<sup>1</sup>This series documents the scientific basic for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.

<sup>1</sup>La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte Atlantique du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

## Abstract

The fishery for white hake in NAFO division 4T is at its lowest level since the first quota was put in place in 1982. Low prices and reduced effort contributed to the record low landings of 1,465 t in 1993 (75% below the average for the period 1960-93). In 1993, 47% of the landings were taken by longlines and less than 20% were taken by mobile gears. Since 1988, the majority (90%) of the white hake landings in the Gulf of St. Lawrence has been taken from statistical unit areas occupied by the 'Strait' component of the stock (i.e., 4Tg, 4Th, 4Tj, 4Ti, 4Tm and 4Tn). NAFO 4T landings (1980-93) were consistently greater (frequently several times greater) than the combined landings in adjacent NAFO divisions and subareas (i.e., 4R, 4S, 3Pn, 3Ps and 4Vn).

Fewer older white hake (i.e., age 6 and over) have been caught since 1989 and the fishery is now dependent on only three age groups, compared to five to six in the years before 1989.

Results from the 1993 research vessel survey indicate that the abundance and biomass of white hake in NAFO division 4T are at very low levels. The research vessel abundance index has declined by about 50% since 1992, and is the lowest observed since 1983. An examination of the length composition of white hake caught during the 1993 survey did not indicate significant improvement in recruitment. The research vessel survey also revealed that the number of large hake has decreased and that the distribution of hake along the Laurentian Channel may be shrinking.

Index fishers have reported that hake were "smaller" and "scarcer" in recent years and other comments from industry indicate that the abundance of white hake has declined. Continued closure of the cod fishery and the possibility of competitive prices for hake in 1994 could result in increased effort directed at white hake and a higher rate of exploitation. Considering the low abundance and indications of weak incoming recruitment, rebuilding of this stock will probably occur slowly.

## Résumé

La pêche à la merluche blanche dans la division 4T de l'OPANO est à son plus bas niveau depuis la mise en place des premiers quotas en 1982. La faiblesse des prix et la réduction de l'effort de pêche sont en partie responsables des débarquements de 1465 t en 1993, un niveau jamais enregistré (75 % de moins que la moyenne de la période allant de 1960 à 1993). En 1993, 47 % des débarquements provenaient de palangres et moins de 20 % provenaient d'engins mobiles. Depuis 1988, la majorité (soit 90 %) des débarquements de merluche blanche dans le golfe du Saint-Laurent proviennent des unités statistiques couvrant la composante «Détroit» du stock (c.-à-d. 4Tg, 4Th, 4Tj, 4Ti, 4Tm et 4Tn). Les débarquements réalisés dans la division 4T de l'OPANO (de 1980 à 1993) sont systématiquement plus élevés (et souvent de plusieurs fois) que le total de tous les débarquements réalisés dans les divisions et les sous-zones 4R, 4S, 3Pn, 3Ps et 4Vn de l'OPANO.

Depuis 1989, on capture moins de merluches blanches âgées (6 ans ou plus), et la pêche repose maintenant sur seulement trois groupes d'âge, comparativement à cinq ou six avant 1989.

Les résultats du relevé de recherche de 1993 indiquent que l'abondance et la biomasse des merluches blanches dans la division 4T de l'OPANO sont actuellement à de très faibles niveaux. L'indice d'abondance obtenu par le navire de recherche a diminué d'environ 50 % par rapport à 1992, et il est actuellement au plus faible niveau enregistré depuis 1983. Un examen de la composition des prises de merluches blanches selon la longueur, effectué au cours du relevé de 1993, n'a pas laissé voir d'importante amélioration dans le recrutement. Les chercheurs ont également appris que la quantité de grosses merluches a diminué et que la répartition des merluches le long du chenal Laurentien pourrait être en train de rétrécir.

Les participants au Programme des pêcheurs-repères affirment depuis quelques années que les merluches sont «plus petites» et «plus rares». D'autres pêcheurs de l'industrie se plaignent également d'une baisse de l'abondance des merluches blanches. Si l'interdiction de pêcher la morue se maintient et si les pêcheurs obtiennent des prix compétitifs pour la merluche en 1994, il pourrait y avoir une hausse de l'effort dirigé sur la merluche blanche et une hausse du taux d'exploitation.

Compte tenu de la faible abondance et des signes de faible recrutement, il est probable que le rétablissement de se stock se fasse lentement.

## Introduction

The fishery for white hake (*Urophycis tenuis*, Mitchill) in the southern Gulf of St. Lawrence (NAFO division 4T - Figure 1) has historically been the third or fourth most important groundfish resource in the southern Gulf of St. Lawrence.

Since 1960, the average annual catch of white hake in NAFO division 4T has been about 5,800 t (Table 1). This resource was not managed by a TAC (Total Allowable Catch) until the precautionary quota of 12,000 tonnes was imposed in 1981, for the 1982 season. Subsequent assessments (Clay et al. 1986; Clay 1987; Clay and Hurlbut 1988) suggested long term yields in the range of 5,000 to 6,000 tonnes. The TAC for 1987 was reduced to 9,400 tonnes and for 1988 to 5,500 tonnes. This is the only fishery for this species within the NAFO convention area that is regulated by a TAC.

This fishery usually does not commence until May when the last of the ice has dispersed. Landings usually peak between July and September and decline through October and November. The hake fishery is carried out mainly by small inshore vessels, and is strongly affected by weather and local market conditions. Both fixed (gillnets and longlines) and mobile gears (small otter trawlers (< 20 m) and larger seiners) are used in the hake fishery. The majority of the fishery is conducted in Northumberland Strait, on the western end of P.E.I., and between P.E.I. and Cape Breton Island.

Previously, the hake fishery in the southern Gulf was considered to be a by-catch fishery; however, a recent analysis (Clay and Hurlbut 1990) indicated that it tends to be a directed fishery, traditionally pursued during periods between other, more economically lucrative fisheries (i.e., lobster, scallop, tuna, etc.).

The combined evidence from a discriminant function analysis of morphometric and meristic characters (Hurlbut 1990; Hurlbut and Clay 1990a), seasonal and annual distributional studies (Clay 1991; Clay and Hurlbut 1989) and a tagging study (Kohler 1971) indicates that the management unit for white hake in NAFO division 4T is composed of two different stock components:

- (1) fish from the shallow inshore southern Gulf (depths  $\leq 200$  m), principally the Northumberland Strait area (the 'Strait' component) and
- (2) fish from along the Laurentian Channel in depths in excess of 200 m (the 'Channel' component).

The research vessel data for these two components have tended to be highly variable, and thus of little use in assessment calibration. Furthermore, recent analyses of groundfish survey data indicate that the distribution of southern Gulf white hake extends beyond the limits of the NAFO division 4T management unit in winter (Morin and Hurlbut 1994). As a result of these uncertainties concerning stock definition and the adequacy of the NAFO division 4T management unit, a formal analytical

assessment (SPA based) has not been conducted since 1989. The present document reviews the status of the fishery in 1992 and 1993.

## **Description of the Fishery in 1992 and 1993**

### *A) Landings and Description of the Fishery*

With only a few exceptions, the annual landings of white hake in NAFO division 4T have declined every year from the high of 14,039 t in 1981 (Table 1 and Figure 2a).

The TAC for 1992 was 5,500 t and the provisional landings in 1992 (Table 2a - Figure 2a) were 3,814 t, a decrease of 15% from the 4,510 t landed in 1991, and a difference of -34% from the average landings for the period 1960-93 (Table 1).

The TAC was reduced from 5,500 t to 3,600 t for the 1993 fishing season. The provisional landings in 1993 were 1,465 t (Table 2b - Figure 2a), the lowest level in recorded landings for this resource (a difference of -75% from the average landings for the period 1960-93 (Table 1)).

Clay and Hurlbut (1990) investigated the magnitude of the landings of white hake in adjacent NAFO divisions and subareas. They showed that the landings from NAFO division 4T (1965 - 1986) were an order of magnitude greater than the sum of the landings in 4R, 4S, 3Pn and 4Vn. When NAFO 3Ps landings were included in a comparison, the NAFO 4T landings (fixed and mobile) were found to be consistently greater (frequently several times greater) than the combined landings in the adjacent NAFO divisions and subareas, however, this difference has diminished since 1990, especially for fixed gear catches (Figure 3a). This comparison also revealed that the majority of the landings of white hake in adjacent NAFO divisions and subareas are taken by fixed gear in NAFO 3Ps. The NAFO 3Ps fixed gear landings have been variable since 1980 and do not exhibit a trend similar to that observed for NAFO division 4T (Figure 3a).

Since 1991, the majority of the fixed and mobile gear landings in NAFO division 4T were taken between July and October (Figure 3b). In subarea 3Ps, the timing of the fishery was highly variable, with maximum fixed gear landings occurring in July in 1991, in May in 1992 and in July in 1993.

The seasonal nature of the fishery for white hake in NAFO division 4T reflects the annual migration of hake to and from the overwintering grounds in the Laurentian Channel, with the 'Strait' component gaining access to the shallow southern Gulf via the Cape Breton Trough (Clay and Hurlbut 1989; Clay 1991). We allocated the NAFO division 4T landings (1988 - 1993) to the 'Strait' and 'Channel' stock components by the lowest level of geographical disaggregation available (i.e., statistical unit area) using the depth criteria (depths  $\leq 200$  m Vs. depths  $> 200$  m) defined by Hurlbut (1990) and Hurlbut and Clay (1990a). Excluding those landings that could not be attributed to a specific unit area (i.e., those designated as 4Tu), 79% of the total white hake landings have come from unit areas 4Tg, 4Tj, and 4Ti (Table 3, Figures 4, 5 and 6). These three unit areas comprise the majority of the NAFO division 4T management unit that is occupied by the 'Strait' component. Landings from unit areas 4Th, 4Tm and 4Tn have been minor and constant. Since 1988, the majority (90%) of the white hake landings in the Gulf of St. Lawrence have been from the 'Strait' component of the stock.

Over the same period (1988 - 93), annual landings from the unit areas that encompass the 'Channel' component (i.e.,  $> 200$  m depth - unit areas 4Tf, 4Tk, 4To, 4Tp and 4Tq) have averaged 10% of the total landings (Table 3, Figures 4, 5 and 6); however, the landings for unit areas 4Tf and possibly 4Tk, probably include hake from the 'Strait' component that were caught while migrating through these unit areas, or were produced in the shallower parts (i.e.,  $< 200$  m depth) of these unit areas.

In 1993, the most significant reduction in landings occurred in two unit areas: 4Tg ('Strait' component) and 4Tf (the 'Channel' component).

Since 1960, gillnets have accounted for 30% of the landings of white hake, followed by bottom trawls (26%) (Table 1 and Figure 2b). Over the same time period, longlines and seines have accounted for 16% and 11%, respectively. In 1993, however, 47% of the landings were taken by longlines and less than 20% of the landings were taken by mobile gears.

#### *B) Management Measures Relevant to the Hake Fishery*

Since the early 1980's, the minimum mesh size for mobile gears involved in the hake fishery was 108 mm (diamond mesh). Early in 1993, DFO (Department of Fisheries and Oceans) introduced Conservation Harvesting Plans as a strategy meant to involve industry in the development of conservation measures that would help rebuild fish stocks. Several changes to the regulations were subsequently announced that had impacts on the white hake fishery, including:

- increase in the minimum mesh size from 108 to 120 mm (square mesh) for mobile gears (<14 m (45 feet)) fishing in the Northumberland Strait area
- the minimum mesh size for mobile gears used outside the Northumberland Strait was increased to 130 mm (square mesh)
- a regulation to control excessive dumping/discarding of groundfish at sea was introduced requiring fishing vessels to land all groundfish caught
- criteria were established for the closure of groundfish fisheries, particularly those involving cod by-catch (All groundfish fisheries were closed in sectors where the cod by-catch exceeded 10% by weight, of the total catch - It was felt that closures had a minimal impact on the white hake fishery in 1993)
- the TAC was reduced from 5,500 t to 3,600t

Following the closure of the cod directed fishery (1/09/93), the minimum mesh size for mobile gears (<14 m (45 feet)) targeting hake in the Northumberland Strait was increased to 130 mm (square mesh). At the same time, the minimum mesh size for mobile gears fishing hake outside the Northumberland Strait, was increased to 145 mm (square mesh).

#### *C) Information from Department of Fisheries and Oceans (DFO) Sources*

Field staff from the Gulf Nova Scotia area reported the following:

- fishers complained that hake were not very abundant in that area in 1993 (there was speculation that there were fewer 'runs' of hake last year)
- most fishers from Gulf Nova Scotia agreed with the conservation measure of increased mesh sizes; however, many indicated concern that the increase to 130 mm (square mesh) this year, will allow most of the hake to escape
- longliners that used the larger #12 circle hooks were apparently satisfied with their performance and some fishers expressed interest in #13 hooks
- the low prices paid for hake in 1993 were the result of a large quantity of hake that was purchased from Soviet vessels by Nova Scotia processors
- participation by fixed and mobile gear hake fishers was reduced in all areas of Gulf Nova Scotia in 1993 due mainly to low prices (estimates of reduced participation were as high as 20% in some areas)
- local processors reported that the size of hake has been declining each year (the percentage of "large" hake processed in 1993 was approximately only 10%)
- both mobile and fixed gear fishers reported an abundance of very small hake

throughout the area

- several fishers switched from mobile to fixed gears in 1993

A port sampler from the Gulf Nova Scotia area confirmed that participation (fixed and mobile) in the hake fishery was considerably reduced in 1993. In contrast, more effort than usual was directed at hake in 1992, including six seiners from the Cheticamp area and two longliners from western Newfoundland that fished intensively for several weeks in St. Georges Bay, N.S. She also mentioned that several seiners complained about the preponderance of small hake in 1992.

#### *D) Information from Fishers*

In 1992, 57 groundfish fishers volunteered to participate in the Gulf Region's Groundfish Index Fisher Program (G.I.F.P.). Eighteen of the 29 index fishers that submitted log records indicated that they directed for white hake (main species). The anecdotal comments of these 18 fishers can be summarized as follows:

- 12 (67%) indicated that hake were scarce in 1992
- 8 (44%) indicated that hake were small(er) in 1992
- 3 (17%) indicated that they switched to another fishery (i.e., tuna, herring, etc.) or switched gears and continued fishing for groundfish (i.e., switched from longline to handline)
- 11 (61%) complained that dogfish interfered with their fishing operations

Fifty-six fishers volunteered to participate in the G.I.F.P. in 1993, and of this group, 32 fishers (57%) actually fished and submitted log records. The main comments of the 17 index fishers from this group, that directed for white hake, can be summarized as follows:

- 13 (76%) indicated that hake were scarce in 1993
- 7 (41%) indicated that hake were small(er) in 1993
- 6 (35%) indicated that they switched to another fishery (i.e., tuna, herring, scallops, etc.) instead of continuing to fish for groundfish
- 2 (12%) indicated that they were limited by closures of the fishery (i.e., cod by-catch).
- 3 (18%) complained that dogfish interfered with their fishing operations
- 1 (6%) complained about low prices for their catch

The 7 participants that would normally have directed for hake but did not submit any log records in 1993, made the following comments:

- 5 (71%) indicated that hake were scarce
- 5 (71%) indicated that they switched to another fishery instead of fishing for groundfish

During public hearings of the Fisheries Resource Conservation Council (FRCC) held in Gaspé, Que. (27/9/93), Shippegan, N.B. (28/09/93) and Charlottetown, P.E.I. (29/09/93) there was a consensus that the abundance of hake has declined everywhere. Some fishers also expressed the opinion that the 4T hake fishery is in as bad a state as the 4T-Vn cod fishery.

In a news release (29/11/93), the FRCC made the following recommendations:

- as a precautionary measure, the 1994 TAC for NAFO 4T hake should be reduced to 2,000 t.
- measures such as those instituted in 1993 (increased mesh sizes) to protect small fish should

be continued

- key areas and times of spawning activity for NAFO 4T hake should be delineated and that, if feasible, measures should be taken to establish closures during spawning areas/periods

Participants at the Gulf Groundfish Advisory Committee meeting held in Moncton, N.B. (02/12/93) made the following recommendations:

- introduction of a minimum fish size regulation
- examination of sexual maturity at the proposed minimum size
- investigation of the by-catch of small hake in smelt fisheries
- work on the management unit for white hake in the Gulf of St. Lawrence

## **Commercial Fishery Data**

### *A) Commercial Samples and Age Determination*

Commercial port samples of NAFO division 4T white hake were obtained according to previously established protocols (Clay et al. 1985; Clay and Hurlbut 1989; Clay and Clay 1991). In 1992, DFO port samplers collected 44 length frequency samples (7,565 fish measured) and 1,524 otoliths, of which 1,416 provided acceptable age estimates. In 1993, port samplers collected 37 length frequency samples (5,827 fish measured) and 743 otoliths, of which 708 provided acceptable age estimates. In 1992 and 1993, the majority (> 92%) of the commercial white hake samples from NAFO division 4T were obtained from unit areas occupied by the 'Strait' component (Samples from the 'Channel' component consisted of the following: 259 fish measured for length and 63 otoliths in 1992 and 404 fish measured for length and 77 otoliths in 1993).

Quality control tests were conducted during the entire period of age determination, after every 200 to 250 otoliths that were read. In 1992, agreement with the reference ager ranged from 77 to 83% with a mean of 80%, when two trays from the reference collection (minimum 100 otoliths) were aged.

A new ager was trained during the fall of 1993 and winter of 1994 (the training was conducted over 12 weeks). His agreement with the reference reader in 1993, ranged from 59 to 92% with a mean of 71%.

### *B) Catch, Weight and Length at Age (1992 and 1993)*

Low sampling intensity in 1992 and 1993 allowed for separation of aged samples into only two gear groupings for both years (Table 4 a and b). As with previous assessments of this resource, otter trawls and seines were combined because they were considered comparable, as were gillnets and longlines.

Eight combinations of time and gear were selected for the length frequency data from the available samples for 1992 and six combinations were selected for the 1993 samples (Tables 4 a and b). The appropriate age-at-length keys were used to determine the age composition of the length frequencies from the landings.

The catch-at-age, weight-at-age and length-at-age were calculated for each key for 1992 and 1993 (Tables 5, 6 and 7 a and b) using the AGELEN program (ver 3.21) for sexes combined. As well, the catch-at-age, weight-at-age and length-at-age were re-calculated for the years 1984-91, to comply with revisions to the NAFO landings statistics for these years. These data were added together for the final catch numbers-at-age and a weighted average (by numbers in each age group) was calculated for

the weights- and lengths-at-age.

The mean length-at-age in 1992 and 1993 (Table 7 a and b) was compared with the mean length-at-age for 1990 and 1991 (Table 7 c and d). The largest fish at-age were those obtained from gillnet samples, however, the mean length- and weight-at-age of fish caught by longline has tended to be smaller/lesser, and more similar to the mean length-/weight-at-age for the two mobile gears. It is likely that this similarity in length- and weight-at-age is attributable to the limited number of samples obtained from longlines. There was a considerable reduction in the mean age of hake in the otter trawl and gillnet keys in 1993. The weight-at-age for white hake aged 8 years and older in 1993 was considerably less than for white hake of the same age in 1992, which in turn were lighter at age than those in 1991. This probably reflects the reduction in the numbers of age 8+ white hake.

Comparing the catch-at-age for 1992 and 1993 with that for previous years (Table 8 and Figure 7), it is evident that fewer older fish (i.e., age 6+ and 8+) have been caught since 1989. The modal age has shifted from age 6 in 1988 and 1989 to age 5 in the years since. This fishery is now dependent on only 3 year-classes (ages 4 - 6) and, as a result, it will be sensitive to annual fluctuations in recruitment.

### *C) Catch Rates From Index Fishers*

A commercial catch rate series was used in past assessments of this resource, when it was assumed that each purchase slip represented one unit of fishing effort (day). This approach has not been used since 1989 because the model explained only a small percentage (< 25%) of the variation in previous years and because of errors encountered in the coding of inshore otter trawlers.

As a long term solution to this problem, the Groundfish Index Fisher Program was established in 1990. Since its start, 50 to 58 fishers have volunteered to participate in this program each year, about one quarter of which are considered to fish at least part-time for white hake. Six participants that direct for white hake have submitted log record information since 1990 (Figure 8).

Although the trends are variable for 1990 to 1992, the catch rates for all six of these fishers show a marked decrease between 1990 and 1993, confirming their comments and those of their fellow participants in the program.

## **Research Vessel Data**

### *A) Fall Groundfish Surveys of 1992 and 1993*

Research vessel surveys have been conducted every autumn since 1971 in the southern Gulf of St. Lawrence, to provide an index of groundfish stock abundance. A stratified random survey design was initially adopted and has been maintained, except for the period 1984-87, when randomly chosen fixed stations were surveyed. The surveys are conducted in the month of September before groundfish commence their migration out of the Gulf. Survey procedures and protocols are standardized and are documented in Hurlbut and Clay (1990b).

In 1992, the Alfred Needler replaced the Lady Hammond as the survey vessel for the annual resource survey. In early August 1992, before the replacement, a comparative fishing experiment was conducted between the two vessels. Results from this analysis indicated that there was no significant difference in the efficiencies of the two vessels for catching white hake (Nielsen 1994).

During the 1992 survey (N178), 176 valid sets were made and 197 valid sets were made during the 1993 survey (N192).

#### i) Geographic Distribution

The distribution of white hake catches during the 1992 and 1993 surveys was similar to the pattern observed in previous years (Figure 9) with concentrations of hake in areas east and west of PEI, off northwestern Cape Breton, and on slope water of the Laurentian Channel between Quebec and Cape Breton, south of the 4T-4S boundary. White hake were seldom caught in the shallow, central zone adjacent to the Magdalen Islands. However, the area of distribution appears to be shrinking.

#### ii) Length Frequency Distribution of Survey Catches

Length frequencies were produced for the series of abundance surveys of the southern Gulf conducted since 1986 (Figure 10). With the exception of 1990, when the modal length was only 33 cm, the modal length (1986-93) has varied between 39-44 cm.

The length frequency of white hake caught during the 1993 survey does not indicate significant improvement in recruitment (the first fully recruited age group was estimated at age 6 - 7 years (Clay and Hurlbut 1989) which corresponds to a size between 60 - 90 cm). The abundance of larger fish has continued to decline.

#### iii) Size at Age

The weight-at-age for white hake age 1 to 6 years old was comparable to that observed during the Lady Hammond surveys (1986-91; Table 9c). The mean length and weight of all white hake sampled during the research vessel surveys in 1992 and 1993 was again low, as it has been since 1987, which is consistent with fisher's opinions about this stock (Figure 11).

#### iv) Abundance Indices and Biomass Estimates

The research vessel mean catch (numbers) per tow, and C.V.'s of the mean catch per tow (Tables 9 a and b) were estimated using the RVAN analysis programs. The mean number of white hake caught per tow during the 1993 September groundfish survey declined by about 50% from the 1992 level and was the lowest observed since 1983 (Figure 12). There were fewer 1, 2, 3 and 4 year old's caught than in 1992 (Table 9a). The estimates of population abundance and biomass for 1993 decreased by just less than 50% from 1992 (Table 10).

As previously mentioned, two stock components have been identified for hake in the southern Gulf, a 'Strait' component with a September distribution in shallow inshore areas at either end of the Northumberland Strait and a 'Channel' component that occupies deeper water along the edge of the Laurentian Channel in September (Hurlbut 1990; Hurlbut and Clay 1990a). We calculated separate abundance indices for these two components for the period 1984-1993. Earlier surveys were not included in this analysis because we judged sample sizes in these earlier surveys to be insufficient to support separate analyses by region and because earlier surveys did not include stratum 403, an important area for hake. We selected strata 403, 420-422, 432 and 433 for analyses of the 'Strait' component and strata 415, 425 and 437-439 for analyses of the 'Channel' component (Figure 13).

An assumption of this analysis is that there has been no significant expansion of hake range to strata outside of these "preferred" subsets during periods of high hake abundance. Because the selected strata contained 95% of the hake caught in the 1984-1993 surveys (Figure 14), we believe that this assumption is reasonable.

Hake catches (all ages and both sexes combined) were analyzed using a multiplicative model with year, stratum and their interaction as effects:

$$\ln(Y_{ijk} + 0.5) = \alpha_j + \beta_k + \gamma_{jk} + \epsilon$$

where  $Y_{ijk}$  is the number of hake (standardized to a 1.75 nautical mile tow) caught in tow  $i$  in stratum  $j$  in year  $k$ . The interaction term was dropped from the model if not significant ( $P > 0.05$ ). To respect the stratified random design of the survey, the data were weighted by  $A_j/n_{jk}$ , where  $A_j$  is the area of stratum  $j$  and  $n_{jk}$  is the number of tows in stratum  $j$  in year  $k$ . Analyses used the GLM procedure of SAS (SAS Institute 1990). Weighted means were calculated for each year to provide indices of relative abundance for each of the two stock components.

Stratum effects were highly significant ( $P < 0.0001$ ) in all analyses. The year\*stratum interaction was highly significant for the 'Channel' component ( $F=1.95$   $df=36,138$   $P=0.003$ ) but was not significant for the 'Strait' component ( $F=1.08$   $df=44,249$   $P=0.34$ ). The year effect was significant for the 'Channel' component ( $F=2.69$   $df=9,138$   $P=0.007$ ) but only approached significance for the 'Strait' component (after dropping the interaction term:  $F=1.89$   $df=9,293$   $P=0.053$ ). Catch rates for hake in the shallow 'Strait' strata were low in 1984 and 1993; the 1993 catch rate was the lowest in the 10-yr time series (Figure 15). Catch rates in the deeper 'Channel' strata were relatively high in 1984-1988 and low in 1989-1993; the 1992 and 1993 catch rates were the lowest in the 10-yr time series.

The different annual patterns in catch rate between the shallow and deep strata (Figure 15) support the hypothesis that the hake occupying these two areas represent different stock components (cf. Hurlbut 1990). Density-dependent range expansion and contraction could also produce regional differences in annual variation in catch rate (cf. Swain and Wade 1993). However, this alternate explanation is not supported by the earlier decline in catch rates in the region with the higher annual average catch rate (i.e., the deep strata).

We examined annual variation in catch rate by stratum for the 'Channel' component (which exhibited a significant year\*stratum interaction). Catch rates declined in the shallower strata (37 and 38) in the late 1980's but have remained high in the deeper strata, except for a recent decline in stratum 15 (Figure 16). This suggests a recent contraction of range into the eastern deep strata 25 and 39 for the 'Channel' stock component.

#### v) Stock Area

The theory of density-dependent habitat selection predicts that population range should contract into the area of optimal habitat as population size decreases (MacCall 1990). We examined annual variation in population range for each stock component using the index of distribution described by Swain and Sinclair (1994). This index estimates the minimum area over which a specified percentage of the population is spread. First, we calculated the cumulative distribution functions (cdf's) for the hake catch for each year and region, as follows:

$$F(c) = 100 \frac{\sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h} X_{hi} I}{\sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h} X_{hi}} \quad \text{where } I = \begin{cases} 1 & \text{if } X_{hi} \leq c \\ 0 & \text{otherwise} \end{cases}$$

where  $A_h$  is the area of stratum  $h$ ,  $n_h$  is the number of trawl tows in stratum  $h$ ,  $X_{hi}$  is the number of hake caught in tow  $i$  in stratum  $h$  (standardized to a tow length of 1.75 nautical miles),  $L$  is the number of strata, and  $c$  is a level of hake density (i.e., number per standard tow). We also calculated cumulative area in relation to hake catch:

$$G(c) = \sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h} I \quad \text{where } I = \begin{cases} 1 & \text{if } X_{hi} \leq c \\ 0 & \text{otherwise} \end{cases}$$

We evaluated  $F$  at intervals of 1.0, and calculated the 5<sup>th</sup>, 10<sup>th</sup>, 25<sup>th</sup>, and 50<sup>th</sup> percentiles of hake catch (Sokal and Rohlf 1981 p.46). We calculated the area associated with each of these levels of hake catch from  $G$ , and an index of distribution  $D_X$  as

$$D_X = A_T - G(c_{100-X})$$

where  $A_T$  is the total area surveyed and  $c_{100-X}$  is the 100- $X$ <sup>th</sup> percentile of hake catch. For example,

$$D_{95} = A_T - G(c_{05})$$

where  $c_{05}$  is the 5<sup>th</sup> percentile of hake catch and  $G(c_{05})$  is the area over which hake density is at or below the 5<sup>th</sup> percentile level.  $D_{95}$  can be thought of as an estimate of the minimum area over which 95% of the population is distributed.  $A_T$  was 8,277 km<sup>2</sup> for the 'Channel' component and 13,564 km<sup>2</sup> for the 'Strait' component, except in 1988 when only 12,434 km<sup>2</sup> were surveyed for the 'Strait' component. For this year, when not all strata were sampled, the calculated values of  $D_X$  were standardized to a total area of 13,564 km<sup>2</sup>. We calculated  $D_X$  for  $X$  equal to 95, 90, 75 and 50.

Stock area has tended to decrease over the 1984-1993 time period (Figure 17), but this tendency was not significant for either stock component (Table 11). Likewise, the area over which hake densities were relatively high ( $D_{50}$  and  $D_{75}$ ) was not significantly correlated with indices of abundance for either stock component (Table 11). On the other hand, the area containing most of the hake stock ( $D_{90}$  and  $D_{95}$ ) was significantly correlated with the index of abundance for the 'Channel' component but not for the 'Strait' component (Table 11). This indicates that population range has contracted as abundance decreased for the 'Channel' component but not for the 'Strait' component. This suggests that competition for density-dependent resources (e.g., food) has been significant for the 'Channel' component but not for the 'Strait' component, when abundance has been relatively high. This difference between the 'Channel' and 'Strait' stock components, is consistent with higher food resources in shallow inshore areas than in deeper water along the edge of the Laurentian Channel.

#### vi) Temperature Distribution

We examined relationships between hake density (fish per standard tow) and temperature using cumulative distribution functions (cdf's) following Perry and Smith (1994). The cdf (in percent) for temperature was calculated from the 1993 survey data as follows:

$$f(t) = 100 \frac{\sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h} I}{\sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h}} \quad \text{where } I = \begin{cases} 1, & \text{if } x_{hi} \leq t \\ 0, & \text{otherwise} \end{cases}$$

where  $t$  is a level of temperature,  $A_h$  is the area of stratum  $h$ ,  $n_h$  is the number of tows in stratum  $h$ ,  $x_{hi}$  is the bottom temperature at the end of tow  $i$  in stratum  $h$ , and  $L$  is the number of strata. For each sex and each age from 3 to 6, the cdf for hake catch in relation to temperature was calculated similarly:

$$g(t) = 100 \frac{\sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h} y_{hi} I}{\sum_{h=1}^L \sum_{i=1}^{n_h} \frac{A_h}{n_h} y_{hi}} \quad \text{where } I = \begin{cases} 1, & \text{if } x_{hi} \leq t \\ 0, & \text{otherwise} \end{cases}$$

where  $y_{hi}$  is the number of hake caught in tow  $i$  in stratum  $h$ . The significance of temperature selection by hake was tested by randomization tests based on the maximum absolute difference between the cdf's of temperature and of hake catch in relation to temperature (Perry and Smith 1994).

The September temperature distribution in 1993 is summarized in Figures 18 and 19. Hake of both sexes and all ages tended to select warm temperatures in relation to those available. Temperature selection was statistically significant for all cases except age-6 females (Table 12). Temperature distribution appeared to be somewhat broader (i.e., extended into cooler water) for older hake of both sexes (age 5 vs age 3 in Figure 19). Temperature preferences appeared to be strongest for temperatures between 4 and 7°C and 13 and 15°C (age 6 female hake). If this apparent preference for warm water is not related to selection of some other correlated variable, then much of the southern Gulf is unavailable to hake in September, especially in recent years of cold bottom temperatures (Chouinard and Swain 1994).

#### B) January 94 Survey of Cabot Strait

A groundfish survey was conducted in the Cabot Strait (NAFO divisions 4T to 4Vsb) from January 13-25, 1994 using the Alfred Needler and standard Gulf survey protocols (i.e., stratified random design, etc.). The primary objective of this survey was to determine the distribution and relative abundance of groundfish species in the Cabot Strait area during winter (Chouinard 1994).

During the survey, 71 valid sets were completed. White hake catches were almost entirely made in areas 4Vn and 4Vs in waters deeper than 200 m (Figure 20). Catches in the northern part of Cabot Strait were also limited to depths deeper than 200 m and only small catches were realized within the Gulf.

#### C) Distribution in Adjacent NAFO Divisions and Subareas

An analysis of the distribution of white hake from survey data for the northern and southern Gulf (fall and winter) was conducted to assess the adequacy of the 4T management unit for white hake (Morin and Hurlbut 1994). Data for this study originated from groundfish surveys conducted by the Québec and Gulf Regions.

In all of the summer surveys examined, the majority of white hake were caught in the NAFO division 4T management unit (Figure 21). Results from the winter surveys (Figure 22) indicated that hake increasingly occupy the deeper, eastern portion of the Gulf in winter and their distribution appears to be continuous with divisions outside of the Gulf, including 3Pn and 4Vn.

The observation that white hake in the Gulf of St. Lawrence select deeper water in winter is consistent with other studies. Clay (1991) inferred the annual migration of white hake in the southern Gulf from a series of seasonal surveys which indicated that as the shallow waters of the southern Gulf cool in the fall, the inshore ('Strait') group, which had been acclimated to warmer waters, migrates to the deep (> 200 m), relatively warm water of the Laurentian Channel. He suggested that this is the probable overwintering area for three groups of white hake: inshore and offshore components of the

southern Gulf (i.e., 'Strait' and 'Channel' groups) and hake from the northern Gulf (NAFO divisions 4R and 4S).

The results of this analysis and the Jan. 94 survey of Cabot Strait suggest that the NAFO division 4T management does not circumscribe the seasonal distribution of white hake and therefore may not account for all catches from this resource.

### **Estimation of Mortality Rates**

Sinclair et al. (1993) described a method for estimating trends in fishing mortality at length, using commercial and research vessel survey length frequency data. With this method, the ratio of catch at length ( $C_l$ ) to the RV estimate ( $A_l$ ) is used as a direct estimate of relative fishing mortality at length ( $R_l$ ).

$$R_l = C_l/A_l$$

A variation of this method was used to estimate trends in fishing mortality at age ( $R_a$ ) from the ratio of catch at age ( $C_a$ ) to the RV estimate ( $A_a$ ).

$$R_a = C_a/A_a$$

The results (Figure 23) indicate a trend of increasing fishing mortality on the year-classes that supported the fishery (ages 4-6) from 1988-92, followed by a reduction in 1993, consistent with the reduction in fishing effort. These results are consistent with an analysis of instantaneous mortality rates (Paloheimo Z's), calculated from research surveys (Hurlbut and Chouinard 1992), which indicated that the fishing mortality was high (approximately 1.0) in the late 1980's and early 1990's (to 1992).

### **Multispecies Considerations**

Small hake are taken as by-catch in estuarine smelt fisheries in some areas of the southern Gulf. One smelt fisher who fishes in the Miramichi estuary, maintained a daily logbook of his catch of smelt, tomcod and white hake (Figure 24). His records indicated that he caught 822 kg of small white hake during a one month period in 1992 (average size 23 cm). Assuming an average weight of 100 g per hake, the reported catch for this fisher could represent 8,220 small hake. The magnitude and extent of this type of mortality is currently unquantified.

### **Prognosis**

The fishery for white hake in NAFO division 4T is at its lowest level since the first quota was put in place in 1982. Low prices and reduced effort contributed to the record low catch in 1993. Fewer older (i.e., age 6 and over) white hake have been caught since 1989 and the fishery is now dependent on only three to four age groups, compared to five to six in the years before 1989. Recovery of this resource will depend on the occurrence of favourable recruitment.

Results from the 1993 research vessel survey indicate that the abundance and biomass of white hake in NAFO division 4T are at very low levels. The research vessel abundance index has declined by about 50% since 1992, and is the lowest since 1983. An examination of the length composition of white hake caught during the 1993 survey did not indicate significant improvement in

recruitment. The research vessel survey also revealed that the number of large hake has decreased and that the distribution of hake along the Laurentian Channel may be shrinking.

Index fishers have reported that hake were "smaller" and "scarcer" in recent years and other comments from industry indicate that the abundance of white hake has declined. Continued closure of the cod fishery and the possibility of competitive prices for hake in 1994, could result in increased effort directed at white hake and a higher rate of exploitation.

## ACKNOWLEDGEMENTS

We would like to thank John Hanlon and Phil George (DFO, Antigonish) and Janice Fennel (DFO, Science Branch) for their descriptions of the Gulf Nova Scotia fishery in 1993. Janice Fennel and Yves Richard (DFO, Science Branch) sectioned the white hake otoliths and Yves commenced ageing white hake in 1993. We would like to thank Bernard Morin (DFO Québec Region) for providing data files and documentation for the surveys of the northern Gulf. We would also like to thank John Peppar and Alan Sinclair (DFO, Science Branch) for many constructive comments on an earlier draft of this manuscript.

Table 12. Randomization tests of temperature selection by white hake in the southern Gulf of St. Lawrence, September 1993.  $D_{\max}$  is the observed maximum absolute difference between cumulative distribution functions for temperature and for hake catch in relation to temperature.  $N$  is the number of random permutations of the data that produce a  $D_{\max}$  greater than or equal to the observed value (out of 2999 random permutations).  $P$  is the probability that hake are randomly distributed with respect to temperature ( $P = (N+1)/3000$ ).
