An Update of the Inshore Cod Stock
in Subdivision 4 Vn (May-Dec) for 1980
by

S.J. Smith and B.A. Charlton<br>Marine Fish Division<br>Bedford Institute of Oceanography<br>P.O. Box 1006<br>Dartmouth, Nova Scotia<br>B2Y 4A2

Abstract
The status of the 4 Vn (May-Dec) cod fishery for 1980 is studied here by considering the apparent trends in the stock size indices available (e.g. commercial CPUE and research survey estimates).

Previous studies on this stock have determined that this fishery is supported by three stock complexes - 4T cod stock, 4Vs cod stock and the $4 V n$ 'inshore' stock. The major proportion of the catch is assumed to be taken from the inshore stock. Recent changes in the behaviour of the major inshore gear, the longliners, from fishing inshore areas to the present situation of fishing out to the Laurentian Channel suggests that the offshore stocks of 4 T and 4 Vs are now contributing proportionally more to the fishery. The 1980 reported catch of 10,378 mt (a nine year high) seems therefore to be a result of increased effort toward the offshore components rather than an increase in population size of the inshore component.

Rēsumé
Ce document donne un aperçu de l'état de la pêcherie de morue dans 4 Vn (mai-déc.) en 1980, fondé sur les tendances des indices de la taille du stock (p. ex. PUE commerciales et estimations des relevés par navire de recherche).

On a constaté dans des études antērieures que cette pêcherie exploitait trois complexes de stocks - stock de 4T, stock de 4Vs et stock "côtier" de 4 Vn . On suppose que la majeure partie des prises provient du stock côtier. Les récents changements observés dans le déploiement des palangriers, l'élément principal de la flottille côtière, donnent à penser que les stocks de $4 T$ et $4 V$ s contribuent maintenant proportionnellement plus aux captures. En effet, les palangriers pêchent maintenant beaucoup plus loin des côtes, se rendant jusqu'au chenal Laurentien. Les prises de 10378 t signalẻes en 1980 (un sommet depuis neuf ans) semblent donc rēsulter d'un effort de pêche accru au large plutôt que d'une augmentation des effectifs du stocks côtier.

Introduction
This is the third CAFSAC Document devoted exclusively to this stock. Much of the historical information contained in this report is taken directly from Beacham et al. (1980) (after Gray et al. (1979)). Some changes have been made for the information presented in Tables 1, 2, and 3. The previous scientific documents cited above included catches by the Faroese (and a proportion of the Portuguese catch in 1972) for the years 1972 to 1976 inclusive which were listed as unknown in the ICNAF Statistical Bulletins with respect to the month in which the catch was taken. Knowledge of when the catch was taken is extremely important for this stock since it is defined to exist within a specific time period. These catches have been removed from these tables and are presented seperately in an appendix for historical interest.

For this analysis the catch of cod in 4 Vn is divided between the inshore and offshore components according to gear type used. The offshore stock is assumed to be that which is fished by otter trawls only. This stock division was originally proposed by Halliday (1974) but recently this differentiation has become less marked with traditional inshore gear such as longliners now fishing out to the Laurentian Channel (Russel MacPherson personal communication). The Marine Fish Division is at present completing tagging studies in the area in order to improve our knowledge of the stock structure in 4 Vn .

The general historical trends in this fishery have been reviewed in Beacham et al. and Gray et al. The 1980 data indicate a dramatic increase in catches taken by otter trawls and longliners and handlines. In fact the quota set for this stock was exceeded by a little over $100 \%$.

## Nominal catch

At present only Canada and France (St. Pierre-Miquelon) fish this stock with Canada taking greater than $99 \%$ of the reported catch. The historical breakdown by country along with this year's catches are contained in Table 1. This year saw a $64 \%$ increase in the total nominal catch over last year (total catch of $10,378 \mathrm{mt}$ ). Although the fishery is mainly prosecuted by "inshore" gear (see Fig. 1) all of the major gear types showed dramatic increases in catch (Table 2). The increase was also over all tonnage classes listed in Table 3 for otter trawls, longlines and handlines. A more detailed breakdown of catch by gear (for Canadian catches only) is given in Table 4. No significant seasonal pattern in the catches is readily evident in the monthly breakdowns presented in Table 5d. As reported for 1979 by Beacham et al. the landings from the major gears remain dispersed throughout the year.

According to the department's quota reports the major proportion of the quota set for 1980 was in the form of a fixed gear allowance $(3,600 \mathrm{mt})$. This allowance was exceeded by mid-September and as of December 31 the reported landings for this category were well over double the set allowance ( $7,386 \mathrm{mt}$ ).

## Research trawl survey abundance indices

In the reports previous to this one by Beacham et al. and Gray et al. general trend patterns in the research trawl survey abundance indices were found through the use of 3 year running means. Data from time trends can be considered to consist of two components the so-called 'smooth' and 'rough' (after Tukey 1977). The rough component is a reflection or a representation of the variability inherent in the data while the smooth is the pattern we are interested in extracting. Extraction of the smooth is generally referred to as filtering or smoothing the data. Define our observations as $y_{t}(t=1,2, \ldots . . K)$. A three year running mean extracts the smooth by replacing each point $y_{t}$ with an average of the $y_{t-1}, y_{t}$ and $y_{t+1}$ points. If there is an outlying data point, that is, outlying in the sense that the inherent variability or the rough is large in absolute value in comparison to the adjacent points then this point will dominate in the extracted smooth by contaminating the sequence it participates in (Velleman 1980). Tukey (1977) and others, have suggested that nonlinear smoothers based on medians would provide protection against these unsupported spikes in the data.

In Figure 2 we illustrate the behaviour of three year running means and the M3R when applied to the abundance indices for 4 Vn for for ages 4 and up.

The M3R method smooths by replacing each value of $y_{t}$ with the median of the $y_{t-1}, y_{t}$ and $y_{t+1}$ points. The 'span' or region of support is defined as the three points from which the median is taken. The difference between the two methods of smoothing can be best understood by considering the effect of the points for 1977 to 1980 inclusive. The 1978 point is much higher than the two adjacent years and pulls the running average point for 1978 up from the 1977 and 1979 points. In contrast the M3R point for 1978 treats the observed point as an outlier as it is not supported by the other points within its span. With the addition of the high 1980 point the 1979 point is now regarded as atypical within its span and the M3R point gives the 1978 point as the smoothed point while in the running average smooth the 1979 point contaminates the smoothed points for 1979 and 1980. Information provided by the 1981 survey will help us judge how atypical 1979 was.

We have used the M3R method throughout this paper not only for the survey data but for the catch per unit effort (CPUE) data as well so we feel that the explanation above albeit brief is necessary for this paper.

The smooths for the trends of the survey data for ages $4+, 5+, 6+$, and $7+$ are presented in Figure 3. The actual data are given in Table 6. Figure 3 indicates that increases exhibited by the smoothed trends are very much dependent upon the contribution made by the age 4 fish. Excluding the age 4's leaves the large 1980 points for ages 5, 6, and 7 unsupported in their spans and hence the trend is interpretated to be more or less flat for the recent years. With reference to Table 10 which contains the catches at age for longliners it seems that the age 4 signal picked up in the surveys has little effect in the 'inshore' fishery. This is not a totally unexpected result since the offshore stock, that is the stock available to otter trawls (such as used in the survey) has been postulated to the more related to the 4 Vs cod stock at this time of year (Halliday 1974) than to the inshore stock. Research surveys are carried out in the two adjacent areas 4 T (September) and $4 V s$ (with the $4 V n$ survey). In Figure 4 we plot the smoothed trends of the $4+$ mean catch per tows from these surveys. From 1974 the $4 V n$ stock shows more relationships to the $4 T$ stock than 4 Vs . The aforementioned tagging studies will help to bring this observation into perspective.

## Catch per unit effort

The available catch per unit effort for otter trawls and longliners is presented in Table 7. The breakdown according to groups of months was originally presented in Gray et al. in order to discern if the migrations of the $4 T$ and $4 V s$ cod stocks were affecting the catch patterns. The groups identified as May + December (otter trawls) and November + December for (Longliners) were hypothesized as being part of the 4 T stock and therefore the summer months as being part of the 4 Vs stock.

Smoothed plots for the otter trawl CPUE's (May + Dec) in Figure 5 show that there is very little similarity between the trawler tonnage classes and only tonnage class 5 exnibits a persistent increase in recent years. From Figure 6 where seasonal differences are compared for tonnage class 4 it seems that there is a marked difference in CPUE patterns between the time periods considered.

Since longliners are the most important major gear type in this fishery $(71 \%$ of the total inshore catch and $62 \%$ of the total Canadian catch) it is more relevant to look at the trends in Figure 7. The November + December CPUE's exhibit a stronger increase (since 1976) than the summer and fall CPUE's. This is in contradiction to Gray et al. who stated that the time periods do not show very much difference. Again changes noted in the areas now being fished by the longliners is probably contributing to this recent trend.

Although there has been an increase in catch by longliners in 1980 over that reported for 1979 a comparison of catch per unit effort calculated over the period May to December between the two years shows very little difference. Specifically for the major tonnage class (LL2) the 1979 and 1980 catch per unit efforts (t/1000 hks.) are 0.5475 and 0.5404 respectively.

## Catch composition

Mean weight at age and catch at age obtained from commercial samples for longliners are contained in Tables 9 and 10 respectively. The sampling of the inshore gear has always been fairly sparse with the main attention directed to longliners (see Table 8). The 1980 results are based upon one sample taken in December. Given the differences noted in the CPUE's for longliners over time it is certain that the December sample is not representative of the year in general. Therefore because of this reason and also due to the changing importance of the longliner catch with respect to the total catch no cohort analysis was attempted on the information in Table 10.

Summary
The catch obtained in 1980 from the $4 V n$ (May-Dec) cod stock is the largest catch reported in nine years. This increase was evident for all of the major gear types and tonnage classes. The amount caught was over double the quota set for the stock with a major proportion being taken by the 'inshore' fishery.

Given the changes noted in the fishing patterns by the longliners it is possible that the 'offshore' component, which is thought to be part of the 4Vs stock, is contributing to the increase in the catch for the 'inshore' component. The catch per unit effort data for the longliners over the May to December period indicate that an increase may also be due to increased effort directed toward the offshore component.

Until the changes in areas being fished by the longliners have been studied fully and the seasonal interactions of the various stocks in the area have been understood it is felt that the available stock indices (i.e. survey indices and CPUE) are of dubious value in determining overall stock trends.
