pin, and the Environment Canada monitoring facility discharge records, May 10 - July 31, 1993. The Environment Canada facility is located immediately below Conne Pond, above the Bernard Brook and Twillick Brook tributaries.

Fishery closed for 1 month in 1990 Quota of 100 fish in 1991 Quota of 330 fish in 1992

Figure 3. Summary of the small salmon recreational catch (bars) and effort (rod-days fished, in thousands, solid line) for Conne River, Newfoundland, SFA 11, 1960-92. Recreational fishery was closed in 1993.

Figure 4. Length-frequency distribution of adult Atlantic salmon sampled at Conne River, 1986-93.

Year

25th, 50th (median), and 75th percentiles

Figure 5. Run timing of smolt and adult small salmon at Conne River, Newfoundland. The median point, along with the $25^{\text {th }}$ and $75^{\text {th }}$ percentiles are illustrated.

Figure 6. Index of Conne River smolt condition: varying over years (upper); in relation to the April-May air temperature index (middle); and as it relates to estimated sea survival of adult salmon returning in the following year. Vertical bars in upper graph represent $\pm$ one standard error.

## Number of Fish

## Percent survival to 1SW return

Recruits (Thousands of smolt)

Figure 9. Relationships between estimated egg deposition and subsequent smolt production, by year class (year of egg deposition) (upper), and smolt production (year of smolt run) (by smolt class) and return of adult salmon (lower). Brackets around the 1989 year class in the upper diagram indicate incomplete information on numbers of age 4 smolt which will migrate in 1994. Therefore, an average of numbers of age 4 smolt (1987-1993) has been used.
