> Capelin in SA2 + Div. 3KL

Science Branch
Department of Fisheries and Oceans
P. O. Box 5667

St. John's, NF A1C 5X1
Canada
${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte atlantique du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

## Abstract

This document contains a number of discrete research results which were considered during a March 1995 assessment of capelin in SA2 + Div. 3KL. These results are arranged in fifteen chapters. In addition, a consensus meeting report, cross-referenced by chapter, is provided. The data available included the results of studies on inshore capelin, acoustic survey results, bycatches of capelin in groundfish surveys, predation studies, analyses of capelin distribution, lengths and ageing. Two alternate assessment techniques were also evaluated, one of which, the multiplicative model, formed the basis for the assessment.

## Résumé

Le présent document contient des données discrètes de recherche qui ont été prises en considération durant une évaluation du capelan dans SA2 + div. 3KL réalisée en mars 1995. Les données en question sont organisées en quinze chapitres. Le document contient aussi un rapport consensuel de réunion à renvois par chapitre. Sont également présentés les résultats d'études sur le capelan côtier, les résultats de recherches acoustiques, des données sur les prises accidentelles de capelan dans les relevés de recherche sur le poisson de fond, des études sur la prédation ainsi que des analyses sur la distribution, la longueur et l'age du capelan. On analyse aussi deux méthodes d'évaluation, dont l'une, appelée modèle multiplicatif, a servi à l'évaluation de mars.

## Introduction

This document contains a number of discrete research results which were considered during a March 1995 assessment of capelin in SA2 + Div. 3KL. These results are arranged in fifteen chapters in this research document. In the past, each of these chapters would have formed a separate research document but beginning in 1994, all contributions were arranged into one research document with the aim of simplifying the extensive technical background to the assessment. In a further effort to provide a coherent presentation, a consensus meeting report, cross-referenced by chapter, is provided at the end of this document. A stock status report has been published elsewhere.

The data available for this assessment were extensive and varied. They included the results of studies on inshore capelin, acoustic survey results, bycatches of capelin in groundfish surveys, predation studies, analyses of capelin distribution, lengths and ageing. The last two chapters provide alternate types of assessments, one of which, the multiplicative model, formed the basis for the accepted assessment.

# Results of a Telephone Survey of 1994 Fixed Gear Capelin License Holders <br> by <br> Brian S. Nakashima <br> Science Branch <br> Department of Fisheries and Oceans <br> P. O. Box 5667 <br> St. John's, NF A1C 5X1 

## Introduction

A questionnaire was designed to quantitatively evaluate biological and fishery-related information obtained from capelin fishers in 1994. The survey was undertaken because concerns were expressed at a March 1994 capelin stock assessment meeting about the utility of qualitative information coming from comments made by some research logbook fishers. Questions were developed to supplement information collected by the research logbook and beach sampling programmes and to provide background data on the survey population of capelin fishers.

## Methods

The survey population of 2159 was defined as all capelin fixed gear (traps and beach seines) fishers licensed to fish capelin in NAFO Div. 3Ps, 3L, and 3 K in 1994. A list of names and telephone numbers was provided by the Resource Management Division, Fisheries and Habitat Management Branch, DFO. Employing a simple random sampling design and assuming an expected response rate of $75 \%$ a sample population of approximately 450 names was required to achieve a margin of error within $\pm 5 \%$ at $95 \%$ confidence intervals (Gower and Kelly 1993). Questions relating to the fishery in 1994 were expected to have a low response rate due to low fishing effort requiring 128 responses to achieve $\pm 10 \%$ margin of error. Because of time constraints the survey was conducted by telephone rather than as face-to-face interviews.

Earlier drafts were reviewed by Pelagic Section staff and by members of the MUN contact group chaired by L. Felt. A pretest was conducted by telephone in late January with eight fishers who are currently in the research logbook programme, for comments on the survey questions and overall intent of the survey. The questionnaire was revised as a result of their input with the final questionnaire as shown in Appendix A.

Telephone interviews commenced February 3, 1995 and were completed on March 19, 1995. As of February 28, 1995 responses were obtained from 204 fishers and four declined to participate in the survey. Interviewers were unable to contact 18 others despite five or more attempts to do so. Since the presentation of preliminary results at the regional assessment meeting on March 1-3, 1995 interviews continued until March 17, 1995 resulting in a final count of 371 responses received achieving a response rate of $82 \%$. Of the 79 non-responses nine refused or were uncomfortable with participating and 70 could not be reached. Of the latter, 27 no longer had a telephone number as listed on the license, five had moved out of the province, and one was deceased.

Despite repeated attempts (maximum of five), interviewers were unsuccessful in reaching 33 license-holders in the sample population.

Results have been expressed in terms of final results (N) based on the 371 completed interviews and preliminary results (Np) from the first 204 completed interviews. The latter was provided because only this information was tabled at the assessment meeting. In general survey trends did not vary between the preliminary and final results.

Results and Discussion

## Abundance Questions

Three questions (Appendix A) comparing abundance of capelin in 1994 to previous years were asked in the survey. Response rate of the preliminary ( $\mathrm{Np}=204$ ) and final results ( $\mathrm{N}=371$ ) were consistent and suggested low abundance in 1994. Over $50 \%$ of respondents in answering question 1 (Appendix A) ranked 1994 abundance on the lowest scale of '1' and $75 \%$ at '3' or less (Fig. 1a). Over $60 \%$ in answering question 2 (Appendix A) felt that capelin in 1994 were only half or less than half as abundant as in 1993 (Fig. 1b). When given three options in question 3 (Appendix A) respondents overwhelmingly indicated that capelin abundance in 1994 was lower than when they had first started to fish capelin (Fig. 1c).

## Spawning Questions

Respondents of questions 4-13 (Appendix A) related to spawning generally indicated that spawning on beaches was lower in 1994 than in previous years, that spawning continued to be later than 'normal', and that spawning in deeper water away from beaches was more noticeable in 1994 than in other years. In general there are 1-10 spawning beaches near $70 \%$ of the respondents (Fig. 2a), however that percentage declined to $47 \%$ in 1994 with most reporting spawning on $1-5$ beaches (Fig. 2b). There was also a substantial number of areas where no beach spawning was observed in 1994 (Fig. 2b). Questions 6 and 7 were answered by only those who had observed beach spawning in 1994 resulting in 115 preliminary and 184 final responses. Capelin spawned on more beaches in 1993 than in 1994 (Fig. 3). Not only were the number of spawning beaches reduced in 1994 the intensity of spawning was also very low. Over $70 \%$ of respondents indicated that spawning intensity was '3' or less on an increasing intensity scale of '1' to '10' in 1994 (Fig. 4). Spawning intensity in 1994 compared to 1993 was generally lower but over $30 \%$ thought it was the same or higher (Fig. 5). These results support the lower estimates of egg density at the six spawning beaches surveyed on the northeast coast in 1994 (Nakashima and Winters 1995).

There was evidence for capelin exhibiting off beach spawning behaviour in deeper water in 1994. In asking question 8 about spawning in deeper water $36 \%$ ( $\mathrm{Np}=34 \%$ ) didn't know, $18 \%$ ( $\mathrm{Np}=17 \%$ ) said 'no', and $46 \%$ ( $\mathrm{Np}=49 \%$ ) said 'yes'. In comparison to the perceived norm (Fig. 6) there appears to have been an increase in the incidence of capelin spawning off beaches in 1994. Question 9 (Appendix A) was asked of the 172 ( $\mathrm{N} p=100$ ) persons who responded in the affirmative to question 8 to explore reasons why capelin may not have spawned on beaches and spawned elsewhere in 1994. The majority suggested water temperatures ( $N=56 \%$, $N p=57 \%$ ) as a likely possibility. Other possibilities were the presence of predators ( $\mathrm{N}=5 \%$, $\mathrm{N}=8 \%$ ), unsuitable beach habitat ( $\mathrm{N}=4 \%, \mathrm{~Np}=5 \%$ ), capelin only found offshore ( $\mathrm{N}=4 \%$, $\mathrm{Np}=2 \%$ ), no 'capelin' weather in 1994 ( $\mathrm{N}=2 \%$, $\mathrm{Np}=1 \%$ ), and low capelin abundance ( $\mathrm{N}=1 \%, \mathrm{~Np}=2 \%$ ). Approximately $28 \%$ ( $\mathrm{Np}=25 \%$ ) who indicated off beach spawning had occurred in 1994 could offer no reason why this may have occurred.

Spawning times were delayed compared to the 1980 s and are similar to late spawnings experienced since 1991. Of those answering question ila who recalled when spawning began in 1994 the majority suggested late June to late July (Fig. 7) with most responses from mid to late July. Comparing the start of the spawning season in 1993 to 1994 in question 11b most respondents who expressed a time indicated that it was the same in both years (Table 1). A lower percentage thought 1993 was earlier or later than 1994. There was a large percentage of non-responses. When asked to indicate the end of the 1994 spawning season the number of non-responses to question 12 a was higher (Fig. 8) than for the start of the season (Fig. 7). The results suggest that spawning in 1994 ended between mid July and mid August (Fig. 8). Answers to question 12 b suggested that the end of spawning was similar in 1993 and 1994 for $25 \%$ (Table 1). Approximately 15\% thought spawning was later in 1993 and 10\% thought it was earlier than in 1994. Over 50\% were unable to estimate a time. Compared to when fishers started fishing capelin there was general agreement that spawning in 1994 has been later (question 13, Table 1). Nakashima and Winters (1995) have observed late spawning times on the northeast coast comparable to the ranges reported in this survey. The results continue a trend of delayed spawning seasons in the 1990 s (Nakashima 1994).

Questions on the Fishery
Almost all licensed respondents intended to fish capelin in 1994 (question 14a: $N=96 \%, N p=95 \%$ ), however less than 45\% ( $\mathrm{Np}=59 \%$ ) set traps or bothered to search (question 14b). of the 168 ( $\mathrm{N}=120$ ) who were asked question 15 a 81\% ( $\mathrm{Np}=77 \%$ ) fished only capelin traps, 5\% ( $\mathrm{Np}=4 \%$ ) fished beach seines, and $14 \%$ ( $\mathrm{Np}=19 \%$ ) fished both traps and seines. Of the 156 ( $\mathrm{Np}=111$ ) trap fishers $49 \%$ ( $\mathrm{Np}=42 \%$ ) set one trap, $44 \% ~(\mathrm{~Np}=51 \%)$ set two, and $6 \% ~(\mathrm{~Np}=7 \%$ ) tended
more than two. Question $15 c$ concerning the capacity of traps to hold capelin was answered poorly and could not be evaluated for this report. Most ( $\mathrm{N}=85 \%$, $\mathrm{Np}=86 \%$ ) fishers had always fished the same gear type, however the $15 \%$ ( $\mathrm{Np}=14 \%$ ) who had changed went from beach seines to traps except one who converted from a trap to a beach seine. The dominance of traps as the fixed gear of choice in the survey population was also evident in the research logbook survey and in the proportion of fixed gear commercial landings attributed to traps and beach seines (Nakashima 1995).

About $75 \%$ of fishers $(\mathrm{N}=168, \mathrm{~Np}=120)$ intending to fish did not have any landings in 1994 (question 16) and very few reported landings greater than 20,000 lbs (Fig. 9). This reflected a very poor fishery in 1994 as reported in research logbooks and was obvious from the provisional low landings (Nakashima 1995). Discards were low for most fishers because the majority did not fish in 1994. Approximately 5\% ( $\mathrm{Np}=6 \%$ ) reported discards in excess of $100,000 \mathrm{lbs}$ (question 17, Fig. 10). The returns from the research logbook survey indicated that very few actually fished in 1994 and that for those who did discarding was high (Nakashima 1995). Research logbook fishers reported 100 \% survival of discards in 1994 (Nakashima 1995). Of the 54 ( $\mathrm{Np}=32$ ) fishers reporting discards in the questionnaire survey $82 \%$ ( $\mathrm{Np}=88 \%$ ) responding to question 18 reported over $90 \%$ survival of capelin released (Fig. 11). Reasons provided for discarding in question 19 were small females ( $N=65 \%, N p=51 \%$ ), fishery closures ( $N=8 \%$, $\mathrm{Np}=10 \%$ ), monitoring ( $\mathrm{N}=8 \%, \mathrm{~Np}=7 \%$ ), combination of two or more of the previous four reasons ( $\mathrm{N}=10 \%, \mathrm{~Np}=17 \%$ ), and redfeed ( $\mathrm{N}=2 \%$ ). The remainder who reported discards did not cite specific reasons for discarding capelin. Based on a few returned research logbooks catches of small females were the predominant reasons for discarding capelin in 1994 (Nakashima 1995). Fishers overwhelmingly indicated that the amounts discarded in 1994 were less than in 1993 (question 20a: $N=61 \%, N p=75 \%$ ) and less than other years fished (question 20b: $N=75 \%, N p=89 \%$ ). This is not surprising because many fishers did not catch any capelin in 1994 resulting in no discards.

Many fishers did not fish as mentioned earlier resulting in $72 \% ~(\mathrm{~Np}=74 \%)$ of $168(\mathrm{~Np}=120)$ surveyed reporting no bycatch in 1994 (question 21). In response to question 22 asked of the $28 \%$ ( $N=47$ ) who had bycatches there were 33 reports of cod, 9 of tomcod, 9 of salmon, 9 of herring, 6 of squid, 3 of mackerel, 2 of flounder, and 2 of lumpfish. In most cases fishers reported catching more than one bycatch species. Estimates of the amount of bycatch were unavailable. The condition of the bycatch was $92 \%$ ( $\mathrm{Np}=94 \%$ ) alive, $4 \%$ ( $\mathrm{N}=0 \%$ ) dead, and $4 \% \quad(\mathrm{~Np}=6 \%$ ) mixture of live and dead (question 23). We asked question 24 (Appendix A) to fishers who reported bycatches of cod or tomcod in 1994. Over half thought their bycatches had no effect on cod populations while $16 \%$ felt the
effects were significant or very significant (Fig. 12). Specific answers as to why a particular response was given when answering question 24 were few. From the reactions to questions 24 and 25 it was clear that these questions will have to be reworded for future surveys.

Questions on Climate and Ocean Conditions
The entire survey population of 371 ( $\mathrm{Np}=204$ ) was asked questions 26 and 27 (Appendix A) pertaining to general weather and ocean conditions during the summer of 1994. For question 26 most respondents tended to classify the weather into poor, average/fair, or good/perfect rather than using the three suggested categories posed by the interviewer. Consequently $92 \%$ ( $\mathrm{Np}=91 \%$ ) reported good/perfect weather in 1994 compared to $2 \%$ ( $\mathrm{Np}=2 \%$ ) who experienced bad weather and $6 \%(\mathrm{~Np}=7 \%)$ said fair conditions. Respondents were asked specifically to classify ocean conditions. The responses were similar to what one would expect with good weather conditions. Generally most reported no ice ( $\mathrm{N}=89 \%$, $\mathrm{Np}=99 \%$ ) and none or few storms ( $\mathrm{N}=\mathrm{Np}=97 \%$ ). A majority noted water temperatures were warm ( $\mathrm{N}=57 \%$, $\mathrm{Np}=55 \%$ ) while $21 \% ~(\mathrm{NP}=19 \%$ ) said temperatures were cold. Almost one quarter could not recall relative water temperatures. No ice, few storms, and warm water are indicative of favourable weather throughout the south and northeast coasts. The contrast between cold and warm water along the coast may be related to where respondents live. Nakashima and Winters (unpublished data) noted that beaches such as Bellevue and Hampden experienced cooler (<5C) water temperatures into late July in 1994, whereas water temperatures near other beaches at Arnolds Cove, Chapel Cove, Eastport, Cape Freels, and Twillingate were much warmer (>8C) by late June to early July.

Characteristics of Survey Population
All respondents were asked questions 28-31 to help characterize the survey population of fixed gear fishers and to be able to relate in a subsequent analyses responses to areas fished and experience in the fishery. The distribution of responses to question 28 indicates that $30 \%$ began fishing capelin in the late 1970s when the Japanese roe fishery started (Fig. 13a), more entered from 1984 to 1989, and very few began in the 1990s. Most fishers are in the age $40-55$ range followed by the 25-39 range (Fig. 13b). Fishing vessel lengths varied from 17-52 feet with the majority less than 35 feet (Fig. 14a). Estimated vessel capacity for capelin was less than $18,597 \mathrm{~kg}(41,000 \mathrm{lbs})$ for most fishing vessels used in the fixed gear capelin fishery (Fig. 14b). Responses were distributed along the south and northeast coasts with the highest number from Notre Dame Bay (Fig. 14c).

## Summary

Results from the telephone survey of fixed gear capelin fishers support many of the observations made from beach spawning and research logbook programmes. In 1994 capelin spawned later than in the 1980s, spawned on fewer beaches at a low intensity, and spawned subtidally away from beaches more so than in previous years. Most licensed fishers intended to fish in 1994 but many did not due mainly to monitored areas remaining closed because of small fish. The weather was generally considered favourable for being out on the water and water temperatures were considered warm. Overall respondents felt capelin abundance was low in 1994 and lower than in previous years. The reported results of the telephone survey for most questions were considered accurate for the survey population within $\pm 5 \%$ to $\pm 10 \%$, 19 times out of 20 depending on the number of responses. For questions $18,19,22,23$, and 24 the number of responses was too low to fall within acceptable levels of error.

A variety of comments were provided by $4 /$ of respondents at the end of the interview (Table 2). The most frequent comment was to close the capelin fishery, however, it was uncertain whether this referred to 1994, 1995 or all years. Future surveys can incorporate specific questions to resolve the nature and extent of the comments provided. The quality of responses can be improved by rewording questions which were poorly understood and by conducting the survey soon after the capelin fishery is closed.

## Acknowledgements

The development of the questionnaire benefited greatly from suggestions by J. Carscadden, B. Slaney, B. Neis, A. -M. Powers, the MUN contact group chaired by L. Felt, and by several fishers. A. Murphy, L. Chafe, and J. Mitchell conducted the telephone interviews. I am also indebted to D. Lawrence of Statistics Canada for advice.

## SURVEY QUESTIONNAIRE OF FIXED GEAR CAPELIN FISHERS

Questions on Abundance.

1. Using a scale of 1 to 10 with 1 being the lowest and 10 the highest how abundant (ie numbers of fish) were capelin in your area in 1994?
$\begin{array}{lllllllllll}\text { Ans: } & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10\end{array}$
2. How abundant were capelin in 1994 compared to 1993 ?

Ans: $1 / 4 \quad 1 / 2$ same 2 X 5 X don't know
3. How would you describe the abundance of capelin compared to when you first started fishing capelin?
Ans: lower he same higher don't know
Questions on Spawning.
4. Approximately on how many beaches in your area do capelin usually spawn?

Ans: none don't know
5. Approximately on how many beaches did capelin spawn in 1994 ?

Ans: none don't know
If 'none' or 'don't know' go to Ques. 8
6. Compared to 1994 how many beaches did capelin spawn on in 1993?
Ans: more same less none don't know

7a. On a scale of 1 to 10 with 1 being low and 10 being high how intense was capelin spawning in your area in 1994 ?

| Ans. | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |

7b. What was the intensity of capelin spawning in 1994 compared to 1993 ?
Ans: lower same higher don't know
8. Did capelin spawn off beaches in your area in deeper water?
Ans: yes
no
don't know

If yes go to Ques. 9
If 'no' or 'don't know' go to Ques. 10
If no spawning on beaches or in deep water go to Ques. 14
9. Why do you think capelin spawned in deeper water in 1994 ?

Ans:

Appendix A - Continued
10. How often since you started fishing have you observed capelin spawning off beaches in deeper water?
Ans: every yr most yrs some times
rarely
never

11a. When did capelin first spawn in 1994 ?
Ans:
11b. Did spawning start at the same time in 1993 as in 1994?
Ans. later same earlier don't know
12a. When did capelin finish spawning in 1994 ?
Ans:
12b. Did spawning finish at the same time in 1993 as in 1994 ?
Ans: later
same
earlier
don't know
13. How does the timing of capelin spawning (beginning and end) in 1994 compare to when you first started fishing capelin?
Ans: later same earlier don't know
Questions on Fishery Data.
14. Did you intend to fish for capelin in 1994?

Ans: Yes No
If 'yes' continue if 'no' go to Ques. 26
14b. Did you set your fishing gear or go out and search for capelin in 1994 ?
Ans. Yes
No
If 'yes' continue if 'no' go to Ques. 26
15a. What type of fishing gear did you use in 1994 ?
Ans: trap beach/bar seine purse seine
If a 'trap' go to Ques. 15b if other gear types go to Ques. 15d
15b. How many traps did you fish in 1994 ?
Ans: one two more than two
15 c . How much capelin does your trap(s) hold (ie maximum amount)?
Ans.
15d. Did you always fish this gear type or have you fished other types in the past?
If fished other types what were they?

```
Appendix A - Continued

Ans:
16. Approximately how much capelin did you and your crew land in 1994 ?

Ans: lbs
17. Approximately how much capelin (live or dead) did you and your crew discard (ie did not land or sell) in 1994?
Ans: lbs
If discarding \(>0\) continue if discarding is ' 0 ' go to Ques. 21
18. What percent of the discarded capelin do you think survived?
\(\begin{array}{llllllllllll}\text { Ans: } & 0 & 10 & 20 & 30 & 40 & 50 & 60 & 70 & 80 & 90 & 100\end{array}\)
19. Why were the capelin discarded? Please give reasons in order of importance.

Ans:
20a. How does the amount you discarded in 1994 compare to 1993 ?
Ans: less same more don't know
20b. How does the amount discarded in 1994 compare to all the other years you've fished capelin?
Ans: less same more don't know
21. While fishing capelin did you and your crew catch any other species (ie bycatch)?

Ans: yes no
If 'yes' continue if 'no' go to Ques. 26
22. What species were they and approximately how many of each?

Ans:
23. What was the condition of the bycatch when released?

Ans: alive some dead/some alive dead
24. How much of an effect do you think your bycatch of small cod (less than 17") in 1994 had on cod populations in your area?
Ans: none some significant very significant don't know
25. Why?

Ans.

Questions on Climate/Ocean Conditions.
```

Appendix A - Continued

```
26. Weather plays an important role in the biology of capelin. While overall weather patterns are similar over the entire island there are instances when local conditions may be different from average conditions. Please describe the weather in your area during the summer (June to early Sept) of 1994.
Ans: Winds:
Air Temperature:
Sun-Overcast:
27. Similar to the weather, ocean conditions can sometimes vary between areas. Please describe the general ocean conditions in your area during the summer (June to early Sept) in 1994.
Ans: Ice:
Stormy:
Water Temperature:

\section*{General Information}
28. In what year did you start fishing capelin?

Ans:
29. What is the length and capacity (how much capelin) of your vessel?

Ans:
30a. Have you always fished for capelin in the same location?
Ans: Yes No

If 'no' continue if 'yes' go to Ques. 31
30b. Where else have you fished capelin?
Ans.
31. How old are you?

Ans: less than \(25 \quad\) 25-39 40-55 over 55
32. Do you wish to receive a summary of the results of this survey when the analyses are completed?
Ans: yes no
33. If there is a capelin fishery in 1995 would you consider keeping a diary of your fishing activities in a capelin research logbook if asked?
Ans: yes no
34. Thank you for your patience and your time. Are there any comments you wish to make on the questionnaire or in general?
Ans:

\section*{Chapter 2}
The Inshore Capelin (Mallotus villosus) Fishery in NAFO Div. 3KL in 1994
by
Brian S. Nakashima
Science Branch
Department of Fisheries and Oceans P. O. Box 5667
st. John's, NF A1C 5X1

\section*{Introduction}

Reported landings in 1994 were 938 t in Div. 2J3KL compared to a market-based quota allocation of \(32,280 \mathrm{t}\). Landings were the lowest in the series (Table 1). A summary of the 1994 commercial capelin roe fishery, the age composition of the catch, trends in mean lengths and weights, and the information compiled in research logbooks given to commercial fishers is presented.

\section*{Materials and methods}

Commercial samples were collected by fishers and at fish plants by reliable collectors at the rate of two samples per gear type per week per statistical section (Fig. 1). From each sample, length, sex, and maturity stage were measured on 200 fish and a stratified sample of 2 otoliths per sex per \(1 / 2 \mathrm{~cm}\) length was taken for ageing.

Research logbooks were mailed to 44 purse seine and 133 fixed gear licensed fishers residing in Div. 3KL. Of these four purse seine and nine fixed gear logbooks have been returned to date. Twenty-five purse seiners and 90 fixed gear fishers in the programme did not fish in 1994. Information was not available for 15 purse seiners and 34 fixed gear fishers. The records of five fishers who fished traps and three with purse seine were used in this analysis. Records from beach seines were not presented in this report.

Fishing effort was estimated from research logbook records for both purse seines and capelin traps. Fishing days for purse seines are defined as those days when the vessel was out searching for capelin schools. Similarly fishing days for traps were defined as those days (24-hour basis) when the trap was fishing. In 1994, two trap fishers fished one trap each and three fishers fished two traps per trap crew. Trap logbook records were only available from the Southern Shore and St. Mary's Bay areas in 1994.

Mean lengths and weights for Div. 3 K and 3 L were estimated from commercial samples for each gear type and combined weighted by landings.

Results and discussion

\section*{The Inshore Fishery}

The inshore fishery in Div. 3KL is prosecuted by purse seines, capelin traps, and beach seines and has been regulated by quota management since 1982. Quotas by area and gear type are presented in Appendix A. Opening and closing dates varied considerably in 1994 (Appendix B). Monitoring programs in most areas were set up to close and reopen areas to fulfill market demands. Small fish (50 females/kg) was the main reason areas were never opened or
opened for brief periods (Appendix B). Area and gear sector allocations were not reached in 1994.

\section*{Age Composition of the Commercial Catch}

In 199411 biological samples were processed from commercial catches throughout Div. 3KL (Table 2). The mean number of otolith pairs per sample was less in Div. 3 K than in Div. 3L (Table 2).

The 1994 catch in numbers was dominated by the 1991 year-class as three-year-olds (46.3\%) followed by the 1992 year-class as two-year-olds (31.1\%) and the 1990 year-class as four-year-olds (19.7\%) (Table 3). Some interesting patterns arise. The 1991 year-class was suspected to be poor due to poor larval emergence patterns and appears to be as three-year-olds despite the high proportion of mature two-year-olds in 1993 (Nakashima and Winters 1995).

\section*{Mean Lengths and Weights in Div. 3K and Div. 3L}

In Div. 3 K (Fig. 3) there is no apparent trend in mean length at age 2. For ages 3 and 4 and all ages combined, there has been a general decline in the mean length from 1991-93 followed by an increase in 1994 especially evident at age 3.

The mean lengths-at-age in Div. 3L during 1981 were small (Fig. 4). For age 2, the 1982-90 mean lengths did not vary much or exhibit any trends then declined slightly during 1991-93 with an increase in 1994. For ages 3 and 4, mean lengths showed only small variations between 1982 and 1988 but have shown a gradual decline since then. For all ages combined, the decline seemed more severe during 1991 and 1992 with an apparent increase in 1994.

The interpretation of the estimated lengths-at-age in 1994 must be considered with care due to the very small sample sizes involved and the limited spatial and temporal distribution of the samples.

Age 2 females have contributed more to the spawning stock than age 2 males especially since 1991 (Table 3). In most years, Div. 3L two-year-old females were smaller than Div. 3 K females. This was true since 1991 when age 2 fish made a significant contribution to the spawning stock and contributed to the decline in overall mean size (all ages combined) of females in the population. Females in Div. 3L at age 3 were only slightly smaller than females at the same age in Div. 3 K except in 1992 when the difference was larger. At age 4, females in Div. 3 L and 3 K were approximately the same length until 1993 when Div. 3L females were smaller than in Div. 3K.

The sample mean weights from the inshore fishery are given in Table 4. For Div. 3 K the sample mean weights-at-age are only available since 1984.

\section*{Research Logbook Survey}

The predominant reasons reported by fishers for discarding capelin in 1994 were small females with redfeed also important to traps in St. Mary's Bay (Table 5).

Discarding as a percentage of landings for traps in 1994 in Div. 3L was \(67 \%\) of the Southern Shore and \(293 \%\) in St. Mary's Bay (Table 6). For purse seines most of the catch was let go (Table 7). Discarding rate was the highest since 1981 when estimates were available for traps (Table 8) and for purse seines (Table 9). According to information provided in the research logbooks \(99 \%\) of trap and \(100 \%\) of purse seine discards were released alive at sea. In the analyses presented in Tables 6-9 discards are defined as all capelin caught but not landed by the fishers who caught them and includes both live and dead fish. The amount of reported discarding in 1994 was low because catches and fishing effort were negligible.

The average fishing effort in 1994 decreased for traps and for purse seiners in 1994. Traps averaged 7.5 fishing days and were hauled 9.8 times in 1994 compared to 5.1 days and 11.1 hauls per trap in 1993 (Table 8). Purse seiners had 2.7 searching days and made 13 sets per vessel in 1994 compared to 8.0 searching days and 13.9 sets in 1993 (Table 9).

Catch/effort (CPUE) estimates were available since 1981 for capelin traps and for purse seines (Tables 8 and 9). All catch rates are very low in 1994 except for the catch/set for purse seines. The 1994 CPUEs are not comparable to previous years and may not be indicative of stock status due to low numbers of completed research logbooks and responses limited to a very small portion of the island. Trap catch rates in 1994 could not be analyzed as suggested by Winters (1994).

Conclusions
Because many areas were closed to fishing and others only opened for short periods of time, the interpretation of the 1994 commercial fishery data (commercial samples and research logbooks) must be considered anomalous. These circumstances emphasize the value of having fishery independent evaluations of stock status.

\section*{Acknowledgements}

We especially are grateful to the fishers who have diligently reported their fishing activities in our research logbooks. The inshore commercial sampling programme was organized by
P. J. Williams. Samples were processed by the technical staff of the Pelagic Fish Section. Otoliths were aged by P. G. Eustace. M. Y. Hynes assisted in the preparation of the manuscript.

\title{
Results of the 1994 CASI Aerial Survey of Capelin (Mallotus villosus) Schools
}
by
Brian S. Nakashima
Science Branch
Department of Fisheries and Oceans
P. O. Box 5667
st. John's, NF A1C 5X1

\section*{Introduction}

Areal estimates of capelin (Mallotus villosus) schools conducted since 1982 have been used as an index of inshore abundance of mature capelin in NAFO Div. 3L (eg. Nakashima 1994). From 1982 to 1989 school areas were measured from aerial photographs (Nakashima 1990). Since 1990 school areas have been estimated from digital imagery data collected by the Compact Airborne Spectrographic Imager (CASI). The digital images collected using the CASI and processed by image classification techniques were easier to interpret than aerial photographs (Nakashima et al. 1989, Borstad et al. 1990, Borstad et al. 1992).

This report presents the results of the 1994 CASI aerial survey.

Materials and methods

\section*{Instrument Operation}

The CASI is an imaging spectrometer which uses a two dimensional (612 \(x\) 288) charge couple device (CCD) and a diffraction grating to collect image and spectral data. The CASI operates in the range of \(423-946 \mathrm{~nm}\). A 512 pixel width spatial image is formed in "pushbroom" fashion by reading out the cross track information as the aircraft moves forward. The remaining elements are used to obtain dark and electronic offset reference values. The spectral resolution of each element is 1.8 nm and the spatial resolution of each element is 1.2 rad . Integration times are a function of ambient light levels, aircraft speed, and band selections.

In spatial or imaging mode the CASI operates like other pushbroom imagers except that band widths, positions and number are programmable during the flight. High spatial resolution imagery is collected in several spectral bands which can be programmed as narrow as 1.8 nm or wider. Different spectral band widths were used for sunny days and for overcast days:
\begin{tabular}{lcccr} 
& \multicolumn{4}{c}{ Band widths } \\
\cline { 2 - 5 } \begin{tabular}{c} 
Light \\
Condition
\end{tabular} & 1 & 2 & 3 & 4 \\
\hline Overcast & \(450-510\) & \(525-591\) & \(640-691\) & \(735-755\) \\
Sunny & \(476-501\) & \(525-590\) & \(651-671\) & \(744-755\)
\end{tabular}

These bands selections were used in 1993 (Nakashima 1994).

\section*{Survey Method}

Particulars of previous aerial surveys including aircraft type, equipment used, survey time, and altitudes flown are listed in Table 1. Weather conditions in 1994 were almost always favourable allowing CASI surveys to be flown at 1220 m to obtain a swàth width comparable to aerial photographs taken at 457 m . The 1994 survey covered three transects as often as possible; the inside of Trinity Bay from Masters Head to Hopeall Head, the outside of Conception Bay from Bay de Verde to Harbour Grace Islands, and the inside of Conception Bay from Bryant's Cove to Portugal Cove (Fig. 1).

During each flight capelin schools were detected by experienced spotters prior to digital recording of the area. If there was any doubt as to the presence of schools imagery was collected and examined later. Flight tapes and survey records were examined following each flight or shortly thereafter to assess the quality of the imagery.

Analytical Methods
CASI imagery data were transferred to a PC-based image processor for classification and analysis. Data were calibrated and set up as PCI image files. An algorithm, first tested in 1989 to estimate school areas from the digital survey data (Borstad et al. 1990), was used to analyze the 1994 data. Schools on the imagery were identified by an experienced observer. For each transect flown, the mean and median surface areas of capelin schools, the total number of schools, and the total surface area of all schools observed along a transect were estimated.

The school surface area index for each year was estimated by summing the highest total school surface area observed on each of the three transects. I assumed that the peak in school surface area was indicative of inshore abundance for each transect for that year (Nakashima 1985). In transect three there were two occasions when the survey had to be spread out over two days due to cloud cover over part of the survey area on both days. Visual inspection of the area not imaged indicated that on both occasions the distribution of schools was similar on adjacent days.

I did not adopt the method suggested by Winters (1994) because the problem of multiple counting of the same schools over several days was not resolved and the survey time used included transit time between the airport/seaport and transects. Survey times reported in Table 2 are best estimates of actual survey time.

Results añ Discussion
In 1994, the aerial survey provided frequent coverage of both Conception Bay transects and Trinity Bay. Complete data were collected in Trinity Bay eight times (Table 2a), along the outside transect of Conception Bay six times (Table 2 b ), and the inside of Conception Bay ten times (Table 2c). A visual reconnaissance survey flight on July 2 found few capelin schools in the survey area (Tables 2a, b, c). Four days (July 11, 24 and 25 and August 4) were not flown because of poor weather conditions. In Trinity Bay the highest school area estimate was observed on July 15 (Table 2a). In Conception Bay the highest total for both transects occurred on July 12-13 (Tables 2b, c). The total school surface area taken from the highest estimates in Conception and Trinity Bays was \(675,727 \mathrm{~m}^{2}\) which is the second highest in the series (Table 3, Fig. 2). The estimate in Trinity Bay was the highest ever observed, whereas the school area in Conception Bay was the second lowest excluding the 1991 estimates (Table 3, Fig. 2). The index in 1994 was dominated by the presence of several large schools in Trinity Bay (Fig. 3).

\section*{Acknowledgments}

The CASI data were collected by Geomatic Technologies Incorporated, St. John's, Nfld. School counts and area measurements were completed by Borstad Associates Ltd., Sidney, B.C. I am especially grateful to R. Linehan for assistance during the flights. M. Y. Hynes assisted in the preparation of the manuscript.

Results from an Acoustic Survey for Capelin (Mallotus villosus) in NAFO Divisions 2J3KL in the Autumn of 1994
by
D. S. Miller

Science Branch
Department of Fisheries and Oceans
P. O. Box 5667

St. John's, NF A1C 5X1

\section*{Introduction}

From 1981 to 1992, east coast Newfoundland and Labrador capelin stocks have been surveyed acoustically by a spring (AprilMay) survey of Division 3 L and an autumn (October-November) survey of Division 2 J 3 K . In 1993, these surveys were combined into a combined \(2 J 3 K L\) survey covering the all the area covered by the separate surveys of the \(1981-1992\) period. Estimates of stock biomass from acoustic surveys declined dramatically in 1990 for the Division 2J3K survey and in 1991 for the Division 3L survey.

Methodology
The survey was conducted from the research vessel Gadus Atlantica during the period September 12 to October 29, 1994. The depth sounder and transducer used in 1994 changed in frequency to 38 kHz compared to the 49 kHz frequency used on all previous surveys. The same value for target strength ( \(-34 \mathrm{~dB} / \mathrm{kilogram}\) ) was used as for the past surveys as the change in sounder frequency is not expected to have any signifigant effect on target strength (George Rose, pers. comm.). A Biosonics ES2000 receiver was used with a Instruments Inc. S14 transmitter. A 38 kHz dual beam transducer was used in single beam mode and was mounted in a towed body that was deployed at a depth of about eight meters astern and abeam of the starboard side of the vessel. The acoustic system was calibrated at the beginning, during, and at the end of the survey. The geometric mean of the combined source level /receive sensitivity measurements from each calibration was used to integrate the data. Calibration parameters used were as follows:

Calibration date: September 11 October 13 November 1
Combined source level/ 63.80dB 64.68dB 64.01dB
receive sensitivity:
Geometric mean=64.18dB

Fixed receiver gain:
TVG gain:
Attenuation coefficient:
Pulse length:
Bandwidth:
Average beam pattern:
Target strength:
0.63625 dB
\(20 \log R\)
\(0.012 \mathrm{~dB} / \mathrm{m}\)
0.8 millisecs
2.5 kHz
\(-28.18 \mathrm{~dB}\)
\(-34 \mathrm{~dB} / \mathrm{kg}\)

The survey design and area covered was identical to that in 1993 with the exception of the two southern most strata which had to be eliminated because of time lost due to equipment problems at the beginning of the survey.

Fishing sets were made on an opportunistic basis throughout the survey. It was attempted to have at least one set for each twelve hour watch and at least one set for each transect. For those midwater trawl sets that contained capelin, a random sample of 200 capelin was obtained for length, sex, and maturity observations and a stratified age sample was selected from each length/sex/maturity sample. Length composition and an age/length key was constructed for each stratum from the samples obtained in that stratum. As an acoustic estimate of biomass was made for stratum \(H\) but no biological sampling was carried out in that stratum, samples from the adjacent strata (G and I) were combined to estimate the length and age composition.

\section*{Results}

Figure 1 Shows an outline of the strata that were surveyed along with acoustic transects and fishing set locations. Figure 2 shows contoured capelin densitiy from estimates of acoustic density for each 3.1 kilometer segment of survey track. When compared to a similar plot from the 1993 survey (Miller, Chapter 6 in Carscadden 1994), it is evident that the occurrence of capelin in Divisions 2J3K is reduced from that observed in 1993 and has increased in Division 3L, particularily in the south.

Table 1 provides the biomass estimate and acoustic estimation parameters for each stratum from the survey. Stratum \(K\) is equally divided by the boundary line between NAFO Divisions 3 K and 3 L so the biomass estimate for this stratum was split equally between 3 K and 3 L .

Table 2 provides the acoustic parameters and the biological sampling of capelin for each transect in the survey. Catches from midwater trawl sets in strata \(A-F\) indicated that capelin were not present in this area.

Tables 3 and 4 provide the acoustic estimate broken down by age groups into numbers and biomass respectively. For purposes of comparison with the surveys from the 1981-92 period when distinct surveys were carried out in Divisions \(2 J 3 \mathrm{~K}\) and 3L, the 1993 and 1994 estimates are shown for Division \(2 J-3 K\), Division 3 L and Divisions 2J3KL in total. The 1994 age distribution is similar to that observed in 1993 with one year old capelin predominant in Division 3 L and two year olds predominant in Divisions \(2 J 3 \mathrm{~K}\). Overall abundance of \(2+\) capelin declined in 1994 compared to 1993.

Table 5 provides age composition and mean length at age by survey stratum. Larger (3+) capelin occurred almost exclusively in Divisions \(2 J-3 \mathrm{~K}\) while one year old 1992 yearclass capelin were predominant in Division 3 L .

\title{
Results from Monitoring Six Spawning Beaches on the Northeast Coast of Newfoundland
}
by

\author{
B. S. Nakashima and G. H. Winters Science Branch Department of Fisheries and Oceans P. O. Box 5667 \\ St. John's, NF A1C 5X1
}

\section*{Introduction}

In 1990 we monitored spawning times, egg deposition and development, larval emergence and various environmental variables (eg. sunlight hours, wind direction and speed, air temperature, water temperature, precipitation, beach sediment temperatures, beach disturbance) on two capelin spawning beaches located at Arnold's Cove in Div. 3Ps and at Bellevue Beach in Div. 3L (Fig. 1). The number of sites was expanded in 1991 to include five more beaches in Div. 3KL at Chapels Cove, Eastport, Cape Freels, Twillingate, and Hampden (Fig. 1). In this report we present information on age compositions, fish lengths, spawning times, egg deposition estimates, and estimates of emerging larvae from the six beaches located in Div. 3KL.

Materials and Methods

\section*{Adult Samples}

Random samples of 25 males and 25 females were collected at each beach whenever significant spawning had taken place. Fish were measured for length and weight and otoliths removed for age determination. In 1990 only females were collected from Bellevue Beach.

Egg Samples
During low tide conditions egg samples in beach sediments were collected every time substantial spawning had taken place and once every 48 hours until eggs were no longer on the beach (<500 eggs per sample). Nine samples subdivided into three samples per tidal zone (low tide, mid tide, high tide) were collected each time. A steel sediment corer \((6.5 \mathrm{~cm}\) internal diameter) was used to collect each sample as described in Nakashima and Slaney (1993). Samples were preserved in \(4 \%\) formalin and seawater solution buffered with sodium borate. To separate eggs from sediments, samples were immersed in \(2 \% \mathrm{KOH}\) solution for \(24-36 \mathrm{hr}\). To estimate egg abundance, eggs were counted by subsampling with a whirling vessel (Pitt 1965) or by using a volume displacement technique.

At each sampling at least 50 eggs were placed in stockard's Solution (Bonnet 1939) to fix and clear the eggs. Stages I-II which include eggs from fertilization to the formation of the blastula accounts for egg development up to the first 1.5 days according to Fridgeirsson (1976).

\section*{Egg Density}

The ratio of stage \(I-I I\) eggs to all eggs in the stockard's sample was used to estimate the number of Stage I-II eggs occurring in each beach core sample assuming that these eggs had been deposited recently on the beach. The daily average density of Stage I-II stage eggs in all cores per tidal zone on a given beach was then estimated. An average beach density as assumed to be the
mean of the three tidal zones. Total egg density per beach was the sum of the daily average beach density estimates of stage I-II eggs.

\section*{Larval Emergence}

Newly emerging larvae were collected in the intertidal zone at high tide water conditions generally twice a day. A \(165 \mu \mathrm{~m}\) plankton net was towed parallel to the beach, rinsed, and the contents preserved in \(4 \%\) formalin and seawater solution buffered with sodium borate. Two tows were conducted each time. Larvae were enumerated by subsampling when sample size was large using splitting techniques. Larvae were categorized into 'good' and 'bad' condition larvae based on visual inspection. Larval density was expressed as larvae per \(\mathrm{m}^{3}\). Total production of larvae per beach was the sum of all high tide estimates in a given year.

Results and Discussion

\section*{Age Composition}

Age compositions from samples of spawning fish from 1990 to 1994 indicate that age 3 fish dominated in 1990, 1993 and 1994 and age 4 in 1991 and 1992 (Table 1). Samples collected over the entire spawning season in 1994 may be more representative of the spawning population than commercial samples which were primarily from one area.

\section*{Egg Density}

Egg density was based on four complete (1991-94) and one incomplete (1990) survey and was high in 1991 and 1993 and low in 1992 (Table 2). Egg density on the monitored beaches was very low in 1994 with no spawn being deposited on the beach in Cape Freels. Unfortunately, there are no estimates from these beaches in the 1980's when spawning times were earlier. Consequently, there are insufficient years to adequately assess trends in the estimates.

Larval Emergence
For the four years available with full coverage 1992-93 appears to have higher production of larvae than 1991 or 1994 (Table 2). Although only Bellevue Beach was monitored in 1990 larval production relative to later years at Bellevue Beach was relatively high (Fig. 2).

Spawning Time
The spawning period was noticeably short at Chapel Cove, Twillingate, and Eastport in 1994 compared to other years, whereas Hampden had an extended spawning season (Table 2). Spawning tended to be earlier and shorter at beaches where water temperatures were warm and drawn out where water temperatures were cooler.

\title{
Changes in Distribution of Capelin in Divisions 2J3KL During Autumn, as Inferred from Cod Stomach Contents
}

\section*{by}

\author{
G. R. Lilly \\ Science Branch \\ Department of Fisheries and Oceans \\ P. O. Box 5667 \\ St. John's, NF A1C 5X1
}

\section*{Introduction}

The occurrence of capelin in the stomachs of cod caught in the offshore environment of Divisions \(2 J 3 \mathrm{KL}\) during the autumn (Lilly 1987, 1991, 1994b) provides a source of information on capelin distribution and relative abundance which is independant of the information obtained from capelin acoustic surveys and the offshore capelin fishery. During the period 1980-1988, the average quantity of capelin in cod stomachs, expressed as a stomach fullness index, was moderate to high in two broad regions: (1) northern and western Divisions \(2 J 3 K\) (Hamilton Bank, western Belle Isle Bank, and the inner shelf off northeastern Newfoundland) and (2) northern Division 3L (northern and northeastern slopes of Grand Bank) (Fig. 1). In many years, such as 1984 and 1985 (Fig. 2), the capelin in Divisions 2 J 3 K were primarily on Hamilton Bank and along the coastal shelf off southern Labrador and northeastern Newfoundland, whereas in some other years, notably 1986 and 1987 (Fig. 3), they were more aggregated on the central Northeast Newfoundland Shelf. The capelin in Divisions \(2 J 3 K\) experienced a pronounced shift from the northwest to the southeast during the early 1990s. The apparent distinction between a Division \(2 J 3 \mathrm{~K}\) group and a Division 3L group was less clear in 1990 and absent in 1991 and 1992 (Fig. 4).

These changes in capelin distribution, as inferred from examination of cod stomach contents, are similar to those revealed from other sources, including the by-catches of capelin during the autumn bottom-trawl surveys (Lilly and Davis 1993). The latter have been examined during the annual capelin assessment meetings since 1989 to determine if there is evidence of substantial quantities of capelin outside the area covered by the Canadian acoustic surveys (Carscadden et al. 1989; Carscadden et al. 1990; Miller and Lilly 1991; Lilly 1992, 1994a). The information from cod stomach contents has not been presented routinely to the annual capelin assessment meetings because the meetings have generally been held early in the year, before the cod stomach content data have become available. Nevertheless, such information may be of value in assessing historical patterns in the distribution and relative abundance of capelin.

This chapter provides information on the occurrence of capelin in cod stomachs in Divisions 2J3KL during the autumn of 1993.

\section*{Materials and Methods}

Cod stomachs were collected during the autumn bottom trawl survey in 1993 (see Lilly 1994a for details of the survey), and examined as described in Lilly (1994b).

To study the geographical distribution of capelin, it was assumed that the average quantity of capelin in the stomachs of cod collected at a specific locality reflected the relative abundance of capelin at that locality (Fahrig et al. 1993). The average quantity of capelin in the stomachs of the cod in a specified sample was expressed as a mean partial fullness index:
\[
P F I_{c}=\frac{1}{n} \sum_{j=1}^{n} \frac{W_{c j}}{L_{j}^{3}} * 10^{4}
\]
where \(W_{c j}\) is the weight ( \(g\) ) of capelin in fish \(j\), \(L_{j}\) is the length (cm) of fish \(j\), and \(n\) is the number of fish in the sample. This index is based on the assumption that stomach capacity is a power function of length, and is analogous to Fulton's condition factor (body weight/length \({ }^{3}\) ). For simplicity, the present analysis was restricted to cod within the \(36-71 \mathrm{~cm}\) length range, and all cod within this range were pooled. Cod smaller than about 30-35 cm cannot feed on the largest capelin and cod larger than about 70 cm tend to feed to an increasing extent on groundfish and crabs (Lilly 1991).

The geographic distributions of cod catches and capelin in cod stomachs ( \(\mathrm{PFI}_{\mathrm{c}}\) ) are presented in expanding symbol plots in order to provide visual information on annual changes in the spatial distribution of fishing stations, the among-station variability in cod catch and \(\mathrm{PFI}_{c}\), and the relationship between fish distribution and bathymetry. This presentation also permits station-by-station comparison of the cod catch and the quantity of capelin in cod stomachs.

Results and Discussion

\section*{Distribution}

Catches of cod during autumn 1993 were very small, with the exception of a few moderate catches near the shelf break just south of the \(3 \mathrm{~K} / 3 \mathrm{~L}\) boundary (Fig. 5). This greatly limited the value of cod as a sampling tool for capelin.

Capelin were found in greatest quantities in the stomachs of those cod caught in southeastern Division 3 K and in northern Division 3L (Fig. 5). The northern limit of the occurrence of capelin in cod stomachs in large quantities was approximately the middle of Funk Island Bank, which is further south than in any previous year. The lack of a distinction between a Division 2 J 3 K group and a Division 3L group has continued.

The distribution of capelin, as inferred here from cod stomachs, is similar to that revealed by the by-catches of capelin during the survey (Lilly 1994a). However, for Division 3K, the stomach content data revealed capelin primarily in the southeastern quadrant, whereas the by-catches were largest in the northern and central areas (especially the western flank of St. Anthony Basin, the flanks of the southern half of Funk Island Deep, and the saddle between Belle Isle Bank and Funk Island Bank).

\section*{Potential indices of capelin abundance}

The intensity of feeding by cod on capelin may be positively correlated with capelin abundance ( Lilly 1991; Fahrig et al. 1993). Potential indices of capelin abundance are (1) percentage occurrence (the percentage of stations in which capelin were found in cod stomachs) and (2) average \(\mathrm{PFI}_{c}\) (the average quantity of capelin in cod stomachs, expressed as the mean of station \(\mathrm{PFI}_{\mathrm{c}}\) values). In Division 2 J 3 K , the percentage occurrence (48\%) was just below the median of \(52 \%\) and the average \(\mathrm{PFI}_{\mathrm{c}}\) (1.03) was above the median of 0.91 but far below the maximum of 1.95 (Table 1). In Division 3L, both the percentage occurrence (64\%) and the average \(\mathrm{PFI}_{\mathrm{c}}\) (1.29) were the maximum values in their respective time-series.

The value of these simple statistics as potential indices of capelin abundance was diminished by a change in survey design, which occurred in 1991, and the reduction in cod distribution, which has become increasingly dramatic since 1989. An adjustment for the change in survey design could be applied, using the procedure adopted for the capelin by-catch data (Lilly, this meeting). However, an appropriate adjustment for inadequate spatial coverage (that is, the absence of cod from many strata) is not readily apparent. There is also a concern about the potential influence of the high proportion of small cod catches. It has been demonstrated that there is a tendency for large \(\mathrm{PFI}_{\mathrm{c}}\) values to be found only in cod obtained from small catches, whereas individual cod taken from large catches tend to have small \(\mathrm{PFI}_{\mathrm{c}}\) values (Lilly 1994b). Therefore, average \(\mathrm{PFI}_{\mathrm{c}}\) values may be inflated in recent years. It is therefore recommended that the cod stomach content data not be used to provide a potential index of capelin abundance. If these data are to be explored as potential indices, there should also be consideration of that portion of the stomach contents which was recorded as unidentified fish (Lilly 1991). The ratio of identified fish to unidentified fish varied among years.

The possibility of using the stomach contents of Greenland halibut to identify changes in capelin distribution and to provide an index of capelin abundance should be investigated. Medium-sized

Greenland halibut in Division \(2 J 3 \mathrm{~K}\) feed almost exclusively on capelin in the autumn (Bowering and Lilly 1992) and have not experienced the severe reduction in distribution which has been observed in cod.

\section*{Introduction}

Capelin are frequently caught during bottom trawl surveys directed toward demersal fish off southern Labrador and eastern Newfoundland. The distribution and magnitude of capelin catches from the surveys in Divisions \(2 J\) and \(3 K\) during the autumns of 1978-93 have been compared with geographic coverage by acoustic surveys for capelin to help determine whether coverage by the acoustic surveys has been adequate (Carscadden et al. 1989; Carscadden et al. 1990; Miller and Lilly 1991; Lilly 1992, 1994a) and to provide supporting data on changes in capelin distribution (Lilly and Davis 1993). This chapter continues this series of comparisons with data from the bottom trawl survey in autumn 1994. In addition, the broader-scale distribution of capelin in autumn 1994 is examined with catch data from bottom trawl surveys on Grand Bank (Div. 3LNO). These surveys provide information on capelin distribution south of the \(上 r a s\) covered by the acoustic survey, which was restricted to Divisions \(2 J\) and 3 K in 1981-1992 and extended to Division 3L in 1993 and 1994.

There has also been interest in exploring the extent to which the frequency of occurrence of capelin in bottom trawl catches might provide an index of capelin abundance. This chapter provides information on the frequency of occurrence of capelin in Division 2J3K (1978-1994) and Division 3L (1981-1994, excluding 1984), where the frequency of occurrence is adjusted to take into account the high proportion of sets allocated to certain strata in each year beginning in 1991. Estimates of biomass from areal expansion of mean catch per tow are also provided.

Materials and Methods

\section*{Surveys}

Capelin were caught during random-stratified bottom trawl surveys designed to assess the biomass of demersal fish during October-December 1978-1993 (Table 1) and 1994 (Table 2). All surveys in Divisions 2 J and 3 K were conducted with the 74 m stern trawler R.V. 'Gadus Atlantica'. Surveys in Division 3 L were conducted with the 51 m side trawler R.V. 'A. T. Cameron' and the sister 50 m stern trawlers R.V. 'Wilfred Templeman' and R.V. 'Alfred Needler'. There were no autumn surveys in Division 3L in 1978-1980 and 1984. The 'Gadus Atlantica', 'Wilfred Templeman' and 'Alfred Needler' deployed an Engel-145 trawl, whereas the 'A. T. Cameron' deployed a Yankee 41-5 trawl. In all instances, a 29 mm meshliner was inserted in the codend. Tows were made at 3.5 knots for 30 min at each fishing station, and catches from the few tows of duration other than 30 min were appropriately adjusted. No adjustments were made for possible between-vessel differences in catching efficiency. Additional details regarding areas and
locations of strata and changes in survey pattern are provided by Bishop et al. (1994), Lilly and Davis (1993) and Bishop (1994). The most notable change in survey coverage was the addition of depths between 100 and 200 m in northwestern Division 3 K (St. Anthony Shelf and Grey Islands Shelf) in 1984 and subsequent years. Fishing in all Divisions and years was conducted on a 24-h basis.

Distributions
The distribution of capelin is presented in expanding symbol plots, as opposed to contour plots generated from modelling of the catches, in order to provide visual information on the spatial distribution of fishing stations, among-station variability in catch of capelin, and the relationship between capelin catches and bathymetry.

\section*{Estimation of frequency of occurrence of capelin}

The frequency of occurrence of capelin in the bottom trawl catches is simply the number of occurrences expressed as a percentage of the number of sets. The number of sets assigned to each stratum was approximately equal to stratum area in 1978-1990, but in subsequent years a proportionally higher number was assigned to sets in which the variance of the cod catch had been high for some years previous. An adjusted percentage occurrence was calculated as
\[
O_{a d}=\frac{\sum_{i=1}^{m}\left(\frac{n C_{h}}{N_{h}} \times 100\right) A_{h}}{\sum_{h=1}^{m} A_{h}}
\]
where \(n C_{h}\) is the number of sets in which capelin were caught in stratum \(h, N_{h}\) is the number of sets in stratum \(h ; A_{h}\) is the area of stratum \(h\), and \(m\) is the number of strata fished.

Estimation of capelin biomass and numbers
The biomass of capelin in each stratum was estimated as
\(W_{h}=\frac{A_{h} \sum_{i=1}^{n_{h}} W_{h i}}{a n_{h}}\)
where \(W_{h i}\) is the weight ( \(k g\) ) of capelin in set \(i\) ( \(i=1,2, \ldots, n_{h}\) ) in stratum \(h\), and \(a\) is the area sampled by a standard tow (estimated to be \(4.58 \times 10^{4} \mathrm{~m}^{2}\) ). The biomass in each Division was obtained by summing over strata. Population abundance was estimated in the same way.

Results
Surveys in 1994
Divisions 2J3K
Capelin were recorded at \(46 \%\) of the 237 fishing stations conducted at depths of 750 m or less (Table 3). This is the third highest frequency of occurrence in the period 1978-1994. Catches were moderate compared to previous years ( 95 th percentile \(=10 \mathrm{~kg}\); maximum \(=30 \mathrm{~kg}\) ) (Table 3 ).

Very few capelin were caught on Hamilton and Belle Isle Banks and near the coast off southern Labrador and northeast Newfoundland (Division \(2 J\) and western Division 3 K ) (Fig. 1). Largest catches were in Funk Island Deep, on western Funk Island Bank, and southeast of Funk Island Bank. In general, the distribution in 1994 was similar to that observed in 1991-1993 (Lilly 1992, 1994a; Lilly and Davis 1993).

All of the large catches in Divisions \(2 J\) and 3 K occurred within the area covered by the acoustic survey, although several near the southern corner of Division 3 K were very close to the boundary of the survey (Fig. 1).

Division 3L
Capelin were recorded at 42\% of the 200 stations (Table 2). This is the third highest frequency of occurrence in the period 1985-1994 (Table 4). Catches were small compared to earlier years (95th percentile \(=1 \mathrm{~kg}\); maximum \(=2 \mathrm{~kg}\) ) (Table 4).

Capelin were caught in northern and northeastern Division 3L and in the Avalon Channel in western Division 3L (Fig. 1,2). There were no catches on the plateau of Grand Bank. There were also no catches in the extreme northeast of Division 3L, where catches had been taken in 1992 and 1993.

\section*{Division 3NO}

Capelin were recorded in just \(3 \%\) of the 148 stations (Table 2). Small catches occurred primarily on Whale Bank and the southwestern slope of Grand Bank (Fig. 2).

\section*{Frequency of occurrence of capelin in bottom trawl surveys}

The adjustment of the frequency of occurrence, to take into account the allocation of a relatively large number of sets to certain strata in 1991-1994, did not substantially change the estimate of the frequency of occurrence, except in Division 3L in 1992 (Table 5, Fig. 3). Increased sampling intensity in strata with a high frequency of occurrence of capelin was usually offset by increased sampling intensity in strata with a low frequency of occurrence.

In Division \(2 J 3 \mathrm{~K}\), the adjusted frequency of occurrence increased, with irregular fluctuations, from 20-35\% in the early 1980s to 40-50\% in the 1990s. Since 1985, the frequency of occurrence in Division 3 L has fluctuated more widely than in Division 2J3K. Low values of about \(20 \%\) in 1990-1991 were followed by high values of about 50\% in 1992-1993 and a decline to an intermediate level of about \(40 \%\) in 1994.

\section*{Estimates of abundance and biomass}

The minimum trawlable abundance and biomass were relatively high in 1979-1981 (Fig. 4), due almost entirely to a few very large catches on the plateau of Hamilton Bank (Carscadden et al. 1989). The values have fluctuated without trend since 1981.

Discussion
Capelin distribution
Bottom trawl surveys during the autumn of 1994 covered the area from southern Labrador (Division 2J) to the Tail of the Bank (Division 3NO). Largest catches of capelin were taken in central and southeastern Division 3 K . Small catches occurred in western Division 3 K and northern Division 3 L . Only a few very small catches were recorded in Division \(2 J\) and Divisions 3NO. As in 1991-1993 (Lilly and Davis 1993; Lilly 1994a), there was no clear distinction between capelin catches in southeastern Division 3 K and northern Division 3L. There is no evidence from these surveys that large quantities of capelin occurred outside the boundary of the acoustic survey in Divisions \(2 \mathrm{~J}, 3 \mathrm{~K}\) and 3 L , but several large catches were very close to the boundary in southeastern Division 3 K .

Comparisons between capelin distribution as observed during the acoustic survey and capelin distribution as inferred from the bottom trawl survey must be treated with caution because the bottom trawl survey did not start until the acoustic survey had finished and required about 6 weeks to complete. Thus, for any point in space, the duration between coverage by the two surveys could be as great as two months.

Capelin abundance
Neither the frequency of occurrence of capelin nor the estimates of capelin abundance and biomass have shown declines in the 1990s, compared with levels in the period 1982-1989. However, the extent to which either of these metrics may serve as indices of capelin abundance or biomass is not known. There has been no directed study of the relationship between catches in a bottom trawl and the density and behaviour of capelin in the immediate vicinity as measured and observed with hydroacoustics. It is possible that a large catch of capelin indicates a high density of capelin near the bottom, especially since large catches are frequently taken close together, often in sequential sets. However, the existence of such large catches does not necessarily indicate a high stock abundance. For example, the large catches of capelin on Hamilton Bank in 1979-1981 (Carscadden et al. 1989) contributed to high estimates of biomass at a time when estimates from both Russian and Canadian acoustic surveys indicated that the abundance of the \(2+3 \mathrm{~K}\) capelin stock was relatively low (Lilly 1994b). (It may be noted, though, that the estimate from the Canadian acoustic survey in 1981 was the third highest in the time-series).

A major difficulty with employing bottom trawl catches as indices of capelin abundance is inadequate understanding of the manner in which changes in capelin behaviour may change the vulnerability of capelin to a bottom trawl. For example, if capelin tend to stay near the bottom in both night and day, instead of migrating upward at night as has often been observed, then they may be captured more frequently and in greater numbers. Shackell et al. (1994) reported that the capelin found during the acoustic survey of Division 3L in spring 1992 were relatively deep and did not surface at night as in previous years. Such behaviour might result in inflated estimates of frequency of occurrence and biomass from a bottom trawl survey.

\title{
By-catches of Capelin During Spring Bottom-trawl Surveys in Divisions 3LNO
}
by
G. R. Lilly

Science Branch
Department of Fisheries and oceans
P. O. Box 5667
st. John's, NF A1C 5X1

\section*{Introduction}

Bottom-trawl surveys, designed to assess trends in the abundance and biomass of demersal fish, have been conducted in the spring in Divisions 3LNO since the early 1970s. By-catches of capelin during these surveys have been examined to illustrate that capelin occur outside the 200 mile limit in some years (Lilly and Carscadden 1986), but the surveys have not been used to provide information on changes in capelin abundance and biomass. This chapter provides plots of the geographic distribution of capelin by-catches in Divisions 3LNO during the years 1971-1994, and provides, for Division 3 L only, estimates of the frequency of occurrence of capelin in the trawl catches and estimates of the biomass of capelin as determined from areal expansion of the stratified mean catch per tow.

Materials and Methods

\section*{Surveys}

Capelin were caught during random-stratified bottom trawl surveys of Divisions 3LNO during April-June 1971-1994, excluding 1983 (Table 1). Surveys were conducted with the 51 m side trawler R.V. 'A. T. Cameron' and the sister 50 m stern trawlers R.V. 'Wilfred Templeman' and R.V. 'Alfred Needler'. The 'A. T. Cameron' deployed a Yankee 41-5 trawl, whereas- the 'Wilfred Templeman' and 'Alfred Needler' deployed an Engel-145 trawl. In all instances, a 29 mm meshliner was inserted in the codend. Tows were made at 3.5 knots for 30 min at each fishing station, and catches from the few tows of duration other than 30 min were appropriately adjusted. No adjustments were made for possible between-vessel differences in catching efficiency. Additional details regarding areas and locations of strata are provided by Doubleday (1981). Fishing in all Divisions and years was conducted on a 24-h basis.

Most surveys in Division 3L were conducted in May (Fig. 1). The 1971 survey was conducted entirely in June, and the 1981 survey was conducted primarily in April. The 1985 survey was part of special seasonal surveying, and was conducted by three consecutive trips of the 'Wilfred Templeman' over a period of 40 d . The median dates of fishing in 1993 and 1994 (June 1 and June 2 respectively) were the latest since 1971.

\section*{Distributions}

The distribution of capelin is presented in expanding symbol plots, as opposed to contour plots generated from modelling of the catches, in order to provide visual information on the spatial distribution of fishing stations, among-station variability in catch of capelin, and the relationship between capelin catches and bathymetry.

Estimation of frequency of occurrence of capelin
The frequency of occurrence of capelin in the bottom trawl catches is simply the number of occurrences expressed as a percentage of the number of sets. The number of sets assigned to each stratum was approximately equal to stratum area, with the provision that at least two sets be allocated to each stratum. To adjust for variation in line number of sets per unit areà, añ adjusted percentage occurrence was calculated as
\[
O_{a d}=\frac{\sum_{i=1}^{m}\left(\frac{n C_{h}}{N_{h}} \times 100\right) A_{h}}{\sum_{h=1}^{m} A_{h}}
\]
where \(\mathrm{nc}_{\mathrm{h}}\) is the number of sets in which capelin were caught in stratum \(h, N_{h}\) is the number of sets in stratum \(h, A_{h}\) is the area of stratum \(h\), and \(m\) is the number of strata fished.

Estimation of capelin biomass
The biomass of capelin in each stratum in Division 3L was estimated as
\[
W_{h}=\frac{A_{h} \sum_{i=1}^{n_{h}} W_{h i}}{a n_{h}}
\]
where \(W_{\text {hi }}\) is the weight (kg) of capelin in set \(i\left(i=1,2, \ldots, n_{h}\right.\) ) in stratum \(h\), and \(a\) is the area sampled by a standard tow (estimated to be \(4.58 \times 10^{4} \mathrm{~m}^{2}\) ). The biomass in the Division was obtained by summing over strata. The abundance of capelin was not estimated because numbers were not always recorded, especially in some years in the 1970s.

Results

\section*{Catches}

The frequency of occurrence of capelin during the surveys in Division 3L ranged from 8\% in 1978 to \(80 \%\) in 1986 (Table 1). During the period 1991-1994, the frequency of occurrence was steady at an intermediate level (48-52\%).

The size of the catches varied greatly (Table 2). The 95th percentile was 2 kg or less in 3 years and 100 kg or more in 5 years. The largest single catch was 544 kg in 1975. During the period 1991-1994, the 95th percentile was no greater than 5 kg in any year, and the maximum catch was 26 kg .

Distributions
Capelin were caught on the eastern, northern and northwestern slopes of Grand Bank, and toward the shelf break along the southwestern and southeastern parts of the bank (Fig. 2). Largest catches tended to occur in the eastern and southern Avalon Channel and on the adjacent northwestern slope of Grand Bank. Catches tended to be small in the deeper water of the Northeast Newfoundland Shelf north of Grand Bank. Only in a few years were moderate to large catches obtained on the plateau of Grand Bank.

The timing of the surveys may influence the pattern observed in the capelin catches. In 1981, when the survey was early, the largest catches in Division 3L tended to be in the northern Avalon Channel. In 1971, when the survey was late, large catches occurred on the plateau of Grand Bank in southern Division 3L. In many years, especially 1986 and 1990, there was a strong contrast between large catches in southwestern Division 3L and very small catches across the boundary in Division 30. This is most likely caused by the pattern of surveying, wherein surveys usually started in northwestern Division 30, moved to Division 3 N , and finished in Division 3L. There was often a period of several weeks between fishing on either side of the \(3 \mathrm{~L} / 30\) boundary, during which period capelin may have moved into the area from northern Division 3L.

Frequency of occurrence
Analysis of frequency of occurrence was restricted to the years 1977-1982 and 1985-1994 because there was no survey in 1983 and coverage was inadequate in 1971-1976 and 1984.

The adjustment to the frequency of occurrence did not substantially change the estimates (Table 3; Fig. 3).

The adjusted frequency of occurrence of capelin in sets made in 750 m or less varied from a low of \(6 \%\) in 1978 to a high of \(80 \%\) in 1986 (Table 3; Fig. 3). The frequency of occurrence in 1991-1994 was at an intermediate level of about 50\%.

Biomass estimated from areal expansion
The minimum trawlable biomass varied from a low of 25 t in 1978 to a high of \(34,000 \mathrm{t}\) in 1986 (Table 3; Fig. 4). The biomass has been very low for the most recent 4 years. The estimate for 1994 was 432 t , the third lowest level in the 16 y time-series.

Comparison between bycatches and acoustic surveys
To determine if bycatches of capelin during bottom-trawl surveys in Division 3 L provide information on the quantity of capelin in the area, both the adjusted frequency of occurrence in the bottom-trawl survey and the biomass estimated from the by-catches were compared with the biomass estimated from the acoustic survey (Table 3; Fig. 5,6). In both cases the association was positive but not significant. However, many of the catches in the bottom-trawl surveys were outside the area covered by the acoustic survey. This included in particular catches east of \(50^{\circ}\) W and south of the Avalon Peninsula. The frequency of occurrence and biomass were recalculated for a smaller area corresponding approximately to the area covered by the acoustic survey. This smaller area included those strata west of \(50^{\circ} \mathrm{W}\) but excluded the one stratum south of the Avalon Peninsula. Recalculation of the frequency of occurrence and the trawlable biomass increased their correlations with the biomass estimated during the acoustic surveys, but the correlations were still not significant (Fig. 5,6).

Discussion

\section*{Distribution}

The distribution of capelin in Division 3L during April-June, as inferred from by-catches during bottom trawl surveys, corresponds in a general way with distributions inferred from other sources. The tendency for large catches to be obtained in southwestern Division 3 L is in agreement with the migration of maturing capelin from northern Division 3L to southwestern Division 3 L and northwestern Division 30, as described by Kovalyov and Kudrin (1973). A visual comparison between plots of by-catches,
presented in this chapter, and plots of capelin biomass, as recorded during acoustic surveys (Miller 1991), reveals many similarities, but also many differences. A detailed comparison between the two sources of information has not been conducted. Such a study would be confounded by differences in timing between the bottom trawl surveys and the acoustic surveys (Fahrig et al. 1993), but may nevertheless yield important insight into the manner in which catches during the bottom trawl survey may be influenced by factors such as water depth and capelin behaviour (including their density, average depth in the water column, and extent of their diel vertical migration).

The moderate and large catches obtained on northeastern Grand Bank in some years, notably 1982 and 1985-1990, occurred outside the area covered by the acoustic surveys in those years. Additional study is required to determine if those capelin to the east of the acoustic survey were primarily immature or mature. Acoustic surveys were extended to the east in 1991 and 1992 (Miller and Carscadden 1991; Miller 1992), but failed to detect sizable concentrations of capelin. Catches of capelin on eastern Grand Bank were generally small in those two years.

The stock affinity of the capelin found toward the southern tip of Grand Bank in some years is not known. They could belong to either the \(2+3 \mathrm{KL}\) stock or the 3 NO stock.

The distribution of capelin, as inferred from the bottom trawl catches, varied among years. Additional study is required to determine the extent to which these differences may be related to changes in stock size, age and maturity composition of the stock, water temperature (compare Shackell et al. 1994), and the timing of the surveys.

Capelin biomass
The extent to which the by-catches of capelin in the spring bottom trawl surveys may be used to infer the status of the capelin stock is not known. The two potential indices presented in this chapter (frequency of occurrence and trawlable biomass) may be influenced not only by the size of the capelin stock but also by the behaviour of the capelin (including aspects such as degree of aggregation, average depth in the water column, and extent of diel vertical migration). Another concern is the change in survey gear from the Yankee 41-5 trawl deployed from the 'A. T. Cameron' (1971-1982) to the Engel-145 trawl deployed from the 'Wilfred Templeman' and the 'Alfred Needler' (1984-1994). There is evidence that the Engel-145 trawl may be more efficient at catching capelin, at least in Division 3L in the spring. During the 1979 survey, the 74 m stern trawler R.V. 'Gadus Atlantica' fished beside the 'A. T. Cameron', and obtained more frequent and larger catches of
capelin than did the 'A. T. Cameron' (unpubl. data). During that comparative fishing exercise the 'Gadus Atlantica' deployed an Engel-145 trawl very similar to the trawls deployed by the 'Wilfred Templeman' and the 'Alfred Needler'.

The frequency of occurrence and the trawlable biomass were both positively (but not significantly) related to the biomass estimated from the acoustic survey. However, it is known that biomass estimates from the acoustic surveys may not closely track the biomass of the capelin stock. For example, the estimates are influenced by water temperature (Shackell et al. 1994), and the sudden decline from high biomass levels in 1989 and 1990 to very low levels in 1991 and 1992 (Miller 1992) has not been adequately explained. In the absence of an accepted index of capelin biomass, it is difficult to determine how well the frequency of occurrence and the trawlable biomass track the true capelin biomass. It is notable, however, that boin meirices were very low in 1978 , when the capelin stock was at its nadir, and relatively high in the mid- to late 1980s, when capelin biomass was relatively high.

The decline in trawlable biomass from a relatively high level in 1990 to low levels in 1991 and 1992 coincided with the decline in the acoustic estimates. The continuing low trawlable biomass in 1993 and 1994 may be a cause for concern.

Table 3. The frequency of occurrence and trawlable biomass of capelin in Division 3L in the springs of 1977-1994, as estimated from bottom trawl surveys, and the biomass in 1982-1992, as estimated from acoustic surveys. The frequency of occurrence of capelin in bottom trawl catches is calculated for the entire survey area and for a reduced area in western Division 3L, corresponding approximately to the area covered by the acoustic surveys prior to 1991. Both unadjusted and adjusted values are presented. The method of adjustment is described in the text. The trawlable biomass of capelin was estimated from the capelin catches during the bottom trawl surveys, and is provided for both the entire survey area and the reduced area.

Preliminary Catch Rates of Capelin (Mallotus villosus) in Inshore and Offshore Areas of NAFO Div. 3KL During Recent Demersal Juvenile Cod Surveys
by
E. L. Dalley, J. T. Anderson, and D. S. Miller Science Rranch
Department of Fisheries and Oceans
P. O. Box 5667
St. John's, NF A1C 5X1

\section*{Introduction}

Several types of assessment related research are considered for capelin each year during the regional assessment process. In the offshore, annual acoustic surveys are carried out to estimate abundance of recruiting year classes to be used in projections. In the inshore, catch rate indices, estimates of capelin school areas, and egg deposition estimates are all considered. In addition bycatch of capelin from other sources such as groundfish surveys and indices of cod feeding on capelin have been used. In recent years there has been a divergence of indices with the offshore acoustic survey finding low abundances which have not been reflected in the inshore the next year. The acoustic surveys have not included any of the large inshore bays along the Northeast coast.

During early winter of the past three years surveys hava been carried out under the Northern Cod Science Program to examine the distribution of juvenile cod in inshore and offshore areas of NAFO Div. 3KL. During these surveys capelin were taken as bycatch. To examine an independent index of capelin abundance in recent years and to address the question of relative abundance in inshore and offshore areas during early winter these catches of capelin are reported here. Also, for the most recent survey a biomass estimate is derived for a portion of the survey area to compare with the acoustic estimate from the same area.

\section*{Methods}

Three surveys were carried out using the research vessel Wilfred Templeman in: 1) December 1992, 2) December 1993-January 1994, and 3) December 1994-January 1995 and will be referred to a the 1992, 1993, and 1994 surveys respectively. Line transects were utilized to sample from bays and headlands across the shelf (Fig. 1). Additional sampling was carried out in each of the major inshore bays. Attempts were made to sample available depth strata. Sampling was carried out using a Campelen 1800 shrimp trawl. Catch in numbers and weight of capelin was standardized using a 30 minute tow once the trawl had settled to the bottom, as determined by Scanmar. Depth and temperature along the tow path were monitored using a trawl mounted CTD. Additional information on the trawl and survey design are found in Dalley and Anderson (1995).

Samples were frozen and returned for standard processing by Pelagic Section of Science Branch. Since capelin are assigned an arbitrary birthdate of January 1 ages in this analysis were assigned to correspond to the sampling year noted above (eg. fish caught in January 1994 were given ages as if they had been caught in December 1993).

A biomass estimate was derived for 3 K using mean catch rate from 22 stations within an area (72,633 sq. km.) approximating strata \(G, H, I, J\), and \(1 / 2\) of \(K\) from the acoustic survey (Miller 1995). The Campelen trawl wing spread of \(16.8 \mathrm{~m} .(\mathrm{W})\) and an average tow distance of 2780 m .(L) was used to estimate a swath area ( \(L\) x W) of 0.0467 sq . m. for each tow. Mean arithmetic and geometric catch rates within this swath area were used to estimate the biomass of capelin within the total area to compare to the estimate of biomass derived acoustically for the same area.

\section*{Results}

Mean catch rate for the three surveys (Table 1) varied by a factor of \(\sim 8 x\) in terms of numbers and \(6 x\) in terms of weight. Mean catch rates (numbers) decreased by a factor of ~ 4.5x from 1992 to 1993 but increased by a factor of \(8 x\) from 1993 to 1994. Catch weights wize somewhat less variable with an apprsximate \(3 x\) decrease followed by a 5.6x increase over the same period.

Results of correlation analysis indicate no correlation between the catch rate (in numbers or weight) and tow (bottom) depth or mean temperature along the tow path (Table 2).

A comparison of catch rates (log10) expressed in number of fish and in weight of fish, is shown in Figures 2 and 3 respectively for the three surveys, using expanding symbols for each set. The expanding symbols are scaled the same for all surveys and are therefore comparable from year to year. The results indicate that capelin were widely distributed throughout the survey area, both inshore and offshore, in all three years. In 1992 highest catch rates were concentrated around Funk Island Bank and near the shelf edge at \(\sim 47.5{ }^{\circ} \mathrm{N}\). Capelin occurred in all bays but catch rates in Notre Dame Bay were relatively low. In 1993, when mean catch rate was the lowest of the three years, relatively few capelin were taken near the shelf edge. There were 11 zero catches compared to 7 in 1992 and 5 in 1994. In 1994 high catch rates were again taken on Funk Island Bank, the northern portion of the survey area, and near the nose of the Grand Bank. Overall distribution patterns appeared similar in 1992 to 1994.

In terms of numbers overall mean catch was higher in 3L than 3 K in 1992 but higher in 3K than 3L in 1993 and 1994 (Table 3). The mean catch weight was higher in 3 L all three years indicating a high proportion of small fish in 3L in 1992. Using the ratio of weight/numbers, fish caught in 3 K were larger than those in 3 L all three years.

A comparison of catch rates of stations within the bays compared to those on the offshore transects indicate that in general the percentage of the overall mean catch rate taken inshore was higher for 3 L than 3 K ．In all cases mean catch rates（weight） were higher in the offshore in both 3 K and 3 L during all three years．In 3 K the proportion of total catch rate inshore ranged from \(4.5 \%\) in 1992 to \(32.8 \%\) in 1993．In terms of numbers the same is true except in 1993 mean catch rate was slightly higher inshore in 3L．The proportion of catch rate（numbers）ranged from \(13.9 \%\) to \(37.9 \%\) inshore in 3 K and from 21.5 to \(54.2 \%\) inshore in 3 L over the three surveys．

Samples processed for each survey indicate an age structure that is predominated by young fish（Table 4）．Age 1 fish averaged ～ \(55 \%\) each year．Age 2 fish ranged from \(30.8 \%\) in 1993 to \(43.7 \%\) in ェララえ．The age structure from the sauples was weighted by the overall mean catch rate for each survey to obtain a catch rate at age index（Table 5）．

The arithmetic mean catch rate of the 22 stations sampled in 3 K was \(14,367.3 \mathrm{~g}\) ．or \(0.308 \mathrm{~g} . / \mathrm{sq}\) ．m．representing a total biomass of 22,371 metric tons．Using the geometric mean catch rate of \(2,009.1 \mathrm{~g}\) ．or \(0.043 \mathrm{~g} . / \mathrm{sq}\) ．m．the biomass estimate for the total area is 3，123 tons．

\section*{Discussion}

The results clearly indicate that capelin were widely distributed throughout the area surveyed in early winter，both inshore and offshore，during all surveys．There was not，however， any statistically significant association between catch rate of capelin and either a）water depth or b）water temperature．

In two of the three surveys the mean catch rate of capelin was higher in statistical area 3 K than 3 L ．Mean catch rate in weight of capelin consistently ranked higher in 3 L than 3 K ．The proportion of catch rates within the inshore bays is substantial when compared to that of the offshore．In \(3 L\) the catch rate in weight inshore was approximately equivalent to that offshore in 1992 and also in number of fish in 1993．The proportion of overall catch rate，in the inshore compared to offshore，is consistently higher in the more southern bays（3L）than the bays in 3 K for all three years．These relatively high catch rates inshore indicate that the annual acoustic capelin estimate may be negatively biased by the exclusion of inshore areas．Catch rates of capelin inshore may occur at a level similar to that of the offshore．

The age structure of the population estimated from these demersal trawl surveys, whereby a large proportion consists of younger fish, is similar to that derived from samples collected during the acoustic survey. The fact that the numbers at age 2,3 , and 4 in 1994 were higher than the same age classes at age 1, 2, and 3 in 1993 appears anomalous and may simply be a result of sampling variability among years. Alternatively it may be a result of differences in catchability resulting from distribution differences between years. For instance in 1993 when catch rates were low capelin may have been distributed differently in the water column, decreasing their catchability in a bottom trawl.

The estimate of biomass in 3 K in 1994 derived here, \((22,370\) metric tons) using the arithmetic mean catch rate, is over twice the 10,000 tons estimated from the acoustic survey in September-October (Millei 1995) and substantially higher than the - 2,000 tons derived from the random stratified groundfish survey in November-December (Lilly 1995). It is not surprising that the estimate is higher here than the groundfish survey since the large meshed Engels survey trawl would not be as efficient at catching small fish as the shrimp trawl used here. However, the results may indicate that the acoustic survey underestimates biomass. This is not the case if the geometric mean catch rate is used for the demersal surveys which results in a biomass estimate is only 3,123 tons. Consideration should be given to which of the mean values is more appropriate.

\section*{Introduction}

Previously it has been demonstrated that year-class strength of capelin in the Newfoundland region is established during the first year of life (Leggett et al. 1984). This result was based on the statistical association of two factors. The first factor was the successful release of capelin larvae from beach sediments and the second was warm water temperatures integrated from July-December (op. cit.).

The purpose of this study was to measure the year-class strength of capelin in the early fall, following the period of release from beach sediments. Year-class strength was assessed as a combination of abundance, the size range of capelin present as this related to periods of release, and the geographical distribution of capelin on the shelf.

\section*{Methods}

The sampling program was designed as series of synoptic inshore/offshore surveys. During the first three years of the program, 1991-93, sampling was carried out using one ship targeting the inshore areas along the northeast coast of Newfoundland and the offshore area which covered the southern Northeast Newfoundland Shelf and northern part of the Grand Bank (Fig. 1). These surveys were carried out from late September to the middle of October (Table 1). In 1994 the survey was expanded to cover the entire area from southern Labrador to the southern tip of the Grand Bank using two ships simultaneously (NAFO Divisions 2J3KLNO, Fig. 1). The survey time occurred approximately six weeks earlier in 1994 due to sampling considerations regarding measurements of pelagic juvenile cod (Anderson and Dalley 1995).

A survey grid at 54 km ( 30 nautical mile) station spacing was used. This design is equivalent to a systematic stratified sampling design, where the first station is selected randomly from within a \(54 \times 54 \mathrm{~km}\) stratum with subsequent stations spaced systematically at 54 km (Snedcor and Cochrane 1967). Within the inshore bays stations were positioned to lie approximately 54 km apart along a line running through the centre of each bay to maintain a comparable sampling effort over space within the inshore areas to that offshore. When a line of stations within a bay was not possible, such as Notre Dame Bay and Bonavista Bay, then an approximate 54 km spacing was chosen, spread throughout each bay.

Multiple samplers were used during these surveys. Small larval capelin were sampled using 0.61 m bongos ( 0.505 and 0.333 mm mesh) towed obliquely \(0-100 \mathrm{~m}\) depth at \(1.25-1.5 \mathrm{~m} \mathrm{~s}\) with payout and retrieval rates of approximately \(0.8 \mathrm{~m} \mathrm{~min}^{-1}\) and \(0.3 \mathrm{~m} \mathrm{~min}^{-1}\), respectively (Smith and Richardson 1977). The bongo sampler was instrumented with a CTD which was used to monitor net performance in real time to ensure that each depth was sampled representatively. Volume filtered was estimated from mechanical flowmeters (General Oceanics) 1991-93 and electronic flowmeters (TSK) in 1994. Larger larval capelin were sampled using either a \(4.5 \mathrm{~m}^{2}\) Tucker trawl (Harding et al. 1987) or the International Young Gadoids Pelagic Trawl (IYGPT) (Koeller and Carrothers 1981, Koeller et al. 1986). In 1991 the entire survey was carried out using the Tucker trawl. In 1992 both Tucker and IYGPT trawls were used but both trawls were not used at all stations. In 1993 and 1994 only the IYGPT trawl was used. The Tucker trawl was towed obliquely \(0-100 \mathrm{~m}\) depth using the same sampling criteria as the bongos. The mesh size was 3.2 mm in the main portion of the net, while the cod end was 0.505 mm Nitex netting. The Tucker trawl was instrumented to monitor trawl performance in real time, including electronic flowmeters (TSK), net angle and a CTD. The IYGPT trawl is a \(10 \times 10 \mathrm{~m}\) pelagic mid-water trawl designed primarily to catch pelagic juvenile cod (Koeller et al. 1986). In the 1992-93 surveys it was towed at \(1.25-1.5 \mathrm{~m} \mathrm{~s}^{-1}\) for 30 minutes with the head rope positioned at approximately \(50-60 \mathrm{~m}\) depth. In 1994 the IYGPT trawl was towed between 20-50 m depth. Depth and net configuration were monitored in real time using acoustic net sensors (Scanmar) to measure net depth, net opening, wing and door widths. For both trawls, the net performance data were used to estimate the volume of water ( \(\mathrm{m}^{3}\) ) filtered during the tow.

Bongo samples were preserved in \(90 \%\) formalin and returned to the laboratory for processing. All ichthyoplankton were removed from the sample, identified to species and measured for standard and total length (mm). When sample size exceeded approximately 100 organisms then a sub-sample was taken following the procedures of van Guelpen et al. (1982). The Tucker and IYGPT trawl catches were processed at sea, identifying fish to species level where possible, and recording total length for capelin. Beginning in 1993, with the systematic use of the IYGPT trawl at all stations, one year old capelin were also processed at sea. One year old capelin were classified based on size (from \(50-60 \mathrm{~mm}\) up to approximately 110 mm ) and coloration (they are pigmented more than the translucent larvae but less so than older capelin).

\section*{Results}

Comparison of Lengths Among Samplers
Comparison capelin sizes sampled each year by the different samplers indicates that the bongos sampled capelin representatively from approximately \(3-25 \mathrm{~mm}\), the Tucker trawl from \(18-38 \mathrm{~mm}\) and the IYGPT trawl > 24 mm . These results are based on comparisons of the length- frequencies sampled in different years.

In 1991 there was only one dominant size mode of capelin present, ranging from approximately \(10-30 \mathrm{~mm}\) (Fig. 2). There was a clear overlap in the lengths sampled by the bongo and Tucker trawls. The bongo sampler did not sample capelin abundantly \(>25 \mathrm{~mm}\) length, whereas the Tucker trawl demonstrated that capelin were still relatively abundant up to 28 mm length. On the other hand, the Tucker trawl did not abundantly sample capelin \(<18 \mathrm{~mm}\), whereas the bongo sampler demonstrated that capelin were relatively abundant down to approximately 12 mm length. This comparison demonstrates that capelin were sampled representatively by both samplers in the \(18-25 \mathrm{~mm}\) size range. Comparison between the two samplers demonstrated that there was a statistical difference in the sizes caught (Kolmogorov-Smirnov test, P < 0.01).

There was a statistical difference in the sizes of capelin caught by the Tucker and IYGPT trawls, based on a comparison of nine stations where both trawls were towed in 1992 (Kolmogorov-Smirnov test, \(P<0.01\) ). At these stations the Tucker trawl catch ranged in length from \(13-45 \mathrm{~mm}\) and the IYGPT trawl catch ranged from \(19-61 \mathrm{~mm}\). There was a 6 mm difference in mean size between the two trawls ( 25 mm and 32 mm ). The upper size sampled by the Tucker trawl appeared to be approximately 38 mm .

Larval Release Periods
The length frequency data indicates that there were differences in the periods of larval release from beach sediments among the four years (Figs. 2-5). In 1991 both the bongo and Tucker samplers demonstrated that there was a single length mode which ranged predominantly from \(11-28 \mathrm{~mm}\). In 1992 all three samplers demonstrate that there were two dominant modes, a small mode which ranged from \(7-18 \mathrm{~mm}\) and a larger mode which ranged from \(21-42 \mathrm{~mm}\). The smaller numbers of capelin caught in the \(18-24 \mathrm{~mm}\) length range is not due to sampler bias, as it falls within the common range sampled representatively by both the bongo and Tucker trawl samplers. In 1993 there were again two modes in the length data, although these modes were more widely separated than in 1992, the
smaller mode ranging predominantly from 5-19 mm and the larger mode from 30-44 mm. In 1994 there was only one length mode present, ranging from \(4-15 \mathrm{~mm}\) length. Only a very small number of larger capelin were caught in the range of \(28-40 \mathrm{~mm}\) length.

It is noteworthy that none of the bongo length frequency data were skewed towards the smallest sizes, as would be expected if significant release of small larvae (3-4 mm length) from beach sediments was ongoing during the time of each survey. Also, examination of individual catches indicated that there was no apparent skewness in length data from within each bay. Therefore, it appears that the annual release of capelin from beaches was completed each year by the time of the surveys.

We used average growth rates of \(0.25 \mathrm{~mm}^{-1}\) (Jacquaz et al. 1977) and \(0.35 \mathrm{~mm} \mathrm{~d}^{-1}\) (Frank and Carscadden 1989) to estimate ェ frequency modes sampled during our surveys (Table 2). It is apparent that a growth rate of \(0.25 \mathrm{~mm} \mathrm{~d}^{-1}\) overestimates the age of capelin as it estimates release times which occurred during May in 1992 and 1993; whereas the earliest recorded spawning dates were 4 July 1992 and 1 July 1993 (Nakashima and winters MS1995). By comparison, the earliest calculated release times based on \(0.35 \mathrm{~mm} \mathrm{~d}^{-1}\) growth rates were 21 June 1992 and 16 June 1993 indicating this higher growth rate also underestimates age to a small degree (Table 2). As a first approximation, a growth rate of \(0.35 \mathrm{~mm} \mathrm{~d}^{-1}\) was used to estimate relative release times each year based on the length modes sampled during our surveys.

We estimate that release of capelin larvae from beaches occurred relatively early in 1992 and 1993 and continued into late September (Fig. 6). In 1992 the release of larvae from beaches appears to have been relatively continuous from June to September, whereas in 1993 there were two distinct periods of release; one early and one late. In 1991 larvae were released relatively late (August) as one continuous period of release. In 1994 release of larvae again began late in August. In 1994 we do not have a direct measure of any release of larvae which may have occurred in September.

Distributions
Distributions of smaller capelin sampled by the bongos demonstrated that capelin larvae were distributed widely throughout much of the offshore areas sampled in 1991-93, including the inshore bays along the northeast coast of Newfoundland and along the Avalon Peninsula (Fig. 7). Based on mean sizes and an average growth rate of \(0.35 \mathrm{~mm} \mathrm{~d}^{-1}\), these capelin averaged \(5-6\) weeks since their release from beach sediments. These data indicate that
capelin are dispersed from the beaches over a scale of \(>100-200 \mathrm{~km}\) within a relatively short period of time. In 1994 the capelin were not distributed extensively offshore, as might be expected from the earlier survey time. Capelin sampled in 1994 averaged three weeks of age, based on an average growth rate of \(0.35 \mathrm{~mm} \mathrm{~d} \mathrm{~d}^{-1}\). The presence of small capelin offshore in the vicinity of Belle Isle Bank demonstrates that spawning occurred in southern Labrador in 1994. Notably, no capelin larvae were sampled over the southern Grand Bank.

Distributions sampled by the Tucker and IYGPT trawls demonstrated that the larger, older capelin were largely dispersed away from the inshore bays to the northern part of the Grand Banks in 1991-93 (Fig. 8). The 1991 Tucker trawl distribution offshore was similar to that sampled by the bongos, which would be expected given the similar length range sampled. In 1992 and 1993 the larger capelin sampled by the Tuckei aiu IYGPT trawls demonstrate that the capelin were widely and evenly dispersed over the northern Grand Bank but were noticeably absent from the inshore bays. In 1994 there were very few larger capelin sampled by the IYGPT trawl. The distributions sampled in 1992 and 1993 are consistent with progressive dispersal (drift) of capelin from the inshore areas, where they were spawned, to the offshore shelf, particularly the northern Grand Bank.

Abundances
Mean abundance of capelin sampled by the bongos in 1991-93 indicates that abundance was approximately two times greater in 1993 (Table 2). Abundance estimates based on numbers \(\mathrm{m}^{-3}\) are not available yet for 1994. Comparisons of mean catch/tow indicates that 1991 was less than either 1992 or 1994 ( \(\mathrm{P}<0.007\) ), 1992 was not different than 1994 ( \(\mathrm{P}=0.2745\) ), while 1993 was greater than either 1992 or 1994 ( \(\mathrm{P}<0.016\) ). Based on these data we would rank year-class strength as \(1991<1992=1994<1993\). As the 1994 survey occurred approximately six weeks earlier, and sampled smaller larvae, the numbers are not directly comparable to the other years. Qualitatively, the abundance estimated for 1994 should be reduced compared to the other years, indicating that year-class strength in 1994 may be more similar to 1991.

Mean abundance measured by the Tucker trawl in 1991 was less than 1992, which is a significant difference given that the capelin were larger in 1992 (Table 2). Comparison of abundance sampled by the IYGPT trawl indicates that 1992 was greater than 1993. While standardized abundance estimates are not yet available for the 1994 data, the low numbers caught (Fig. 5) indicates that abundance was very low compared to all previous years. These comparisons indicate that year-class strength in \(1994<1991<1993<1992\). However, it
is difficult to directly compare abundances among years when the mean sizes differ significantly. Qualitatively, the small sizes sampled in 1991 would adjust these abundance estimates lower compared to 1992 and 1993. Similarly, the smaller sizes sampled in 1992 adjust the numbers down compared to 1993. On the other hand, the total absence of larger capelin in 1994 demonstrates a very low abundance compared to 1992 and 1993.

One Year Old Capelin
In 1993 one year old capelin were distributed most abundantly over the northern Grand Bank and to a lesser extent on the southern part of the Northeast Newfoundland Shelf (Fig. 9). They also occurred within all of the inshore bays, but at relatively lower abundances and not at all locations. In 1994 one year old capelin again occurred most abundantly over the Northern Grand Bank and at a lesser extent civer the Northeast Newfoundland Shelf and the Southern Grand Bank (Fig. 9). One year old capelin occurred at relatively high abundances extensively throughout the inshore area in 1994.

In 1993 one year old capelin from the 1992 year-class averaged \(40.3 /\) tow, compared to \(836.5 /\) tow for the 1993 year-class measured in 1994. The significantly greater abundance measured in 1994 indicates the 1993 year-class is relatively large compared to 1992.

\section*{Discussion}

Capelin spawning periods remained relatively constant during 1991-94, ranging approximately from the end of June to the end of August each year (Nakashima and Winters MS1995). However, survival from these spawnings varied among years. In 1992 and 1993 the larger length ranges of larvae sampled in the fall indicates that conditions which favoured larval survival extended over a longer period of time. In contrast, in 1991 and 1994 there was little survival of larvae from the earliest spawning periods. Only larvae which were spawned late in the year survived and dispersed away from the beaches. In addition, years which favoured longer release periods directly scaled with mean measures of larval abundance.

Several factors are thought to contribute to the survival of capelin larvae. Successful release from beach sediments as a function of the frequency of onshore winds has been reported as a significant factor effecting survival (Leggett et al. 1984). There is some indication that this was an important factor in 1991-93, where the total number of emergent larvae measured near beaches (Nakashima and Winters MS1995) closely matched the mean numbers of larvae sampled in this study (Fig. 10). However, in 1994 the low abundance of larvae appears to result from relatively low levels of egg deposition, as opposed to successful release from beach
sediments (op. \(\\) cit.). This suggests that the size of the spawning stock may also have been a significant determinant of year-class strength during these years. It is notable that the spawning in 1994 was primarily made up of fish from the relatively weak 1991 year-class (op. cit.).

Previously, it was reported that warmer water temperatures were related to increase survival (Leggett et al. 1984). There is no indication that water temperature was an important determinant of survival during these years. While 1991 was the coldest year, both 1992 and 1993 were also relatively cold. In contrast, 1994 was much warmer. Therefore, the warmest and coldest years during 1991-94 relate to the lowest estimates of year-class strength. The broad distributions of larval capelin throughout the offshore areas, particularly on the northern Grand Bank, indicates that dispersal from the inshore bays where capelin spawn to the offshore sheif is an important phase in the early life history of capelin. In the Gulf of St. Lawrence downstream dispersal of capelin to important feeding areas was reported (Bailey et al. 1977, Jacquaz et al. 1977, Fortier and Leggett 1983, 1985). It may be that the offshore environment enhances survival of larval capelin. In particular, the northern area of the Grand Bank appears to be an area where capelin concentrated, both as larvae and as one year old capelin.

The absence of larval capelin from the southern Grand Bank in 1994 contrasts with observations made during September 1985 and 1986 (Frank and Carscadden 1989). Our observations indicate that there was no successful emergence of capelin from spawning on the SE Shoal up to the beginning of September 1994.

The greater abundances and larger size ranges of larval capelin in 1993 indicate that the 1993 year-class is greater than 1992. This comparison is confirmed by abundances measured for these year-classes at one year of age. Larval abundances were less in 1991 than either 1992 or 1993. The abundances measured in 1994 are not directly comparable due to the earlier sampling time. However, based on the absence of larger capelin in 1994 we estimate the 1994 year-class will be less than either 1992 or 1993, and may be similar to 1991. Therefore, we rank year-class size as: \(1993>1992\) > \(1991=1994\).

\section*{Capelin Spawning and Release Periods 1991-94}

\section*{June July August September}

Fig. 6. Estimated periods of capelin release from beach sediments each year, based on the dominant length modes and an assumed growth rate of \(0.35 \mathrm{~mm} \mathrm{~d}^{-1}\) (solid line), and the measured spawning times sampled by Nakashima and Winters (MS1995) (dash-dot line). The dashed line following the release period estimate in 1994 indicates that release may have occurred into September 1994 but was not sampled by the 1994 survey.

Fig. 7. Distributions of larval capelin sampled by the bongo sampler 1991-1994. Expanding symbols represent abundance \(\boldsymbol{l o g}_{10}\) number \(\mathrm{m}^{-2}\) ) and a solid dot indicates a null sample.

Fig. 8. Distributions of larval capelin sampled by the Tucker and IYGPT (International Young Gadoids Pelagic Trawl) trawls 1991-1993. Expanding symbols represent abundance ( \(\log _{10}\) number \(\mathrm{m}^{-3}\) ) and a solid dot indicates a null sample.

Fig. 9. Distributions of one year old capelin sampled the IYGPT (International Young Gadoids Pelagic Trawl) trawl 1993 and 1994. Expanding symbols represent abundance ( \(\log _{10}\) number \(\mathrm{m}^{-3}\) ) and a solid dot indicates a null sample.

\section*{Beach vs Bongo Capelin Larvae}

Fig. 10. Comparison of the geometric mean of the total number of larvae emerging from six beaches sampled along the northeast coast of Newfoundland (Nakashima and Winters MS1995) versus the number of capelin larvae (log scale mean number per tow) sampled inshore and offshore by the bongos, 1991-1994. The 1994 bongoestimate is biased high due to a significantly earlier sampling time compared to 1991-1993.

Interaction Between Timing, Capelin Distribution and Biomass Estimates from the Div. 2J3K Capelin Acoustic Survey

}

\section*{Introduction}

Temporal and spatial distribution patterns of fish are often a reflection of feeding and spawning strategies. These strategies, in turn, are closely linked with environmental changes through oceanographic influences on food production and availability. In the Northwest Atlantic water temperatures have been below normal since the early 1980's and have been particularly severe and sustained since 1990. Since 1981 systematic hydroacoustic surveys of capelin abundance have been conducted during October by Canada in NAFO 2J3K. The biomass estimates from these surveys have shown large interannual variations which have not been reflected in subsequent inshore indices of mature fish (Fig. 1) which they were designed to measure. In particular, anomalously low biomass levels were observed in 1983, 1986, 1987, and from 1990 onwards. Lilly and Davis (1993) (but see also references contained therein) have reviewed ine \(2 J 3 K\) acoustic estimate in relation to distribution patterns inferred from bycatches of capelin in the \(2 J 3 \mathrm{~K}\) groundfish survey and from capelin in cod stomachs. The authors observed that the anomalously low acoustic estimates were consistently associated with shifts in capelin distribution to the south and east towards the outer portions of the survey blocks. They recommended that further studies were required to determine whether or not low biomass levels from the October hydroacoustic survey are associated with southerly capelin distribution in \(2 J 3 \mathrm{~K}\) in November-December. In this regard Vilhjalmsson (1994), in an extensive review of Icelandic acoustic surveys of capelin, has noted that the behaviour and distribution patterns of capelin are consistently shifting and that the success of an acoustic survey depends critically on appropriate timing even to the extent of cancelling, delaying, or repeating the survey at a later date. The \(2 J 3 \mathrm{~K}\) acoustic survey has always been conducted in October (also September - beginning in 1993) because of timing restraints imposed by research vessel schedules. The purpose of this paper is to examine the hypothesis that an acoustic survey which is fixed in time and which does not cover the entire distribution area of the stock will exhibit periodic failures to reliably and consistently measure abundance levels. Groundfish bycatch data and cod stomach percentage fullness index (PFI) data (G. R. Lilly, pers. comm.) collected during the November-December 2J3K bottom trawl survey will be the major data sources used to describe statistical associations between capelin distribution patterns and interannual variability in the \(2 J 3 \mathrm{~K}\) capelin acoustic biomass estimates.

Materials and Methods
The reader is referred to Lilly and Davis (1993) and Lilly (1994) for details on the 2 J 3 K groundfish survey methodology and the sampling methods, and statistics for the capelin PFI data. Lilly (1994) also provides an excellent pictorial review of annual
shifts in capelin distribution as inferred from PFI data. Miller ((1994) and references therein) provides information on the survey methodology for the \(2 J 3 \mathrm{~K}\) hydroacoustic surveys for the period 1981-93.

\section*{Results}

\section*{A. Generalized View of Stock Structure and Migrations}

In order to set the stage, it is necessary to provide a composite description of the stock model for which estimates of capelin abundance are derived.

The 2J3KL capelin stock is a mixture of several subpopulations that mix offshore but likely form separate (and probably homing) spawning populations. Spawning occurs inshore in June and July with the majority of spawning occurring on coastal beaches but with a variable amount of bottom (i.e. ©ff-teach spawning (Templeman 1948)) depending upon the match/mismatch of maturation trajectories and optimum requirements for beach spawning. After incubation and emergence it is believed that the larvae are largely advected out of the bays to north-central 3L where they reside until their second year of life. During the summer of their second year (and likely following the spring plankton bloom in 3L) the larger individuals undergo extensive contranatent feeding migrations to northern and northwest 2 J where the maturation process begins. According to Gulimov and Kovalov (1975) this northward feeding migration is along the eastern regions of Funk Island Bank and Belle Isle Bank, an area that roughly corresponds to the polar front associated with the offshore branch of the Labrador current (G. Mertz, pers. comm.). In normal years the summer-fall feeding aggregations are located on Hamilton Bank and the coastal Shelf off southern Labrador. In October these capelin begin their southward migration along the coastwards portions of the Shelf into central 3 K (Carscadden and Atkinson 1986). At this time bottom temperatures increase and the CIL decreases as a result of the fall destratification process (G. Mertz, pers. comm.) which also coincides with the fall phytoplankton bloom in 2 J and 3 K (Myers et al. 1994). By late November these maturing capelin have largely moved out of 2 J and by December they are located northeast of Notre Dame Bay (Kovalev and Kudrin 1973) in a broad distribution from Funk Island Bank to the coastal bays. They remain in this area until February when they move southwards into Div. 3L and mix with the immature recruits (Gulimov and Kovalev 1975). As feeding resumes in March-April the mature fish begin their southward and westward migrations to coastal waters (Shackell et al. 1994) and thence contranatantly northwards to spawn along eastern Newfoundland. Thus the population of capelin surveyed in Div. 2 J 3 K in the fall are mainly maturing fish, those in Div. 3L (in the fall) are almost exclusively immature and those in Div. 3L in the spring are a mixture of both. This is the general picture
extracted from the literature but the details of the migration and annual distribution patterns are much more complex and less predictable than described above.

\section*{B. Effect of Timing}

The distribution patterns of pelagic fish (and, indeed, most fish) have a distinct and predictable seasonal component. Pelagic fish are typically aggregated into large aggregations during the overwintering period. These aggregations begin to disperse into feeding schools during the pre-spawning period. As spawning approaches, these schools of mature fish re-form into aggregations and migrate to their spawning areas. After spawning is completed a period of intense feeding begins which lasts throughout the summer and into early fall. During this feeding season the fish are typically dispersed into smaller schools, often located near the surface waters. These feeding schools form ūp into large concentrations during the fall when the overwintering migration begins. Pelagic fishers take these seasonal distribution patterns into account and usually concentrate on the fall, winter and pre-spawning aggregations.

According to Vilhjalmsson (1994) these seasonal distribution patterns can be an important variable in the success of an acoustic suvey. This observation reflected the Icelandic experience with acoustic surveys for capelin which began in the early 1970's and produced unrealistically low estimates of abundance. These initial surveys were carried out in August-September when the maturing capelin were still in their main feeding season and were distributed into small schools which were often observed feeding at the surface layers above the transducer depth. The Icelandic acoustic surveys were subsequently shifted to October-November when feeding had largely ceased and capelin were concentrated into larger schools and a smaller area more suited for acoustic mensuration.

How does the Icelandic experience apply to the fixed timing of the 2J3K acoustic survey? We know that the biological cycle of our capelin stocks have been out of phase by 4-8 weeks since the early 1990's and that this has likely had consequences for the 3L spring acoustic survey (Shackell et al. 1994). For the 2 J 3 K fall acoustic survey there are two data sources that provide an insight into the effects of timing, viz. the USSR \(2 J 3 \mathrm{~K}\) acoustic survey which usually occurs in November, and the Canadian 3 L acoustic survey which is conducted usually in May of the following spring.

The USSR acoustic surveys of 2 K 3 K which began in the early 1970's. These surveys cover approximately the same geographic areas as the Canadian survey but generally do not include areas near the coast and therefore the actual area surveyed is somewhat
smaller. Significantly, however, the Soviet surveys usually take place in November after the Canadian survey has been completed (Table 1). In all years with one major exception (1984, when the USSR survey was conducted in December) the Soviet estimates are substantially higher than the Canadian estimates until 1991 when both surveys produced very low estimates. In particular the Soviet surveys do not show the catastrophic collapse of capelin abundances that would have been inferred from the Canadian surveys in 1983, 1986, 1987, and 1990. In 1991 and 1992 the acoustic estimates had collapsed for both surveys; this period coincides with the changes in biological cycles associated with the unusually cold temperature conditions since 1990 and will be discussed further below. Table 1 also contains estimates of the biomass of mature fish (age 3+) in the Canadian 3L acoustic survey in May, six months later. Despite predation mortality during the intervening six months, the \(3 L\) acoustic estimates of mature fish are generally 2-3 times higher than those obtained during the previcus fall by either Canada (in October) or the USSR. Thus evidence from the USSR acoustic survey and the Canadian 3 L spring survey indicate that differences in timing by only a month can have large and systematic effects on biomass estimates and these biases can mask the year effects of actual abundance changes. Accepting the 3 L acoustic estimates also suggests that, regardless of timing, a substantial component of the mature biomass remains outside the survey area and/or is not detected during the 2 J 3 K fall acoustic surveys. This is a constraint only when the \(2 J 3 \mathrm{~K}\) acoustic estimates are viewed as absolute abundance; it should not necessarily invalidate the survey when it is used as an index.

\section*{C. Interaction Between Timing, Distribution and Acoustic Estimate in Div. 2J3K}

Lilly and Davis (1993) and Lilly (1994) have extensively reviewed the fall distributions of capelin in \(2 J 3 \mathrm{KL}\) as inferred from bycatch data and PFI data collected from the November-December groundfish survey. This survey occurs immediately after the capelin acoustic survey and the midpoint of the survey is about 5-6 weeks later than the midpoint of the acoustic survey. This point should be kept in mind during the following analyses. Lilly and Davis (1993) and Lilly (1994) show that in normal years, eg. 1981, 1988 and 1989 capelin are largely distributed north of \(51^{\circ}\) latitude and west of \(53^{\circ}\) longitude in the northern and northwestern portions of 2 J 3 K during November. There is also a distinct spatial break between the capelin distribution in \(2 J 3 \mathrm{~K}\) (mainly maturing fish) and those in 3L (mainly immatures). However, in 1986, 1987, and 1990 onwards the fall distribution of capelin shifted towards the south (generally less than \(51^{\circ}\) latitude) and east (generally east of \(53^{\circ}\) longitude) into 3 K such that by 1991 there was a continuous distribution of capelin along the outer regions of 3 K
and 3L. Analyses of the USSR capelin catch and effort data show a similar pattern of fleet movements (south and east) in 1987 and 1990 (D. Kulka, pers. comm.). Bakanev (1981) describes a similar shift in the Soviet capelin fishery for 1973-74 (another cold period) compared with later years. In addition, the Canadian and USSR acoustic surveys in \(2 J 3 \mathrm{~K}\) also show these shifts in distribution. Bakanev and Zubov (1991) report that the Soviet acoustic survey underestimated biomass levels in 1990 because the capelin distribution had shifted \(120-150 \mathrm{~km}\) to the east and outside the survey transects. Likewise, the Canadian surveys report very few capelin in 2 J since the \(1980^{\prime} \mathrm{s}\) and most of the acoustic estimates are obtained from areas east of \(53^{\circ}\) longitude in 3 K (Miller 1994 and references therein).

This shift in capelin distribution (from north and shoreward to south and seaward) has been examined in more detail from analyses of bycatch sucuess \(i \%\) of sets containing capelin) in the fall groundfish survey for the period 1981-94. Bycatch success (i.e. presence or absence) should reflect both local density changes and, more importantly, changes in abundance associated with expansion or contraction of range within the area of study. Interannual changes in range (i.e. habitat occupied) have been shown to be closely associated with population abundance changes for both pelagic and demersal fish species (eg. see Winters and Wheeler (1985), Rose and Leggett (1991) and references therein).

The shift in distribution from \(2 J\) to 3 K noted by Lilly and Davis (1993) is clearly shown in Figure 2. There has been a steady increase in the bycatch success of capelin in 3 K since the early 1980's such that in recent years about \(60 \%\) of the sets contain capelin. This increase in bycatch rates in 3 K should not be construed as only representing a distributional change since inshore indices of mature biomass have shown a general increase since the early 1980's and these indices are positively correlated with bycatch rates in \(2 J 3 \mathrm{~K}\) (Winters 1994). In Div. \(2 J\) there are large year effects but little in the way of trends up to 1990 but a significant decline since then. It is interesting to note that the \(2 J 3 \mathrm{~K}\) acoustic survey estimates are anomalously low for all years in which the \(2 J\) bycatch rates fell below 20\%.

Associated with this shift in the centroid of capelin distribution into eastern 3 K has been a general increase in mean depths at which capelin have been caught by the groundfish trawl (Fig. 3 and Table 2). Typically, capelin are now most frequently caught in 300-350 m whereas in the early 1980's capelin were found most commonly in depths of \(200-250 \mathrm{~m}\). There is also a close inverse relationship between bycatch success of capelin in Div. 2 J and mean depths (Fig. 3) in which capelin have been caught during the groundfish survey. This undoubtedly reflects the large year
effects associated with periodic shifts in distribution towards eastern 3K. There is a general correspondence in annual variations in capelin depth with the extent of the CIL area (Fig. 3) estimated from the Seal Island data (E. Colbourne, pers. comm.). Despite an apparent movement to deeper waters since the early 1980's the mean bottom temperatures at which capelin have been caught have remained fairly stable in the range of \(1-2^{\circ} \mathrm{C}\). This may reflect a temperature preference but it could also reflect a distributional response to other factors (eg. food supply).

There is also a general correspondence between capelin bycatch success and interannual variations in the CIL (Fig. 4a, 4b). When CIL levels are high bycatch success in \(2 J\) is reduced but shows an increase in 3 K . There are obvious exceptions (eg. 1984) but it should be remembered that these bycatch rates reflect, as well, interannual changes in stock abundance which could confound the above-noteu İiáíionships.

The relationship between mean depths at which capelin are caught in the November groundfish survey and biomass estimates from the 2 J 3 K acoustic survey is shown in Figures 5a and 5b. There is a strong inverse relationship between acoustic estimates and mean depth (Fig. 5a); the acoustic survey has failed to detect significant biomass levels in every year in which mean depths have exceeded 300 m (Fig. 5b). This relationship lends credence to the possibility, noted by Lilly and Davis (1994) that in certain years capelin may be dispersed and remain near the bottom at all times of the day. In this situation, they may be less detectable by the hydroacoustic survey but more vulnerable to the bottom-trawl and to predation by cod. There is some support for this possibility since capelin have not been observed undertaking nightly migrations to surface waters in recent years (J. Carscadden, pers. comm.). Analyses of diurnal patterns in capelin bycatches during the groundfish survey do not support this scenario (Fig. 6). The possibility of poor detectability of capelin when schools are dispersed in deep water must remain open since the hydroacoustic system is configured on the assumption that capelin are aggregated into schools and concentrations (integration using a TVG gain \(=20 \log R\) ) and the system is limited by depth ( 500 m ). Bakanev and Seleverstov (1978) and Seleverstov and Serebrov (1978) provide photographic evidence that capelin occurred in dispersed, tiny schools in 3 K during their hydroacoustic surveys in 1977-78. Likewise, Vilhjalmasson (Report on Acoustic Assessments of the Icelandic Capelin Stock in January and February 1995) reports that capelin were distributed into extremely scattered fish which never schooled but remained in low density-scattering layers during their

January 1995 acoustic survey. Alternately, the relationship in Figures 5a and 5b could reflect a distribution shift to the south and east in deeper waters largely outside the eastern boundaries of the acoustic survey transects.

Lilly (MS 1992 and pers. comm.) subdivided the groundfish survey area in \(2 J 3 \mathrm{~K}\) into nine spatial blocks (Fig. 7) for ease of description of shifts in capelin distribution noted above, and presented capelin bycatches and PFI indices for each block. Lilly (MS 1992) noted that years in which capelin were distributed to the south and east (i.e. blocks 6-9) were also years of anomalously low acoustic estimates. In essence this area represents southern 2 J and Div. 3 K east of longitude \(53^{\circ} \mathrm{W}\). This will be referred to as the "offshore" area whereas blocks 1-5 (western, northern 2 J and western 3 K ) will be referred to as "inshore" areas. Bycatches have been calculated for each of these two areas for the period covering tive acuustic surveys (1981-94). In Figurモ= Ca and 8b "inshore" and "offshore" bycatch levels respectively have been plotted against the \(2 J 3 \mathrm{~K}\) acoustic biomass estimates. Clearly, there is a close positive association between high bycatch of capelin in the "inshore" area and high levels of biomass estimated in the acoustic survey (Fig. 8a). Conversely, high bycatches of capelin in the "offshore" area are negatively associated with the year effects in the acoustic survey (Fig. 8b). These effects are statistically described in Figures 9a and 9b. The relationships demonstrate that significant biomass levels are only detected in the 2 J 3 K acoustic survey when the centroid of capelin distribution is located to the north (in 2J) and inshore (western 3 K ). When the centroid is located to the south and east (in the deeper eastern areas of 2 J and particularly 3 K ) the available biomass (as inferred from bycatch rates) is largely undetected.

The relationships in Figure 9 include the year effect of annual changes in abundance as measured by capelin bycatch rates and PFI values. This effect can be removed by expressing the annual distribution shifts as a ratio of the "inshore" (NI) to the "offshore" (SO) abundance, i.e. annual values of (NI/SO). These annual indices of distribution shift are plotted against annual \(2 J 3 K\) acoustic estimates for the bycatch and PFI series in Figure 10a and the statistical relationships are shown in Figures 10 b and 10 c . There is little doubt that shifts in capelin distribution from "inshore" to "offshore" can explain a large proportion of annual variations in the \(2 J 3 \mathrm{~K}\) acoustic estimates and that this factor (particularly in cold years) has obscured and distracted the real abundance changes. This conclusion is supported in Figures 11a and 11b in which the acoustic abundance deviates from annual inshore mature fish indices (Winters et al., this meeting) are plotted against the corresponding annual indices of distribution shifts.

It may be argued that the period 1991-94 is somehow different than the period 1981-90 when, from acoustic comparisons in Table 1, the Canadian 2 J 3 K acoustic estimates were obviously underestimating biomass levels. Comparisons of the slopes and intercepts of the regression lines in Figures \(10 b\) and \(10 a\) show no statistical difference for the periods 1981-90 and 1981-94. Using only the period 1981-90 the relationship in Figure 10b predicts 1993 and 1994 acoustic estimates to be \(55,000 \mathrm{mt}\) and \(46,000 \mathrm{mt}\) respectively and similar prediction for Figure 11a gives 61,000 mt and 48,000 mt for the 1993 and 1994 acoustic estimates respectively. These clearly are no different than the observed estimates.

It has been demonstrated that the \(2 J 3 \mathrm{~K}\) fall acoustic estimates are likely contaminated by systematic biases resulting from periodic distribution shifts perhaps outside the area surveyed, i.e. the relative acoustic estimate contains an abundance component and a distribution comporint. The distribution component is functionally described in Figures \(10 a\) and \(10 b\) and these relationships can be used to remove the distributions effect, thereby exposing more clearly the annual abundance component of the acoustic estimates. The algorithm is simply described as follows:
\(\log (A B U N)_{t}=\log 2 J 3 K A c o u s t i c_{t}-\left(\log N I_{t}-\log S O\right)\)
The relative abundance component (log-scale) of the 2 J 3 K acoustic estimates obtained from this relationship is as follows:
\begin{tabular}{lllllllllllllll} 
Year & 1981 & 1982 & 1983 & 1984 & 1985 & 1986 & 1987 & 1988 & 1989 & 1990 & 1991 & 1992 & 1993 & 1994 \\
\hline Log ABUN & 2.72 & - & 3.82 & 5.41 & 6.59 & 5.72 & 5.13 & 5.96 & 5.11 & 6.55 & 7.10 & 6.60 & 3.96 & 6.19
\end{tabular}

\section*{Discussion}

The picture of the distribution and migrations of maturing capelin in \(2 J 3 \mathrm{~K}\) during the fall, as inferred from a coalition of data sources, can be summarized as follows. In normal years (usually the warmer periods) the northward feeding migration penetrate extensively in \(2 J\) particularly the areas to the northwest of longitude \(53^{\circ} \mathrm{N}\). During October and November, as waters cool and feeding ceases, a denatant overwintering migration takes place towards central and western 3 K and eventually by early winter these fish have extended their distribution to coastal bays where they are fed upon by such predators as seals (Sergeant 1973, G. B. Stenson, pers. comm.). By mid-winter these maturing fish have moved into \(3 L\) where they mix with the immature recruits.

In certain years (nearly always cold years but not all cold years) however, this migration is altered and is perhaps characterized by less extensive penetrations in 2 J during the
summer. The southern denanant migration begins earlier (likely completed by October) and is deflected to the east across Hamilton Bank and thence southwards along the Polar Front forming the eastern boundaries of the Newfoundland Shelf. At the time (October) of the acoustic survey these capelin may be located to the east of the survey area. By November these fish have begun their cross-shelf migration but are still located mainly east of \(53^{\circ} \mathrm{N}\) longitude at the time of the fall groundfish survey. By mid-January bottom trawl surveys in 1993-94 (Anderson and Dalley, this meeting) show these capelin have broad distributions across the northeast Newfoundland Shelf and have penetrated into the coastal bays.

It is likely that temperature is the major, though not exclusive, variable influencing these periodic distribution shifts. Temperature changes have been closely associated with shifts in the distribution and ïigration of Barents Sea capelin (Tjelmeland 1987). Shackell et al. (1994) have shown that maturing capelin in Div. 3L showed distributional anomalies that were associated with interannual changes in water temperature. During the same general time period (1991-94) Carscadden (1994) described extra-territorial distributions of mainly mature capelin to the Flemish Cap, an occurrence that was also observed to take place in 1973, another cold period. Likewise, Frank and Simon (1994) have reported the association between the appearance of capelin on the Scotian Shelf to periods of below normal water temperature particularly since the late 1980's. It is also known that water temperatures largely determine maturation trajectories of capelin (J. Carscadden, pers. comm.) and in the recent cold period (1991-94) the spawning cycle of Newfoundland capelin have been delayed by 4-8 weeks (Nakashima 1994) i.e. there is clear evidence that the biological cycle of these capelin stocks have been out of phase for several years and this effect is largely temperature-induced. Other fish species in the \(2 J 3 \mathrm{~K}\) area have also shown similar extensions and shifts (generally southwards and eastwards to deeper waters) in distribution since the mid-1980's. These include Polar cod (Lilly et al. 1994), cod (Deyoung and Rose 1994), turbot and American plaice (Bowering, pers. comm.) and shrimp (D. Parsons, pers. comm.). The relationship between ocean temperature, food production and fish physiology is complex but its vortex likely contains the answers to many changes in fish behaviour and migration. Unfortunately information on interannual variability in plankton distribution and production in the Newfoundland area is sparse, to say the least.

In summary, the inability of the Canadian \(2 J 3 \mathrm{~K}\) fall acoustic survey to predict subsequent inshore capelin abundance is likely due to the fact that the acoustic estimates are responding more to annual distribution shifts than to interannual changes in capelin
abundance. It cannot be determined from available data sources whether this is a problem of detectability (i.e. anomalous distribution characrteristics within the survey area) or a problem of non-availability to mensuration equipment (i.e. fish being distributed outside (likely to the east) of the survey blocks). Resolution of this problem will best be achieved through development of appropriate hypotheses which can be tested in a rigorously designed experimental survey. Finally, until capelin distributional anomalies can be identified, predicted and taken into account in a flexible survey design, offshore acoustic surveys for capelin will continue to be occasionally vulnerable to periodic failures to reliably measure abundance. Alternative indices of abundance will continue to be important in order to distinguish real abundance changes from non-abundance effects.

St. John's, NF A1C 5X1

\section*{Introduction}

Acoustic surveys to estimate the abundance of recruiting year-classes of capelin are routinely conducted in the Barents Sea, Iceland and the Northwest Atlantic and in the former two areas, the results of these surveys are the basis for predicting maturing biomass. In the Northwest Atlantic, the power of these surveys to predict mature biomass has been variable and seemingly weaker for the fall surveys. Although the biomass estimated from these fall surveys has been extensively reported, there has been little effort expended to examine other data from them. In this paper, I examine the patterns of mean lengths and age compositions collected in the fall acoustic surveys in relation to the mean lengths and age compositions of capelin the following year in the fishery.

The timing and location of the fall acoustic surveys were based on observations from the Soviet commercial fishery and acoustic surveys during the 1970's (see Carscadden et al. 1985). These authors also noted that a high proportion of the capelin captured in the fall commercial fishery were maturing and would spawn the following year. Furthermore, age compositions from catches in the fall fishery were similar to age compositions in the spawning population next year. It would seem reasonable to assume that mean lengths in the fall and in the following spawning season would be correlated. This relationship might be compromised by the fact that the spring is known to be an active feeding period for capelin. If this energy is put into somatic growth, then it is possible that variations in growth at this time would result in no relationship between mean lengths in fall and the following spring. However, there is evidence in the literature that this may not be an important consideration. During the spring feeding period, gonad development is rapid (Fig. 1), fat content declines, and the weight to length ratio decreases (Winters 1970). Gerasimova (1994) suggested that spring feeding by mature capelin is more important for gonad maturation than growth. Further, spawning mortality is relatively high (Shackell et al. 1994) indicating that capelin energy allocation is favouring gonad production rather than post-spawning survival.

Age compositions in the fall would also be expected to be similar to the age compositions the following spring. Variations in mortality between the fall and spring periods could compromise similar patterns. However, given the historical persistence of strong year-classes (eg. 1973, 1983, 1986) throughout the life span of capelin, this compromise probably is not a serious problem.

With these considerations in mind, I conducted a preliminary exploration of the relationship between mean lengths and age compositions of capelin in the fall survey and the same parameters in the spawning population the following year.

Results
a) Length comparisons

I first plotted the relationship between acoustic mean lengths for the entire survey and inshore mean lengths, all ages and both sexes combined (Fig. 2). The relationship was not statistically significant and it was determined largely by the 1992 point. In some years, the acoustic survey encounters small, immature capelin which will not move inshore to spawn the following spring. Therefore, I turned my attention to the portions of the acoustic survey which contained predominantly maturing fish. The survey blocks I used are found in Table 1. In most years, the total biomass in the selected blocks accounted for most of the survey biomass. Most notable exceptions occurred in 1993 and 1994, when the blocks chosen accounted for \(43 \%\) and \(12 \%\) of the total biomass. However, in all years, the maturing biomass occurring in the selected blocks accounted for a large proportion of the overall maturing biomass.

I also examined the proportions of mature individuals at each age by sex in the survey blocks selected. For one-year-olds, the proportion of mature individuals was variable and low. However, for ages 2 and older, the proportions mature-at-age were much higher, especially for females.

Using the combined data for the survey blocks shown in Table 1, I plotted mean lengths by sex for ages 2, 3, and 4 in the acoustic survey with mean lengths for ages 3,4 , and 5 respectively in the commercial fishery inshore in Div. 3KL. (Because of the very low catches inshore in 1994, data for 1994 was not included in the analysis.) In each figure, the years and ages shown are for the inshore, eg. a point labelled 82 in the figure Male Lengths Age 3 compares the length of males at age 2 from the 1981 acoustic survey to the length of males at age 3 in the 1982 inshore fishery. Comparisons for males are found in Figure 3, 4, 5, and 6 and for females in Figures 7, 8, 9, and 10.

The relationships for males are not significant except for age 3 acoustic - age 4 inshore (Fig. 4). The poor statistical relationship at age \(2-3\) may be a result of low proportions of mature males in the acoustic samples. At ages 4-5, the sample sizes are relatively small. Since females are the focus of the commercial fishery, I concentrated on the relationships with females in the remainder of the paper. The relationships for females are stronger. For age 3 females, the relationship is not significant unless the 1991 point (1990 acoustic - 1991 inshore) is treated as an outlier (Fig. 7). For age 4 females, the relationship is significant and the 1991 point does not appear to be an outlier (Fig. 8). For age 5 females, the relationship is
significant although the relationship is heavily influenced by 1993 (Fig. 9). The 1991 point does not appear to be an outlier here.

When all ages are combined, the correlations are significant even including the 1991 point which again appears to be an outlier (Fig. 10).

An examination of the length-length regressions indicates a pattern of recent years (1991-93) to be below the line. These are years of anomalously cold temperatures with 1991 generally regarded as the most severe. To investigate the possible influence of temperature on the relationships especially on the 1991 point which appears to be an outlier in some plots, I compared the residuals from the length-length residuals to water temperatures during the winter-spring period. As an indicator of temperatures during this period, I used mean monthly temperatures from \(0-20 \mathrm{~m}\) from Station 27, February-June summed (Tempsum) (Fig. 11). January temperatures had missing values so this month was not used and the February-June period spans the time period when gonads are developing.

In all cases, the relationships between the residuals and temperature were positive and statistically significant (Figs. 12, 13, 14 and 15). Although such relationships do not necessarily mean there is a direct cause and effect relationship, they are suggestive that in cold years, the growth between fall and spring is less than in warmer years.
b) Age compositions

I used the same selected survey blocks as in the length comparisons. Age compositions from the combined selected blocks were then compared to the inshore age compositions (Fig. 16). In all of the plots, fish from the fall surveys are aged one year older and age compositions are labelled with the year corresponding to the inshore samples, eg. 1982 shows that 1981 survey age compositions, age +1 , and the 1982 inshore age composition. I did not perform any statistical tests but instead visually inspected the age compositions for patterns, especially for the occurrence of dominant year-classes or for obvious differences. In general, the offshore age compositions agreed with the inshore age compositions with notable exceptions being 1984 and 1990. In both years, the relative strengths of the two dominant age groups, three and four, were reversed. Generally, the acoustic surveys tended to produce age compositions with younger fish although in 1991, 1992 and 1993, age 2 (age 1 in the acoustic survey) were not detected, at least not in the blocks I used. Interestingly, 1991 (1990 survey - 1991 inshore) did not appear to be an outlier here as it had in the length comparisons. The strong 1986 year-class was detected in both the acoustic surveys as age 4 in 1990 and inshore as age 5.

\section*{Discussion}

Both the length and age composition comparisons indicate that the acoustic surveys contain information of relevance to the inshore spawning population, even if the biomass estimates continue to be questioned. The length analysis for females is of particular relevance to the inshore fishery. Size has been more important to the industry in recent years with the market preferring larger females. The 1994 (and the provisional 1995) management plan contained a provision that the fishery would not open unless the female count was 50 (or less) females per kg . The mean size (137 mm ) of females age 2 in the 1994 acoustic survey was slightly smaller than previous estimates of age 2; females at age 3 ( 158 mm ) were smaller than average but larger than females of the same age in 1992, and 1993 and females at age \(4(164 \mathrm{~mm})\) were the second smallest on record (1993 were smaller and 1994 the same size). If these estimates of mean length are indicative of the population, growth between November 1994 and the 1995 inshore fishery would have to be above average for these fish to be comparable in size at age as those in the 1980's.

The blocks from the 1994 survey used in this comparison contained \(38 \%\) one-year-old and \(56 \%\) two-year-old males and \(37 \%\) one-year-old, 48\% two-year-old and \(11 \%\) three-year-old females. Even if the proportions are not exact in predicting, it suggests that the inshore stocks in 1995 will again have a substantial proportion of two- and three-year-olds. Surveys in 1990, 1991, and 1992 all tended to underestimate the proportions of one-year-olds that later appeared as two-year-olds inshore (Fig. 16), again suggesting that there will be a substantial proportion of two-year-olds in 1995. These indications plus the overall small size of females in the 1994 survey would be indicative of small fish in 1995.

\title{
Comparisons of Capelin Ageing
}
by
J. Carscadden

St. John's, NF A1C 5X1

\section*{Introduction}

This study was initiated by apparent differences in age-compositions for capelin collected inshore since 1991. Otoliths collected for different studies and read independently by two readers resulted in dissimilar age compositions, even though both age compositions were assumed to be indicative of the same population. Differences in sampling could have contributed to the differences but the possibility of differences in age interpretations could not be eliminated without a formal ageing comparison.

The study was designed to compare readings between two age readers as well as determine whether age interpretation change over time. The two readers who participated in the experiment are experienced at reading capelin otoliths. Reader A had read capelin otoliths during the mid to late 1960 's as part of directed capelin research during that time period. He had not read capelin otoliths during the \(1970^{\prime}\) s and 1980's but had resumed age-reading during the 1990's as part of new capelin research. Some of his earlier capelin age readings as well as the otoliths were still on file thus affording an opportunity to compare age readings from this study with ages assessed during the 1960's. Reader B has been the only person assigning capelin ages since the early 1980's. As a result, we were able to compare ages determined during this study to ages determined more than 10 years ago. At the same time, we were able to compare the ageing by Readers \(A\) and \(B\).

This study does not determine accuracy, therefore, readings made by either reader cannot be declared correct or incorrect. The study does determine precision (sensu Beamish and McFarlane 1983) in that the degree of agreement is a measure of the precision of the determinations, but not the accuracy. The results allow us to assess whether ages are different and whether there is a tendency for either reader to read older or younger (bias).

\section*{Materials and Methods}

The study was conducted in two parts, herein called Phase I and Phase II. Some of the same otoliths were read in both phases which for each reader were read about 5 months apart.

Capelin otoliths are permanently mounted in shallow depressions in black plexiglass trays. During reading, the otoliths are immersed in alcohol. Usually otolith pairs are available and ages are read using a binocular microscope and reflected light. Each otolith tray can accommodate up to 50 otolith pairs which usually comprise a sample.

Otoliths were not randomized' within a tray because of the danger of breakage and loss if detachment of the otolith was attempted. However, each phase contained several trays and presentation of the trays was randomized. The readers received the trays numbered in the same way but order of reading was left to the readers. Ages were assessed by each reader independent of the other reader.

During routine otolith reading, ancillary information such as catch data (date, time, location) and biological information are available. However, for this study only location (NAFO Division), date of capture (month, day, but not year), length, sex and maturity of fish were given. Thus, the information available approximated that available during routine ageing with the major exception being year. Since we wished to examine consistency of readings over years, knowledge of the years was withheld.

Otolith trays were chosen randomly from existing collections. Biological data were examined to ensure that a range of sizes and ages was available in the chosen samples and individual otoliths were visually examined to ensure that otoliths were not obviously damaged or missing.

\section*{Phase I}

Enough trays were chosen from 1967/68, 1987 and 1992 to give between 200 and 250 otolith pairs for each time period (Table 1). In total, there were 701 ages and the trays were labelled in the order shown in Table 1.

This selection of otoliths permitted the following comparisons.

\section*{Between Reader Comparisons}
a) Readings from all otoliths were used to compare ageing by Reader A and B.
b) Readings from otoliths from 1967-68 were used to compare ageing by Reader \(A\) and \(B\).
c) Readings from otoliths from 1987 were used to compare ageing by Reader \(A\) and \(B\).
d) Readings from otoliths from 1992 were used to compare ageing by Reader \(A\) and \(B\).

\section*{Within Reader Comparisons}
e) Since Reader A had originally read the ages from 1967-68, his ageing from that time period could be compared to his ageing of the same otoliths in 1994.
f) Since Reader \(B\) had originally read the ages from 1987, his ages from that year could be compared to his ages from the same otoliths in 1994.
g) Since Reader B had originally read the ages from 1992, his ages from that year could be compared to his ages from the same otoliths in 1994.

\section*{Phase II}

The main objective of this phase was to compare the readings from a selection of otoliths from Phase I read about 5 months apart to determine whether individual readers differed over this relatively short time period. From the Phase I group of otoliths, two trays were randomly selected from each of the three time periods, 1967-68, 1987 and 1992. In an attempt to ensure that individual readers did not recognize these otoliths, additional samples were selected and all trays were randomized. In this case, I selected about 200-250 otoliths from each of two years, 1982 and 1993 (Table 2). Nineteen eighty-two was chosen because Reader B had originally read these ages so it permitted a further comparison of his ageing over a longer time period. Nineteen ninety-three was chosen because it allowed another comparison over a short-time period. In addition, hydrographic conditions since 1990 have been negatively anomalous and readers had noted that otoliths had been more difficult to read, perhaps because of unusual growth patterns.

Therefore this selection of otoliths permitted the following comparisons.

Within Reader Comparisons
a) A comparison of short-term readings for both readers from otoliths from Phase I.
b) Since Reader B had originally read the ages from 1982, his ages from that time could be compared to his ages from the same otoliths in 1994.
c) Since Reader \(B\) had originally read the ages from 1993, his ages from that time could be compared to his ages from the same otoliths in 1994.

In addition to the basic comparisons above, the following comparisons were also made. These between reader comparisons for individual years augmented the previous comparisons in Phase I.

\section*{Between Reader Comparisons}
d) Reader A and Reader B's 1994 readings of 1982 otoliths were compared.
e) Reader A and Reader B's 1994 readings of 1993 otoliths were compared.

\section*{Statistical Analysis}

The ageing comparisons were analyzed using a test of symmetry originally developed by Bowker (1948) and recently applied to ageing data by Hoenig et al. (1995).

Hoenig et al. (1995) briefly describe the test as it is applied to ageing data and this description is extracted directly from their description.
"Bowker's technique (1948) was designed to test the hypothesis that an \(m \times m\) contingency table consisting of two classifications of a sample into categories (eg., ages given by two readers) is symmetric about the main diagonal. The test statistic is distributed as a chi-square variable with \(m(m-1) / 2\) degrees of freedom for a table that has no empty cells. The test statistic is:
\[
\boldsymbol{x}^{2}=\sum_{i>j} \sum_{j} \frac{\left(n_{\mathrm{ij}}-n_{\mathrm{ji}}\right)^{2}}{n_{\mathrm{ij}}+n^{\mathrm{ii}}}
\]
where: \(n_{i j}=\) the observed frequency in the ith row and jth column
\(n_{j i}=\) the observed frequency in the \(j\) th row and ith column

The summation is over all the cells above the diagonal. These cells are paired with the corresponding cells below the diagonal. If there is a systematic difference between methods then the test statistic will tend to be large. If, however, the differences are due to simple random error, then the value of \(n_{j i}\) will be very similar to that of \(n_{i j}\) and the test statistic will not be significant. The number of degrees of freedom is equal to the number of comparisons. If both cells in a pair ( \(n_{\mathrm{ij}}\) and \(n_{i j}\) ) are zero, the pair is dropped from the test statistic and the degrees of freedom is reduced by one."

\section*{Results}

\section*{Phase I}

\section*{Between Reader Comparisons}
a) Comparison between readers using all otoliths.

When all samples are combined the agreement between the readers was \(72 \%\) (Table 3). The test of symmetry shows differences were significant ( \(x^{2}=167.2, \mathrm{df}=7, \mathrm{p} \leq 0.001\) ) with Reader \(B\) showing a tendency to assign younger ages (Table 3, Fig. 1).
b) When the 1994 readings of 1967-68 otoliths were compared, there was 84\% agreement between readers (Table 4). The test of symmetry indicated a significant difference ( \(\boldsymbol{x}^{2}=35.1\), df \(=6, \mathrm{p} \leq 0.001\) ). Where differences occurred, the tendency was for Reader B to assign younger ages (Table 4, Fig. 2).
c) When the 1994 readings of 1987 otoliths were compared, there was \(77 \%\) agreement between readers (Table 5). The test of symmetry indicated a significant difference ( \(\boldsymbol{x}^{2}=40.7\), df \(=7, \mathrm{p} \leq 0.001\) ). The major differences occurred in the assignment of younger ages by Reader B (Table 5, Fig. 3).
d) There was only 52\% agreement between readers for 1994 age readings of 1992 otoliths (Table 6). The test of symmetry showed significant differences ( \(\boldsymbol{x}^{2}=94.5\), df \(=5, \mathrm{p} \leq 0.001\) ). The asymmetry in ageing was reflected in the assignment of younger ages by Reader \(B\) compared to Reader A (Table 6, Fig.4).

\section*{Within Reader Comparisons}
e) Reader A had originally assigned ages to otoliths collected during 1967-68. His original and 1994 readings showed 83\% agreement (Table 7). The mean ages (Table 7) and age compositions (Fig. 5) were similar suggesting that there was no systematic bias in ageing. However, the test of symmetry showed a significant difference ( \(\boldsymbol{X}^{2}=11.18\), df \(=5\), \(\mathrm{p} \leq 0.05\) ). There were more differences above the diagonal in Table 1 indicating a tendency to reader older in 1994 compared to 1967-68.
f) Reader \(B\) had originally assigned ages to these otoliths in 1987. His 1994 and original readings showed \(96 \%\) agreement (Table 8) and age compositions were similar (Fig. 6). The test of symmetry was not significant \(\left(\boldsymbol{x}^{2}=2.67\right.\), \(\mathrm{df}=2\), \(p \leq 0.30\) ).
g) Age readings in 1994 by Reader B for 1992 otoliths showed \(90 \%\) agreement with his original 1992 readings (Table 9, Fig. 7). The test of symmetry was significant \(\left(x^{2}=12.25, \mathrm{df}=3\right.\), \(\mathrm{p} \leq 0.01\) ). Reader B tended to assign younger ages in 1994 compared to 1992.

Phase II

\section*{Within Reader Comparisons}
a) When Reader A read the same otoliths about 5 months later, there was only about \(79 \%\) agreement, although mean ages (Table 10) and age compositions (Fig. 8) were similar. The test of symmetry was not significant \(\left(x^{2}=3.89\right.\), df \(=5\), \(\mathrm{p} \leq 0.30\) ). This illustrates the fact that while overall agreement in ageing was not good, there was no systematic bias in the disagreements. As a result the test of symmetry was not significant and mean ages and age compositions were similar.

Reader B exhibited a higher agreement (94\%) over the 5-month period. As a result, mean ages (Table 11) and age compositions (Fig. 9) were similar and the test of symmetry was not significant ( \(x^{2}=7.8, \mathrm{df}=4, \mathrm{p} \leq 0.10\) ).
b) Reader B had originally assigned ages to the 1982 otoliths. The agreement between the 1994 and original readings was \(83 \%\) (Table 12). The test of symmetry was significant ( \(\boldsymbol{x}^{2}=29.1\), \(\mathrm{df}=6, \mathrm{p} \leq 0.001\) ). There was a tendency to read younger in 1994 with the greatest differences occurring at ages 2 and 6 (Table 12, Fig. 10).
c) When a similar comparison was made for Reader B using 1993 otoliths, there was 95\% agreement (Table 13). The test of symmetry was not significant ( \(x^{2}=5.14\), df \(=3, p \leq 0.20\) ) and mean ages (Table 13) and age compositions (Fig. 11) were similar.

\section*{Between Reader Comparisons}
d) There was 63\% agreement between Reader A and Reader B's ageing of the 1982 otoliths (Table 14). The test of symmetry was significant ( \(\boldsymbol{X}^{2}=89.5, \mathrm{df}=9, \mathrm{p} \leq 0.001\) ). There was a tendency for Reader \(B\) to assign younger ages than Reader A (Table 14, Fig. 12).
e) When the ageings of otoliths from 1993 were compared, there was only 59\% agreement (Table 15). The test of symmetry was significant ( \(X^{2}=90.6\), df \(=5, p \leq 0.001\) ). Reader \(B\) generally assigned younger ages than Reader A (Table 15, Fig. 13).

A summary of the overall results of the comparisons is given in Table 16. Several observations can be made.
1) Reader \(A\) and Reader \(B\) are interpreting the otoliths differently - all between reader comparisons indicated a significant difference using the test of symmetry. In all cases, there was a tendency for Reader A to assign older ages and Reader \(B\) to assign younger ages.
2) In the between-reader comparisons using individual years, the agreements going from best to worst were 1967-68, 1987, 1982, 1993, 1992. Thus, although the trend with years is not exact, the fact that the worst agreement occurred in the most recent years may support the observation that otoliths in recent years are more difficult to read. An explanation for this difficulty may be that environmental conditions have altered growth patterns - this might result in physical changes in the otolith making it difficult to read and it may affect interpretation relative to other years.
3) For both readers, there were no statistical differences in interpretation of otoliths over a short-time period of less than one year ( 5 months).
4) For Reader A, otoliths previously read by him were available for only one time period 1967-68. There was a significant difference in the readings with the more recent readings showing a tendency to assign older ages.
5) For Reader B, several years were examined, namely 1982, 1987, 1992, 1993. Significant differences occurred for otoliths from 1982 and 1992 but not for 1987 and 1993. This may indicate inconsistency in ageing over time but a more definite conclusion is not immediately obvious. Where differences did occur, the 1994 readings showed a tendency to assign younger ages.
6) Out of 13 comparisons that were made, nine showed significant differences using Bowker's test (Table 16). I did not conduct further tests on those comparisons that showed significant differences, but simply examined the age compositions and made a subjective determination on whether there appeared to be differences. The results are given below.
\begin{tabular}{|c|c|c|c|}
\hline Comparison & Description & Differences in age compositions & Reference \\
\hline \multirow[t]{4}{*}{Between A \(\times\) B} & all samples Phase I & Yes & Fig. 1 \\
\hline & 1994 readings of 1967-68 otoliths & No & Fig. 2 \\
\hline & 1994 readings of 1987 otoliths & No & Fig. 3 \\
\hline & 1994 readings of 1992 otoliths & Yea & Fig. 4 \\
\hline \multirow[t]{3}{*}{Within readers} & \begin{tabular}{l}
Reader A - 1967-68 \\
otoliths - original ages compared to 1994 ages
\end{tabular} & No & Fig. 5 \\
\hline & Reader B - 1992 otoliths original ages compared to 1994 ages & No & Fig. 7 \\
\hline & Reader B - 1982 otoliths original ages compared to 1994 ages & No & Fig. 10 \\
\hline \multirow[t]{2}{*}{Between readers} & 1994 readings of 1982 otoliths & Yes & Fig. 12 \\
\hline & 1994 readings of 1993 otoliths & Yes & Fig. 13 \\
\hline
\end{tabular}

Thus in the between reader comparisons I concluded that we would have interpreted age compositions differently in four out of six cases where statistical differences in age readings were also shown to have occurred. When significant differences between ages occurred within ages by the same reader, I concluded that we would not likely have drawn different conclusions by examining age compositions alone.

\section*{Further Work}
1) The analysis will be extended to examine if differences are related to sex of fish. Females appear to have a higher spawning survival and as a result, spawning checks may be deposited on the otolith and interpreted as annuli.
2) Resolve differences in readers. One possibility is to have otoliths read by Icelandic, Norwegian and/or Russian age readers.
3) Initiate a system that will maintain inter-annual consistency. Possibilities include reading a reference collection at the start of each annual age-reading session or have a subsample read by an independent reader.
4) Eventually all otolith images will be stored in an image analysis system. Each image will have the otolith with annuli flagged. This will allow future age readers to retrieve historical images and see what structures former readers interpreted as annuli. Otoliths will continue to be stored as they are at present.

\section*{INTRODUCTION}

Stock assessment generally requires the current status of a fish stock to be inferred from available information. Various analytical assessment procedures have been developed to do this. Here "analytical procedures" are defined as all approaches which result in a numerical estimate of population size from a statistical sample of some quantity that is related to population size in a mathematically describable way. Desirable qualities of such procedures are that they be objective, rigorous, repeatable (give the same answer if applied a second time to exactly the same data) and explicit. Diagnostic tests may be included to judge the validity of an outcome. When there are insufficient data, data of poor quality, or a failure to pass the diagnostic tests, analytical procedures may be abandoned for subjective procedures. Here "subjective procedures" are defined as all approaches which result in a qualitative estimate of stock size from information which does not constitute a valid statistical sample of a quantity related to population size in a mathematically describable way. The subjectivity in such procedures replaces the mathematical description of the relationship between information and population size that is found in an analytical assessment. Unfortunately, such approaches typically lack rigour, are seldom explicitly described, and do not guarantee the same outcome if repeated on exactly the same data.

Many fish stock assessments in the Northwest Atlantic are pursued subjectively. A variety of information that may relate in some way to the status of
a stock is reviewed by a working group and a conclusion is drawn regarding current stock status. There is no guarantee that such assessments are logical, rational and repeatable. One approach to provide rigour and repeatability to subjective approaches is to use Bayesian inference. In this paper this approach is described and then applied to quantify the assessment of three extant cohorts of the NAFO Div. 2J3KL capelin stock. Here "quantify" is defined as making explicit in mathematical terms the procedure used to arrive at an assessment of stock status.

\section*{DESCRIPTION OF THE APPROACH}

It can easily be demonstrated that human reasoning may be flawed when it comes to drawing inferences from evidence, even in the simplest of cases (Plant and Stone 1991). Consider the case where the probability of having disease X is 1 in 10,000 . A test is devised for detecting the disease. The test is not perfect so that 9 times out of 10 it correctly detects the disease when the disease is present, whereas 1 time out of 10 it indicates the person has the disease when in fact they do not (false positive). You take the test and the test is positive. What is the probability that you actually have the disease? Most people will incorrectly assign too high value to the probability that they have the disease, whereas the rational answer, under Bayes rule, is 0.0009 .

Bayes rule is
\[
\begin{equation*}
\mathrm{P}(\mathrm{H} \mid \mathrm{E})=\frac{\mathrm{P}(\mathrm{H}) \mathrm{P}(\mathrm{E} \mid \mathrm{H})}{\mathrm{P}(\mathrm{H}) \mathrm{P}(\mathrm{E} \mid \mathrm{H})+\mathrm{P}(\overline{\mathrm{H}}) \mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})} \tag{1}
\end{equation*}
\]
where \(\mathrm{P}(\mathrm{H} \mid \mathrm{E})\) is the posterior probability of the hypothesis \((\mathrm{H})\) being true given the evidence ( E ). In this example the hypothesis is that you have disease X . The evidence is the positive test. \(\mathrm{P}(\mathrm{H})\), the prior probability of the hypothesis is the probability that you have the disease before you take the test ( 1 in \(10,000=0.0001\) ). \(\mathrm{P}(\mathrm{E} \mid \mathrm{H})\), the probability of the evidence given that the hypothesis is true is the probability of a positive test, given that you have disease \(\mathbf{X}\) ( 9 times out of \(10=0.9\) ).
\(\mathrm{P}(\overline{\mathrm{H}})\), the prior probability that the hypothesis is not true is the probability that you do not have the disease before you take the test \((1-\mathrm{P}(\mathrm{H})=0.9999) . \mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})\), the probability of the the evidence when the hypothesis is false is the probability of getting a positive test when you do not have disease X ( 1 time out of \(10=0.1\) ). Thus
\[
\begin{aligned}
P(H \mid E) & =\frac{0.0001 \times 0.9}{0.0001 \times 0.9+0.9999 \times 0.1} \\
& =0.00089928
\end{aligned}
\]

In other words, the positive test has changed the probability of having the disease from 1 in 10,000 before you took the test to about 1 in 1,000 after you took the test. Although in this example the probabilities provided for resolving the hypothesis using Bayes rule may have been empirically derived, the same rule can be applied to subjectively derived probabilities.

The inherent "strength" or "usefulness" of the evidence for resolving the hypothesis in the above application of Bayes rule is completely determined by the difference between the probability of a false positive ( \(\mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})=0.1\) ) and the probability of a true positive \((\mathrm{P}(\mathrm{E} \mid \mathrm{H})=0.9)\). In addition to the strength of the evidence, application of Bayes rule to assessment problems also requires uncertainty in the evidence to be accounted for. For example, the evidence from an acoustic survey may be that the strength of a cohort is strong, but how certain are we of that evidence? This certainty can be provided directly based on subjective judgment, or it can be derived by further application of Bayes rule (deepening of the inference web), in which the evidence is treated as an hypothesis to be resolved by the evaluation of subjective evidence relating to this hypothesis. In this initial application the certainty of the evidence (that the cohort is strong) must be supplied directly. Duda et al. (1976) provide the following solution for updating the probability of an hypothesis given uncertain evidence
\[
\begin{equation*}
P\left(H \mid E^{\prime}\right)=P(H \mid E) P\left(E \mid E^{\prime}\right)+P(H \mid \bar{E}) P\left(\bar{E} \mid E^{\prime}\right) \tag{2}
\end{equation*}
\]

For most stock assessment problems it is likely that several independent pieces of evidence \(\mathrm{E}_{\mathrm{i}}\) relating to stock status will be available. In the disease example this would be equivalent to several independent tests for the same disease. Duda et al. (1976) provide a method for taking multiple sources of uncertain evidence into account, assuming that the different pieces of evidence are independent. Recall that under Bayes rule
\[
\begin{equation*}
\mathrm{P}(\mathrm{H} \mid \mathrm{E})=\frac{\mathrm{P}(\mathrm{H}) \mathrm{P}(\mathrm{E} \mid \mathrm{H})}{\mathrm{P}(\mathrm{H}) \mathrm{P}(\mathrm{E} \mid \mathrm{H})+\mathrm{P}(\overline{\mathrm{H}}) \mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})} . \tag{3}
\end{equation*}
\]

The complimentary form of (3) is
\[
\begin{equation*}
\mathrm{P}(\overline{\mathrm{H}} \mid \mathrm{E})=\frac{\mathrm{P}(\overline{\mathrm{H}}) \mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})}{\mathrm{P}(\mathrm{H}) \mathrm{P}(\mathrm{E} \mid \mathrm{H})+\mathrm{P}(\overline{\mathrm{H}}) \mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})} . \tag{4}
\end{equation*}
\]

Dividing (3) by (4) gives
\[
\begin{equation*}
\frac{\mathrm{P}(\mathrm{H} \mid \mathrm{E})}{\mathrm{P}(\overline{\mathrm{H}} \mid \mathrm{E})}=\frac{\mathrm{P}(\mathrm{H}) \mathrm{P}(\mathrm{E} \mid \mathrm{H})}{\mathrm{P}(\overline{\mathrm{H}}) \mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})} \tag{5}
\end{equation*}
\]

There are three terms in this equation:
(i) the prior odds
\[
\begin{equation*}
\mathrm{O}(\mathrm{H})=\frac{\mathrm{P}(\mathrm{H})}{\mathrm{P}(\overline{\mathrm{H}})} \tag{6}
\end{equation*}
\]
(ii) the posterior odds
\[
\begin{equation*}
\mathrm{O}(\mathrm{H} \mid \mathrm{E})=\frac{\mathrm{P}(\mathrm{H} \mid \mathrm{E})}{\mathrm{P}(\overline{\mathrm{H}} \mid \mathrm{E})} ; \tag{7}
\end{equation*}
\]
and (iii) the likelihood ratio
\[
\begin{equation*}
\lambda=\frac{\mathrm{P}(\mathrm{E} \mid \mathrm{H})}{\mathrm{P}(\mathrm{E} \mid \overline{\mathrm{H}})} \tag{8}
\end{equation*}
\]

Note that
\[
\begin{equation*}
\lambda=\frac{\mathrm{O}(\mathrm{H} \mid \mathrm{E})}{\mathrm{O}(\mathrm{H})} . \tag{9}
\end{equation*}
\]

The equivalent form of (9) for the ith piece of uncertain evidence is
\[
\begin{equation*}
\lambda_{\mathrm{i}}^{\prime}=\frac{\mathrm{O}\left(\mathrm{H} \mid \mathrm{E}_{\mathrm{i}}^{\prime}\right)}{\mathrm{O}(\mathrm{H})} . \tag{10}
\end{equation*}
\]
\(\mathrm{O}\left(\mathrm{H} \mid \mathrm{E}_{\mathrm{i}}^{\prime}\right)\) is obtained from the updating equation (2). Multiple uncertain evidence is combined to obtain the posterior odds by multiplying the product of the likelihood ratios by the prior odds:
\[
\mathrm{O}\left(\mathrm{H} \mid \mathrm{E}_{\mathrm{i}}^{\prime}, \ldots, \mathrm{E}_{\mathrm{n}}^{\prime}\right)=\left[\prod_{\mathrm{i}=1}^{\mathrm{n}} \lambda_{\mathrm{i}}^{\prime}\right] \mathrm{O}(\mathrm{H})
\]
from which
\[
\mathrm{P}\left(\mathrm{H} \mid \mathrm{E}_{\mathrm{i}}^{\prime} \ldots, \mathrm{E}_{\mathrm{n}}\right)=\frac{\mathrm{O}\left(\mathrm{H} \mid \mathrm{E}_{\mathrm{i}}^{\prime}, \ldots, \mathrm{E}_{\mathrm{n}}^{\prime}\right)}{\left(\mathrm{O}\left(\mathrm{H} \mid \mathrm{E}_{\mathrm{i}}^{\prime} \ldots, \mathrm{E}_{\mathrm{n}}^{\prime}\right)+1\right)} \text { can be obtained, the probability of the }
\]
hypothesis given multiple uncertain evidence.

\section*{APPLICATION TO THE DIV. 2J3KL CAPELIN STOCK ASSESSMENT}

Assessments of the Div. 2J3K and Div. 3L substocks of capelin have in the past commonly been carried out by estimating population numbers at age in the current year from a hydroacoustic survey, and using these estimates to forecast next year's spawner biomass. The recommendation is typically a total allowable catch (TAC) that does not result in an exploitation rate that exceeds \(10 \%\) of the projected spawner biomass. The performance of this procedure has been evaluated for the Div. 3L stock by Shelton et al. (1993) and found to be reasonably conservative despite all the uncertainties. High exploitation rates are thought to be potentially detrimental to cod stocks because capelin is a major forage species for cod. However, the small roe fishery on capelin is lucrative and it is undesirable to constrain this fishery below the market demand by imposing
unnecessarily conservative TACs.

Mature capelin move to inshore areas in summer to spawn on beaches, during which time the trap and purse seine roe fishery is pursued. Supplementary information on stock status from inshore trap catch rates, inshore aerial surveys and spawning activity on beaches has not generally played an influential role in the assessment. However, in recent assessments the biomass of fish detected offshore by means of hydroacoustics has decreased substantially and application of the \(10 \%\) exploitation rate would have severely limited fishing on capelin. In contrast, information on inshore catch rates, inshore aerial surveys and beach spawning activity do not appear to reflect the substantial decline observed in the hydroacoustic surveys (Anon. 1994a).

Faced with this dilemma the projection/10\% exploitation rate procedure was not consistently applied to the Divs. 2J3K or Div. 3L capelin stocks in recent years. For example, with respect to the Div. 2J3K stock, in the 1991 assessment the acoustic estimate was judged invalid because of a very large decline from 1989 to 1990, the projection procedure was not carried out and the TAC recommendation was that the catch should not exceed that of the previous year (Anon 1991). The projection/10\% exploitation rate procedure was carried out in 1993 but not in 1992. In both the 1992 and 1993 assessments the difference between the offshore acoustic survey and inshore information could not be reconciled, and it was recommended that the TAC be set to the lowest possible level (Anon 1992, 1993). In the 1994 assessment much more emphasis was given to the inshore information (Anon 1994a). It is of interest to note that the amount of disbelief in the acoustic estimate that could be tolerated before abandoning it was never quantified. In a further development, the substocks are now assessed as a single Div. 2J3KL stock.

As a consequence of discontinuing the projection procedure based on the offshore acoustic survey, inshore information has become influential in the assessment, as noted above, and scientists now struggle to resolve the multiple
uncertain evidence regarding stock status from the inshore sources and from offshore sources. In addition to the acoustic survey, capelin bycatch and the partial fullness index of capelin (PFI) in cod stomachs in the fall groundfish survey provide two additional offshore indices.

In the most recent assessments the relative strengths of the different pieces of evidence have been evaluated largely on a qualitative basis and discussions have continued until a reasonable level of consensus has been reached regarding stock status. The recommendation regarding TAC (e.g. lowest possible catch, same catch as last year, average catch) based on the assessment is only qualitatively linked with recognised uncertainty in the conclusion regarding stock status. Such an approach is susceptible to irrational reasoning (i.e. inconsistent with the axioms of probability, see simple example given above). Further, there is no explicit trace of the procedure used to reach a conclusion regarding the status of the stock and should the assessment be repeated with exactly the same information there is no guarantee that the same conclusions will be drawn.

Application of the method of Duda et al. (1976) described above as a basis for providing scientific advice for 1995 was carried out by constructing a FRONT END spreadsheet to handle the required inputs and to present the results of the assessment, and an INFERENCE spreadsheet to handle the computations. The FRONT END constructed for the 1995 assessment is described below.

\section*{A SUBJECTIVE ASSESSMENT FOR 1995}

In the FRONT END spreadsheet, (Table 1), the decision options, decision rules, prior feelings regarding cohort strengths and the information from each of the fall and summer indices are considered in turn. The FRONT END was constructed by a subgroup of the assessment participants. It is generally considered that the 1983 and 1986 cohorts were strong and that the 1981 and 1984
cohorts were weak. In order to determine the strength of an index, the past performance of the index with respect to correctly indicating that the 1983 and 1986 cohorts were strong and the 1981 and 1984 cohorts were weak was taken into account.

Decision options
The preliminary Management Plan for 1995 provides for the same TAC recommended to the Minister last year \(-33,000 \mathrm{t}\). In keeping with the subjective nature of the assessment the "advice space" was discretized into 4 options: (i) Double the TAC (i.e. 66,000 t), (ii) Retain the MP TAC (i.e. 33,000 t), (iii) Halve the TAC (i.e. \(15,000 \mathrm{t}\) ), or (iv) Set the TAC to zero. In order to decide on which option is appropriate, the anticipated status of the three cohorts likely to contribute to the fishery in 1995 are assessed - the 1991, 1992 and 1993 cohorts. The objective of the assessment is to infer for each cohort in turn the probability that it is strong from the available information. On the basis of this result a decision rule is triggered leading to one of the 4 advice options.

\section*{Decision rules}

It was considered that 3 rules would be adequate. If it is quite certain (i.e. \(\mathrm{P}=0.9\) ) that either the 1991 or 1992 cohorts are strong, then the TAC could be doubled \(66,000 \mathrm{t}\) from the present MP level of \(33,000 \mathrm{t}\). However, if there is a fairly substantial probability ( \(\mathrm{P}=0.7\) ) that both cohorts are weak, then the TAC should be halved to \(15,000 \mathrm{t}\). If it is more certain ( \(\mathrm{P}=0.9\) ) that both cohorts are weak, then a zero TAC should be imposed. If none of the three rules are triggered, then the present MP TAC of \(33,000 \mathrm{t}\) is considered adequate and is retained.

A strong cohort is defined to be such that should a catch of double the TAC ( \(66,000 \mathrm{t}\) ) come entirely from that cohort, the exploitation rate would not exceed the \(10 \%\) level. The probability that the cohort is weak is given by
\(\mathrm{P}(\) weak \()=1-\mathrm{P}\) (strong).

The strength of the 1993 cohort is not used in the TAC decision rules because it was considered that inferences regarding the strength of this cohort would be considered very preliminary and, because 2-year olds are a minor component of the fishery, the abundance of 2-year olds are not particularly relevant to the 1995 assessment. Nevertheless, an inference is drawn regarding the strength of the 1993 cohort because of the importance of this cohort to the 1996 assessment.

Prior probabilities regarding cohort strengths

The prior probability, before looking at the information contained in the indices, that the cohorts are strong were set equal at \(\mathbf{P}=0.2\). The reasoning behind this choice of prior probability was that strong year classes (as defined above) occur relatively infrequently about 2 years in 10 .

Indices of year-class strength

To aid in deciding on the strength of each index, Fig. 5 (Nakashima 1994) was used to evaluate whether strong or weak year-classes in the historical time-series were detected as such by the indices. Emphasis was on year-classes during the 1980s when there was some confidence in the relative strengths. The 1983 and 1986 year-classes were considered strong and 1981 and 1984 weak. Consideration was also given to general expectations for the index (eg. was it designed for capelin?) and length of the time-series (eg. short time-series might be given less weight since it was difficult to judge the usefulness of the series to discriminate between strong or weak year-classes). These indices are given alphabetical identifiers (e.g. Index F) which correspond to the identifiers used in the multiplicative analysis described in Chapter 15 of this report.

Index F - Groundfish RV trawl bycatch of 1-year-old capelin in 3L
- few data points for early years
- no evidence for strong year-classes
- weak year-classes were sampled but could not be compared to strong because strong year-classes were not sampled
- potentially an area where one-year-olds should occur in abundance
- based on frequency occurrence

Decision: no discriminating power to distinguish strong or weak yearclasses, therefore the index is not used (setting all probabilities to 0.5 results in the index having no effect in the inference of year-class strength).

Index F - Groundfish RV trawl bycatch of 2-year-old capelin in 3L
- two strong year-classes appeared higher than others
- few data points but no strong evidence that a strong cohort is shown when it is actually weak

Decision: 0.7 probability that strong cohorts detected when they are strong 0.5 probability that weak cohorts are mistakenly registered as strong

Index in 1993 for 1991 cohort:
- nothing inherently wrong with survey
- index suggests an "average" cohort
- probability of 0.3 that cohort is strong

Index in 1994 for 1992 cohort
- only one sample from survey
- index appears very weak
- assigned probability of 0.5

Index F - Groundfish RV trawl bycatch of 3-year-old capelin in 3L
- detected strong 1986 year-class, other year-classes weaker

Decision: probability of detecting strong when strong is 0.6 probability of detecting weak when weak is 0.5

Index in 1994 for 1991 cohort - no fish caught, evidence that cohort is strong is 0.

Index G - Groundfish RV trawl bycatch of 1-year-old capelin in 2J3K
- no detection ability for strong year-classes
- weak year-classes show as zeros
- some estimates of year-classes but sporadic

Decision: no certainty about ability to detect cohorts
- dropped from analysis

Index G - Groundfish RV trawl bycatch of 2-year-old capelin in 2J3K - picked up 86 year-class in 1988, no samples for 1983 year-class - weak 1961 year-class detected as weak
- no misleading information about strong year-classes
- many missing years

Decision: probability of detecting strong 0.6
probability of indicating strong when weak 0.5

Index in 1993 for 1991 cohort
- no known problems with survey, reasonable sample size
- the value appears valid and relatively strong
- assigned probability of 0.5

Index in 1994 for 1992 cohort
- good sample size, value indicates strong cohort
- assigned probability of 0.6

Index G - Groundfish RV trawl bycatch of 3-year-old capelin in 2J3K
- would expect these older fish in area
- no data for 83 or 86 year-classes
- 1984 appears weak

Decision: marginal information about this age group
probability of showing strong when strong .5
probability of showing strong when weak . 4

Index in 1994 for 1991 cohort
- value is lowest in series
- probability of being strong 0.3

Index H-Canadian acoustic survey index in 3L
- data for only two years
- target strength values potentially inaccurate for these small fish
- would not be surprised to detect one-year-olds in this area

Decision: evidence too weak to accept index as reliable, mainly because of short data-series therefore not used in analysis for any age group

Index K - Canadian acoustic survey index for 1-year-olds in 2J3K
- did not detect strong year-classes
- indicated 1987 was strong
- one-year-olds in 3K some years, aerial coverage in this area variable early in survey

Decision: not a useful indicator, dropped from analysis

Index K - Canadian acoustic survey index for 2-year-olds in 2 J 3 K - picked up 83 and 86 year-classes as strong - 81 and 84 year-classes were weak

Decision: reasonable expectations of picking up strong cohorts, probability is 0.7
not likely to assign strong year-class designation to a weak cohort, probability is 4

Index in 1993 for 1991 cohort
- no problem with survey, extensive coverage
- low value for cohort, low probability of strong cohort, probability is 0.2

Index in 1994 for 1992 cohort
- no problem with survey, extensive coverage
- low value for cohort, low probability of strong cohort, probability is 0.2

Index K - Canadian acoustic survey index for 3-year-olds in 2J3K
- 1986 year-class was strong but 1993 not
- 1981 year-class relatively weak and 1984 year-class weak
- 1982 and 1985 year-classes were found to be as strong as 1983 therefore some potential to be mislead

Decision: about equal probability of detecting strong year-classes when strong, probability is 0.5
- less probable to assign strong when weak, probability is 0.3

Index in 1994 for 1991 cohort
- no problem with survey, extensive coverage
- low value therefore low probability that cohort is strong, probability is
0.2

Index O-Campelen trawl for 1-year-olds
- occurs in area where one-year-olds expected
- short series, cannot evaluate
- similar gear and timing of 3L fall groundfish survey, although fewer sets therefore should not expect higher probability of detecting year-classes correctly
(Note: index based on numbers per tow rather than frequency occurrence as in other groundfish bycatch indices)

Decision: no predictive ability with existing data set (assigned same probabilities as 3 L fall groundfish bycatch - 0.5 and 0.5 - and therefore index has no effect

Index O-Campelen trawl for 2-year-olds
- not enough data to evaluate index

Index O-Campelen trawl for 3-year-olds - not enough data to evaluate index

\section*{Summer indices}

Index A - aerial surveys of 1-year-old capelin in Trinity and Conception Bays - not applicable for 1-year-olds

Index A - aerial surveys of 2-year-old capelin in Trinity and Conception Bays - picked up good 83, 86 year-classes, poor 1984 year-class but assigned average strength to 81 year-class

Decision: reasonable probability of detecting strong year-classes, probability is 0.6
- some probability of saying weak year-class is strong, probability is 0.4

Index 1993 for 1991 cohort
- different source of age compositions compared to historical
- index shows above average
- probability that cohort is strong, probability is 0.4

Index in 1994 for 1992 cohort
- highest index on record
- different source of age compositions
- probability that cohort is strong is 0.6

Index A - aerial surveys of 3 -year-old capelin in Trinity and Conception Bays
- 1986 year-class strong but 1983 year-class average
- weak 81 and 84 year-classes shown as weak
- some year-classes shown as strong as 83 therefore index may suggest strong when weak

Decision: probability is 0.6 that strong year-class will be detected probability is 0.4 that weak year-class will be declared strong

Index in 1994 for 1991 cohort
- good survey in 1994
- very high value, even if assumed that aging might contribute, probability that cohort is strong is still high, probability is 0.7

Index R - the unadjusted egg deposition index for 2 and 3 year olds on selected beaches
- short time-series
- indirect measure of capelin abundance
- off-beach spawning may contribute substantial variability to unadjusted
- potential for off-beach spawning in 1994

Decision: no value to detect strong/weak cohorts in either time-series without more validation

Index M - Purse seine catch rate for 2-year-olds
- intuitively given less value as indicator of stock status because of known problems with indices from mobile gear
- however, series generally agrees with traps
- detected 83 and 86 strong, 81 and 84 as weak
- no indication that weak year class would be called strong

Decision: potentially good indicator
probability is 0.7 of detecting strong year class
probability of 0.3 of misinterpreting weak year class

Index in 1993 for 1991 cohort
- appears to be average therefore probability is 0.6

Index in 1994 for 1992 cohort
- no fishery in 1994

Index M - Purse seine catch rate for 3-year-olds
-no fishery in 1994

Index T - Trap catch rate for 2-year-olds
- intuitively more reliable indicator of stock status than purse seine
- long series, picked up good and weak year-classes with no apparent misleading years

Decision: probability is 0.8 to detect strong year-classes probability is 0.2 to be mislead regarding strong year-classes when actually weak

Index in 1993 for 1991 cohort
- very high index
- although aging differences may contribute to high value probability is 0.7 that cohort is strong

Index in 1994 for 1992 cohort
- no fishery in 1994.

Index T - Trap catch rate for 3-year-olds
- no fishery in 1994

Index C - Russian acoustic survey for 2-year-olds in 3L
- detected strong 83 and 86 year-classes
- 81 and 84 year-classes were weak

Decision: probability is 0.8 of detecting strong year-classes probability is 0.4 of detecting strong cohort when actually weak

Index in 1993 for the 1991 cohort
- no evidence that the cohort is strong
- probability that the cohort is strong is 0.2

Index C - Russian acoustic survey for 3-year-olds
- no data available for 1994

Index L - Canadian acoustic survey for 1-year-olds in 3L
- no information on 1-year-olds

Index L-Canadian acoustic survey for fish age 2 and 3 3L
- no data after 1992, therefore, no information on year-classes of interest

Index N - Groundfish RV trawl bycatch of 2-year-olds in 3L
- 1983 and 1986 detected as strong, 1984 weak
- no indication of incorrectly providing evidence that year class is strong when it is in fact weak

Decision: probability is 0.7 of detecting strong year-classes probability is 0.3 of misinterpreting weak year-classes

Index in 1993 for the 1991 cohort
- well below strongest but not weakest
- probability is 0.3 that cohort is strong

Index in 1994 for the 1992 cohort
- shows very high value
- small sample size
- some questions regarding \% occurrence versus weight in tows
- probability is 0.6 that cohort is strong

Index N - Groundfish RV trawl bycatch of 3-year-olds in 3L
- 1983 year-class strong, no samples available to assess 1986 year-class
- 1984 year-class weak, no samples for 81 year-class
- no indication of misleading information

Decision: probability is 0.6 of detecting strong cohorts
probability is 0.4 of incorrectly concluding cohorts are strong when actually weak

Index in 1994 for 1991 cohort
- very low value, small sample size, low certainty that cohort is strong, probability is 0.2

\section*{OUTCOME}

Based on the the FRONT END constructed as described above, the INFERENCE spreadsheet was used to calculate the posterior probabilities that the cohorts are strong given multiple sources of uncertain evidence. The outcome is that there is no updating of the prior probability for the 1993 cohort, given the evidence (i.e. the probability that the cohort is strong remains at 0.2 after taking into account the evidence). The probability that the 1992 cohort is strong is increased slightly from a prior probability of 0.2 to a posterior probability of 0.212 . The information from the spring groundfish RV trawl bycatch (Index N ) is influential in this increase. For the 1991 cohort, the posterior probability of it being a strong cohort is reduced from a prior probability of 0.2 to a posterior probability of 0.128 once the evidence is considered. The information from the fall Canadian acoustic survey is influential in this decrease (Index K). Based on these outcomes, and given the a priori decision rules, the FRONT END triggers the rule leading to the decision that the TAC should be halved from \(33,000 \mathrm{t}\) to \(15,000 \mathrm{t}\). Note that this application was considered exploratory and included the input of only a subset of participants. The outcome was not considered further in the determination of stock status, which was based mainly on the results of the multiplicative analysis reported in Chapter 15.

\section*{DISCUSSION}

The absence of adequate statistical samples may prevent a formal analytical approach to drawing inferences from evidence in some stock assessments. In such cases an approach based on subjective probabilities may be appropriate. However, human reasoning is not necessarily rational when combining probabilities. The method of Duda et al. (1976), described and applied above to the capelin assessment problem, provides a rational approach based on Bayes rule to the problem of drawing inferences from subjective probabilities. It differs from the more common use of Bayes rule in statistical inference in that not only are the
priors based on subjective reasoning, so are the likelihoods. It shares the same objectives of composite models such as that of Methot (1989) in that it seeks to combine the information from several indices of stock abundance, but it differs in that the information is subjective. It also differs in that the aim is not to draw an inference regarding abundance in absolute terms. In the application to capelin, the status of the stock is discretized into two mutually exclusive hypotheses GOOD or BAD and the probability that the stock status is GOOD is inferred from the various sources of information. Traditional management rules such as F0.1 are not compatible with such an inference and examples of other rules are explored in the application.

Attempts have been made to incorporate subjectivity in other approaches. Varis et al. (1993) have applied belief functions (Pearl 1986) to the assessment of Baltic salmon. Belief functions allow the use of probability models that are less complete (require less information) than Bayesian models (Shafer 1987) but are less intuitive than Bayes rule. In the application to Baltic salmon subjectivity is used to combine regression and virtual population analysis models to estimate the parameters for the terminal population size, to produce forecasts and aid in determining the TAC. The melding of analytical approaches with subjective reasoning may have application to the capelin problem. For example, in the most recent assessment (Anon 1994a) regression analysis between catch rates of age y and age \(y+1\) fish in the inshore fishery were carried out and results appear to have had a strong influence on the TAC recommendation in Anon (1994b). The Duda et al. (1976) approach would have to be modified if it were to incorporate both subjective reasoning and analytical results. Further, the present net could be "broadened" by adding additional pieces of evidence and "deepened" by considering \(j\) independent pieces of information relating to the uncertainty of the ith evidence (so that \(P\left(E_{i} \mid E_{i 1}^{\prime}, E_{i 2}^{\prime}, \ldots E_{i j}^{\prime}\right)\) could be determined). However, the optimum complexity of an inference net for a particular stock assessment would have to be determined.

With regard to the application to the capelin assessment problem, not all the
information requested by the procedure may seem intuitive to the user. Questions regarding the inherent strength and uncertainty of the evidence may be intuitive, but the questions aimed at determining the prior probability of the evidence may not seem easily separable from the reasoning relating to the strength and certainty of the evidence. What may be of particular interest in the present application was the degree to which the individual inputs to the inference procedure were scrutinised to evaluate their potential usefulness in making inferences about a particular cohort. The outcome in terms of an updated probability that the cohort is strong, is almost a trivial consequence of the decisions regarding the value of the inputs. In contrast, in an analytical procedure (multiplicative model) applied to the same information base at the same assessment meeting (see Chapter 15), most attention was given to interpreting the results.

A Multiplicative Approach to Capelin Abundance Indices by

\author{

}

\section*{Introduction}

Shepherd and Nicholson (1991) and Sinclair and Chouinard (1991) describe the use of multiplicative models for analyzing fish catch-at-age from research vessel abundance indices. Multiplicative models also provide an objective method by which annual abundance indices from a variety of sampling techniques can be statistically integrated into a standardized time series. Gaps in the individual indices can be accounted for, providing there is sufficient overlap in the data for intercalibration of the different indices.

There are a variety of potential abundance indices of capelin in NAFO 2J3KL (Table 1). These indices represent a wide range of sampling techniques and cover a period (1970's to the period) during which the environment and ecosystem in \(2 J 3 \mathrm{~K}\) have undergone extensive changes. In this paper we will descrike the application of a simple multiplicative model to these indices as a first attempt at reconstructing an objective index of capelin abundance during the past 20 years.

Methods and Materials

\section*{a. Abundance Indices of Capelin Abundance}

There are a variety of indices and potential indicators of capelin stock status (Table 1) whose verification and validation remain an ongoing process as it does for most wild populations in which controlled experiments are not feasible. In the past assessments, the 3 L acoustic survey, trap catch rates and the aerial survey estimates have come closest to general acceptance because of their correlated nature. Since the indices represent a wide variety of sampling techniques, it is instructive to provide a brief description of each index.

\section*{1) 3L Spring Acoustic Survey}

This began in 1982 and terminated in 1992 in favour of a combined 2J3KL fall survey. The survey has been conducted in May month with the exception of \(1982-84\) when the survey was done in April. In theory, this survey should be ideally suited to capelin abundance mensuration; 3L is relatively shallow, all age-groups are present (certainly in normal years) and in a relatively small area thus providing high-density acoustic probabilities. The area surveyed generally covers the area to the west of \(49^{\circ} 30^{\prime}\) longitude and to the south of \(49^{\circ}\) latitude. Excluded from survey coverage are the coastal bays, the extreme northern portion of 3 L and the nose of the Grand Banks. In severe years a portion of the 3L capelin biomass may be occluded by ice cover or it may be distributed
elsewhere outside the survey area (Carscadden 1994). Shackell et al. (1993) considered that the 3 L survey data were representative of stock abundance up to 1991 when the acoustic biomass was very low and the proportion of mature fish changed dramatically from previous years. Subsequent analyses by Shackell et al. (1994) associated this distribution change with interannual changes in water temperature.

\section*{2) Trap Catch Rates}

Capelin traps passively intercept adult capelin as they migrate into shallow water ( \(15-30 \mathrm{~m}\) ) for spawning. For the capelin fishery, a voluntary research logbook system was instituted in 1981 covering approximately 100-200 fishers located in each of the bays along eastern Newfoundland (Nakashima 1994). The research logbook data have been reanalyzed by Winters (1994) in terms of the most appropriate expression of density and spawiing biomass proxy. Mean seasonal fish density was estimated as catch per trap haul. Such a seasonal density estimate is of limited value if the duration of the spawning runs varies from year to year, as indeed they do. In order to take this into account, Winters (1994) integrated daily densities across the spawning season and concluded, based on comparisons with other indices that the integrated trap index was a better measure of spawning biomass than the mean density index alone.

Since traps are a passive gear, density-dependent changes in the area occupied by the stock (i.e. catchability changes) is unlikely to affect catch rates, if such catch rates are monitored throughout the historical distribution area. For most years nearly all of the coastal bays are sampled and there is good coherence in both catch rates and age compositions for Div. 3L and 3K (Nakashima 1994, Winters 1994). Potential biases could be introduced by inconsistent reporting of catch or effort levels, annual changes in shallow water migration patterns and saturation effects in years (areas) of high abundance.

\section*{3) Aerial Surveys of Spawning Runs}

This index began in 1982 using aerial photography capable of detecting fish schools at maximum depths of \(25-30 \mathrm{~m}\). Since 1990 schools have been measured from digital data collected by the Compact Airborne Spectrographic Imager (CASI) (Nakashima 1994). The depth restraints of CASI are the same as for aerial photography but greater flexibility is obtained from the ability to survey on overcast days. In each year standard transects are flown in Conception Bay and Trinity Bay. For each transect flown, the mean surface area of capelin schools, the total number of schools, and the total surface area of all schools are estimated.

The traditional method for interpretation of this index was to sum the highest total school surface area observed on each of the three major transects (Nakashima 1994).

This index assumes that interannual changes in the aerial index of spawning schools in Conception Bay-Trinity Bay adequately represents trends in Div. 3K (high coherence of trap catch rates in 3 K and 3 L indicates that this is not an unreasonable assumption for most years). Biases could be introduced since only school area and not school density are measured. Also since the survey is generally timed to measure abundance only during the initial part of the spawning runs, years in which spawning runs are late (eg. 1991) sometimes receive often receive less sampling coverage than normal years.

\section*{4) Groundfish Bycatch Rates}

Bycatch statistics of capelin in bottom trawl surveys in 2 J 3 K (fall), 3L (fall) and 3L (spring) are available from Lilly (1994). Bycatch levels are available as either percentage of sets containing capelin (i.e. probability of capture) or as actual catch/set. Catch-per-set, however, can be heavily influenced by single large catches so that in many years single stratum may contain a high proportion ( \(60-70 \%\) ) of the total catch. Winters (1994) chose the bycatch success rate as a more appropriate indicator of general abundance trends. This was based on the observation that for most pelagic species (see Winters and Wheeler 1985 and references therein) the habitat (range) occupied is a direct function of stock biomass levels. A similar phenomenon has been documented for groundfish species as well (see Rose and Leggett 1991 and references therein).

Bycatch success rates measures only presence or absence and therefore are a coarse index of overall abundance changes. They should be, however, suitable for pelagic species whose populations are more dynamic. From a theoretical viewpoint, the relationship between bycatch success and capelin biomass levels is likely to be asymptotic. That is, as habitats become increasingly occupied, local increases in density will not be linearly reflected in by-catch success rates (small and large by-catches are treated equivalently). For these analyses the bycatch index is provided for 2 J 3 K (mainly maturing fish), 3L (fall) (mainly immature fish), and 3 L (spring) (a mixture of both).

\section*{5) PFI Index (Partial Fullness Index)}

Lilly and Davis (1993) provide data on capelin PFI levels for cod sampled in \(2 J 3 K\) and 3 L (fall). Analyses of PFI data are restricted to the size range of \(\operatorname{cod}(36-71 \mathrm{~cm})\) which prey most frequently on capelin. Fahrig et al. (1993) compared PFI values
with localized acoustic estimates of capelin in the 3 L acoustic survey and concluded that cod stomachs can be viewed as a sampling tool of capelin abundance. In addition, they showed that PFI levels of capelin were statistically independent of cod abundance as measured by trawl catches.

\section*{6) \(2 J 3 K\) Acoustic Survey}

The Canadian survey usually takes place in October and is designed to provide a measure of the abundance of mature fish which will spawn inshore the following summer. These surveys began in 1977 with the Dowd System (Dowd 1974) which was replaced in the early 1980's by a customized HYDAS system built in-house. The area covered has gradually increased with time to include extensions to the east and south. Excluded from the survey area are the coastal bays, extreme northern portion of 2 J and the deeper areas to the east of \(52^{\circ}\) longitude in 2 J and \(51^{\circ}\) longitude in 3 K . This survey has had little success in predicting inshore abundance, as measured by the various inshore indices (traps, purse seiners, and aerial surveys). Winters (1995) has analyzed interannual variations in capelin biomass estimated by the Canadian \(2 J 3 \mathrm{KL}\) survey since 1981 and concluded that the acoustic estimates were largely driven by periodic shifts in capelin abundance from Div. \(2 J\) to the deeper waters to the south and east in Div. 3 K .

The USSR acoustic surveys in 2J3K started in the early 1970's and ended in 1992. These surveys cover approximately the same longitudinal areas as Canada but do not extend as far west (towards the coast) or east as the Canadian survey. The area covered is therefore somewhat smaller and the methodology has changed over the years from the photogrammetric method to conventional acoustic systems. This survey usually occurs in mid November.

\section*{7) Purse Seine Catch Rates}

Catch and effort statistics of the purse seine fleet are captured from the same research logbook program as capelin traps (Nakashima 1994). Fishing days for purse seines are defined as those days when the vessel was out searching for capelin. CPUE data are expressed as catch/day and catch/set. These indices shown similar trends and each is consistent with the trends exhibited by the trap and aerial indices. Purse seine CPUE's however have considerable potential for bias because of the fishing behaviour associated with purse seine in conjunction with the interaction between stock range and the catchability component (Winters and Wheeler 1985).

\section*{8) USSR Catch Rates}

Catch rates are available from the USSR commercial fleet ( \(>200^{\circ} \mathrm{t}\) GRT) for both 3 L (1972-78) and 3K (1973-91). These are available from the FCR Observer Program since 1980 and are available from Soviet sources for years prior to then. Catch rates are expressed as tons per hour trawled.
b. Model Formulation
(i) Year Effect

In this case abundance is expressed as a multiplicative function of year and survey effects as follows:
\(C_{i j}=\mu A_{t} \bar{D}_{j} \in\)
when \(C_{i j}=\) abundance of survey \(j\) in year \(t\)
\(\mu=\) mean abundance over all years
\(A_{t}=\) year effect
\(B_{j}=\) survey effect
\(\epsilon=\) random normal error

The additive model becomes (by log transformation)
\(\ln C_{t j}=\log \mu+\log A_{1}+\log B_{j}+\epsilon\)

Statistical analyses was performed using the general liner models procedure (PROC GLM) of SAS (Anon. 1985).

Interaction terms have not been included but crossover effects will instead be shown by plotting the various permutations of the available indices. These permutations follow from natural associations of the sampling data relating to methodology, population structure sampled and/or geographical area/season. They are as follows (Run \#).
1. All indices (see Table 1).
2. All indices excluding \(2 J 3 \mathrm{~K}\) acoustics.
3. Inshore indices only (trap, aerial, purse seines = mature adults)
4. Offshore indices only (bycatch, CPUE, PFI, 3L acoustics = all age groups
5. Offshore, excluding acoustics (CPUE, bycatch, PFI) = all age groups
6. Acoustics only (USSR + Canada) = all age groups
7. Bycatch only (2J3K, 3L fall, 3L spring) \(=\) all age groups
8. PFI only ( \(2 J 3 \mathrm{~K}, 3 \mathrm{~L}\) fall) = all age groups
9. Immature indices (3L acoustics, 3L bycatch (spring), 3L bycatch (fall), 3L PFI (fall)
10. Mature index (inshore indices, 2J3K bycatch, \(2 J 3 \mathrm{~K}\) PFI and CPUE)
11. Offshore mature index (2J3K PFI, \(2 J 3 \mathrm{~K}\) bycatch, CPUE)
12. All indices excluding acoustics

Unless specifically stated, the following data were excluded (a) 3L acoustics 1991-92 (see Shackell et al. 1994) excluded from all runs except run \#6; (b) USSR 3L acoustics for 1983, 1986 (June surveys); (c) 2 J 3 K acoustics excluded from all runs except run \#1 and run \#6); (d) the integrated aerial and BSN trap indices have been excluded in favour of the integrated trap index and conventional aerial (BSN aerial).

\section*{(ii) Cohort Effect}

In this model catch-at-age is expressed as a multiplicative function of yearclass size (Cohort) and survey-specific survival at age (Myers et al. 1993). Let the number of fish of age i in year \(t\) estimated by survey \(j\) be \(R_{i j}\). If the catchability of survey \(j\) at age \(i=q_{j}\) and the survival of fish of age \(i=P_{i}\) then
\[
R_{i j}=q_{j} * P_{i} * \text { cohort }_{t i} * \in_{t i j}
\]
where
\(\in_{\mathrm{tij}}=\) error term with constant variance. The additive model is described as follows:
\(\log R_{i j}=\log q_{j}+\log P_{i}+\log\) Cohort \(_{t i}+\epsilon_{t i j}\)
From the data available it is not possible to estimate \(q_{j}\) and \(P_{i}\) separately and therefore only the sum of these two parameters are estimated for each survey and age. Since the same gear is used for each survey, it is assumed that age-specific annual changes in the product of these two variables reflects survival changes.

The multiplicative model for extracting the yearclass effect is more attractive than the year effect model because yearclasses are integrated across years and surveys and hence have more information content than annual abundance indices.

For these analyses we have chosen the following selected indices. They are (a) integrated trap catch-at-age (Winters 1994), (b) aerial survey index decomposed by the 3L commercial age compositions (NCSP ages are used for 1991-94), (c) the purse seine index (Nakashima 1994), (d) the 2J3K fall bycatch index, (e) the \(3 L\) fall by-catch index, (f) the \(2 J 3 K L\) USSR FCR catch rate series (1980-91) and (g) 3L acoustics (USSR and Canada and 2J3KL acoustic (USRR and Canada).

The multiplicative model has been applied to the following groups:
1) inshore only
2) offshore only (non-acoustic)
3) acoustic only

\section*{Results}

All main effects were significant for all combinations of the various indices and the models explained a high proportion of the total variance.

Figure 1 illustrates the impact of including the Canadian 2 J 3 K acoustic estimates into the multiplicative model. Divergence occurs after 1990, consistent with analyses by Winters (1995) that the recent 2 J 3 K acoustic estimates are responding mainly to annual distribution changes rather than to annual changes in abundance.

Figure 2a (upper panel) shows the least squares means estimates of the immature index versus the mature index. The two series are significantly correlated when lagged one year (Fig. 2b, lower panel).

Figure 3a (upper panel) shows a similar time series of least squares means for inshore, bycatch and PFI methods. The increase in the bycatch index is clearly less than that by either the inshore or the PFI offshore index, reflecting perhaps the limitation on upper bycatch rates (presence or absence) because a certain proportion of the available habitat will always be unsuitable. Nevertheless both the PFI and bycatch indices are significantly correlated with the inshore index (Fig. 3, middle and lower panels, unlagged).

Figure 4 (upper panel) shows a comparison of the offshore immature index and line inshore (i.e. mature) index. The trends in the two time series are very similar and the statistical fit is highly significant (Fig. 4 (lower panel), lagged one year).

Figure 5 (lower panel) shows a similar comparison of the offshore mature index with the inshore index (mature fish). Again, the trends are very similar and the relationship is statistically significant (Fig. 5 (lower panel), lagged one year).

Figure 6 (upper panel) shows the offshore index (maturing and immatures) including 3 L acoustics compared with the inshore index (mature fish). The two time series show the same overall trend and the relationship is statistically significant (Fig. 6 (lower panel), lagged one year).

Figure 7 (upper panel) shows the offshore index excluding acoustics in relation to the inshore index. The relationship is highly significant (Fig. 7, lower panel) but indicates (in comparison with Fig. 6, lower panel) that the addition of the acoustic data (3L Canada, 3L USSR) does not improve the relationship.

Finally, in Figure 8 the multiplicative indices containing no acoustic data (inshore, offshore) are plotted against the multiplicative least squares means estimates of all acoustic data. This plot shows the incompatible and divergent nature of the acoustic index versus the other offshore and inshore indices since 1990. The combination of these indices into a multiplicative composite is clearly inappropriate since 1990.

\begin{abstract}
The above analyses can be summarized as follows: the offshore annual indices excluding acoustics continue to be a good predictor of inshore annual abundance during the spawning season, whether the prediction is lagged one year (in the case of the offshore mature index) or two years (in the case of the immature index). The acoustic index has been a good predictor of inshore abundance (both current year and projected one year) up to 1990 but has been inconsistent with the inshore indices since then.
\end{abstract}

Results of the cohort multiplicative model runs for the inshore indices, offshore indices, and acoustic indices are shown in Figures 9 and 10 respectively. Year-class strengths estimated from the non-acoustic offshore indices (Fig. 9, top panel) show good coherence with the year-class strengths estimated from the inshore indices (Fig. 20, lower panel). Differences are however evident for the most recent year-classes (1990, 1991, and 1992) with Line inshore data indicating that these are the strongest on record. In the offshore areas the 1990 and 1992 year-classes are also above average whereas the 1991 year-class is about average. The 1992 year-class from the inshore index is considerably stronger than all other year-classes but it relies heavily on a single estimate from the 1994 aerial survey.

Year-class strength estimated from the acoustic surveys (Fig. 10) are in good agreement with the inshore indices up to the 1987 year-class but diverge in the most recent year-classes to the weakest on record. This discrepancy is likely associated with distributional changes observed in the recent cold period both in 3L (Carscadden 1994, Shackle et al. 1994) and 2J3K (Winters 1995, Lilly and Davis 1994).

The log ratios of the offshore to inshore cohort estimates provide an index of year-class survival from the late fall period (as measured in the offshore indices) to the beginning of beach-spawning (as measured by the inshore indices). This pre-spawning survival index is plotted in Figure 11 (top panel) along with an arbitrary cod predation index (sum of minimum trawlable cod biomass for each year-class at ages 2 to 4). The relationship is statistically significant (Fig. 11, lower panel) and could indicate that recent reductions in cod abundance have had differential effects on the survival of capelin in inshore versus offshore areas, i.e. the relatively higher year-class strength from inshore indices in recent years may reflect increased survival relative to the fall offshore where cod predation rates on capelin are likely much lower than during the inshore spawning migrations. Alternatively, the offshore/inshore difference may reflect the fact that bycatch success (presence or absence) in the groundfish
bottom-trawl survey likely underestimate local densities when habitats become increasingly occupied. Likewise, systematic underaging of older age-groups in the inshore indices could also account for some of the observed differences.

The combined (offshore plus inshore) multiplicative estimates of standardized year-class strength are shown ( \(\pm 2 \mathrm{SE}\) ) in Figure 12. The composite index shows that the year-classes contributing to the 1995 inshore fishery (1990, 1991, 1992) are all above average. This multiplicative model was rerun to include the USSR 2J3K acoustic estimates (billions of fish at age) in order to provide a calibration framework for an analytical projection of absolute abundance levels to 1995 (Table 2a). The USSR 2J3K acoustic survey provides conservative estimates of year-class strength relative to the Canadian and USSR spring acoustic survey in 3L. Table \(2 b\) provides a similar projection to illustrate the influences of excluding the estimate of the iss2 yEar-class (at age 2) in the 1994 aerial survey from the multiplicative model. Table 2c is the same as Table 2b except that the more conservative survival estimates of Shackell et al. (1994) are used as a basis for projection.

In summary, the multiplicative cohort model can provide an objective analytical framework for estimating standardized year-class strengths from a wide variety of abundance estimates. It provides for estimates of statistical uncertainty, for gaps in the sampling data and new indices can be added as they become available. Model output is easily replicated from one year to the next and projections can be made either on a relative or absolute basis from the age-specific estimates of survival routinely estimated as part of the model formulation.

\section*{Survival Estimate}

Survival estimates were calculated by Shackell et al. by age, sex and maturity. Sexes were combined, unweighted. For some ages and sexes, one point in the data series was influential in the calculation, so two values were given, with and without the influential data point. When the influential data points were dropped, standard errors were smaller and the amount of variance explained increased (p. 646, Shackell et al.). Since the fit was better in these cases, the data without the influential data points were used in the projections. Values in parentheses include all values. Underlined values were not available but were set the same as adjacent values.

Capelin in SA2 + Div. 3KL

\section*{Introduction}

A capelin assessment committee met several times during March 1995 at NAFC, St. John's to assess the capelin stock in SA2 + Div. 3KL. A list of attendees is given in Appendix 1. The committee noted that the 1994 capelin management plan, attached as Appendix 2, had been maintained for 1995, pending final scientific advice. Under this plan, the major items to be addressed in this assessment were the TAC of \(33,000 \mathrm{t}\) and the criteria of 50 count \(/ \mathrm{kg}\) as a requirement to open the fishery.

\section*{Stock Structure}

Until 1994, capelin in SA2 + Div. 3KL had been managed as separate \(\mathrm{SA} 2+\) Div. 3 K and Div. 3 L stocks. Assessments for SA2 + Div. 3K had been considered by CAFSAC but Div. 3L assessments were cuilucted under the auspices of NAFO. EVidence of movement of these stocks prior to and during the spawning season derived from tagging studies and similarities in age structure and year-class strength in these areas, led us to combine these into one stock complex.

\section*{Catch Trends}

SA2 + Div. 3K
The capelin fishery in NAFO SA2 + Div. 3K was, until 1972, limited to inshore catches during the spawning season. In 1972, substantial catches were taken offshore by vessels from several countries. Catches peaked in 1976 at 212,000 t before declining in the late \(1970^{\prime}\) s to 11,000 t in 1979 (Fig. 1).

Offshore catches during the 1980's were restricted by quota and ranged between 5,000 to \(31,000 \mathrm{t}\). The offshore fishery was generally conducted during August-December with peak catches occurring in September-November. The offshore fishery was closed beginning in 1992.

During the \(1980^{\prime} \mathrm{S}\), an inshore directed roe fishery during June and July has occurred, primarily in Div. 3L. Beginning in 1988, landings increased because of an increased share of the market for Canadian capelin with the closure of the Barents Sea capelin fishery. TACs generally reflected market demand and the increase of the TACs during the late 1980's can be attributed to the larger market share. These did, however, remain below the \(10 \%\) of total spawning biomass that had been set as the biological criteria for setting the TAC.

The 1994 preliminary inshore catch was 67 t , well below the TAC of \(11,400 \mathrm{t}\) and the 1993 catch of \(13,000 \mathrm{t}\). The 1994 fishery did not open in most management areas because the capelin were too small to meet the market size criteria of 50 count \(/ \mathrm{kg}\), defined in the Management Plan. In 1994, capelin continued a trend that began in 1991 of spawning late although the 1994 spawning was somewhat earlier than in 1993.

The offshore fishery first came under quota regulation in 1974 and the inshore fishery in 1982.
Div. 3L

Catches in NAFO Div. 3L were less than \(4,000 \mathrm{t}\) prior to 1970, increased to a peak of \(58,000 \mathrm{t}\) in 1974, and declined to \(12,000 \mathrm{t}\) in 1979 (Fig. 1). During the 1980's an inshore roe fishery employing purse seines, capelin traps and beach seines occurred during June and Jili. This fishery has been later since 1931 due to the late arrival of capelin. In recent years, TACs have reflected market demand. In years when biological data were adequate to advise a specific TAC, the actual TACs have been less than advised on a biological basis.

The 1994 preliminary catch of \(871 t\) was well below the 1993 catch and the 1994 TAC of \(21,730 \mathrm{t}\). Most ( \(82 \%\) ) of the catch came from the Southern Shore, an area that usually accounts for only a small proportion of the Div. 3L catch (no more than \(7 \%\) between 1990-93). The low catches in 1994 occurred because capelin did not exceed the size criteria necessary to open or keep open the fishery.

Catches and TACs (tons \(\times 10-3\) ) since 1988 are shown below.
\begin{tabular}{|c|c|c|c|c|c|c|c|}

\end{tabular}
a data not adequate to advise a TAC
b total inshore and offshore catches could be 200,000-250,000 t without exceeding 10\% target exploitation rate
c provisional
d lowest possible level
e STACFIS concluded that a catch of 50,000 t as jin recent years would not exceed a \(10 \%\) exploitation rate
\(f\) catch should not exceed that of previous year

\section*{Information from Participants in the Fishery (Chapter 1)}

During 1994-95, a questionnaire was designed to quantitatively evaluate biological and fishery-related information obtained from capelin fishers. This survey was undertaken because of concerns about the utility of qualitative information coming from comments in some research logbooks or made directly to research personnel. The survey was being conducted through telephone interviews and was still ongoing at the time of the assessment meeting. From a survey population of 2717 fishers licensed to fish capelin using traps and
beach seines in Div. 3Ps, 3L and 3 K in 1994, approximately 450 were chosen at random for the interviews. This sample size is large enough to calculate statistical confidence limits on the final results. However at the time of the meeting, responses were available from only about 50\% (204) of the interviews.

On a scale of one to ten, with one being the lowest, \(46 \%\) of respondents rated the 1994 abundance of capelin as one and \(87 \%\) rated the abundance as five and lower. Eighteen percent thought the 1994 capelin abundance was about the same as 1993 while \(66 \%\) thought the 1994 abundance was lower than 1993. Ninety-three percent thought the abundance was lower than when they started fishing while \(3 \%\) thought it was the same.

Regarding the number of beaches in their area on which capelin normally spawn, \(2 \%\) of fishers said none, \(45 \%\) reported one to five beaches, \(34 \%\) reported six to ten beaches, and \(17 \%\) reported more than ten beaches ( \(4 \%\) did not know). In comparison, \(33 \%\) reported no veaches with spawn in 1994, 50\% -itth spawning on one to fivebeaches, 5\% with spawning on six to ten beaches, and \(3 \%\) with spawning on more than ten beaches ( \(10 \%\) did not know). Fifty-nine percent of fishers reported spawning on more beaches in 1993 compared to \(1994,37 \%\) reported spawning on the same number of beaches in both years and \(3 \%\) said fewer beaches had capelin spawning in 1993 than in 1994.

On a scale of one to ten with one being lowest, \(24 \%\) ranked the intensity of spawning as one with 85\% ranking the intensity of spawning five or lower. Sixty-two percent ranked the intensity of capelin spawning lower than 1993, 28\% ranked it higher and 7\% ranked it the same.

Forty-nine percent of respondents reported spawning in deeper water in 1994, \(17 \%\) did not observe it and \(34 \%\) did not know. Of the fishers who reported spawning in deeper water, \(57 \%\) attributed it to water temperatures, \(8 \%\) to predation, \(1 \%\) to weather, \(2 \%\) to low abundance, \(5 \%\) to unsuitable beaches, \(2 \%\) to offshore capelin only and \(25 \%\) did not offer a reason. When asked how often since they had started fishing had they observed capelin spawning off beaches in deeper water, \(10 \%\) reported every year, \(18 \%\) reported most years, \(23 \%\) reported sometimes, \(24 \%\) reported it as rare, and \(24 \%\) reported never.

Fishers were given the opportunity to comment at the end of the telephone interview. Forty percent had no comment. Thirty-one percent mentioned fishery closure, \(7 \%\) mentioned seals eat capelin and the seal hunt should be increased, \(5 \%\) mentioned quota management and more monitoring, 3\% mentioned keeping the capelin fishery open, \(3 \%\) mentioned small capelin, \(2 \%\) mentioned a negative effect of trawlers or purse seiners on capelin, \(1 \%\) mentioned water temperatures and \(2 \%\) commented on the questionnaire. These comments
should not be viewed as comparable to questionnaire questions and therefore should be treated with caution. For example, although there were a large number of comments on fishery closure it was not always known whether it was a comment about the fishery in general or specific to a particular year (eg. 1994, given the problems in that year). These comments represent fishers' concerns and provide guidance to the surveyors on formulating additional questions for future surveys.

Age-compositions and Mean Lengths in the Commercial Fishery (Chapter 2)
The 1994 fishery was small, sporadic, and centred mainly on the Southern Shore. The few commercial samples collected were from this area and were collected over a very short time period. As a result, the committee concluded that it would be inappropriate to compare 1994 data to previous years, even though it might adequately represent the 1994 fishery.
 prematurely because females were too small to meet the 50 count/kg criteria. In the few instances when the fishery did open, small females were the predominant reason for discarding. Based on these observations, it appears that capelin were small in 1994.

The observations on smaller mean lengths in 1994 continued a trend that had been observed in recent years. In Div. 3K, the 1993 mean lengths in the commercial fishery were smaller than in previous years and continued a trend that began in 1987. In Div. 3L, 1993 mean lengths from the commercial fishery increased but were still lower than lengths of capelin landed during the 1980's.

Normally, three- and four-year-olds dominate the commercial fishery. However, in 1991, 1992 and 1993 a higher than normal proportion of two-year-olds had occurred. In 1993, age-compositions of the commercial fishery and beach-collected research samples differed although the reasons for the differences could not be identified.

\section*{Inshore Commercial Catch Rates (Chapter 2)}

Because the 1994 fishery was small and sporadic, very few research logbooks were completed. As a result, the committee concluded that the catch rates would not be indicative of stock status.

Trap catch rates have been viewed as more reliable indicators of stock status than purse seine catch rates in past assessments, although the historical trends in the series are similar. In recent years, trap and purse seine catch rates have not declined to the extent that would have been predicted from acoustic estimates.

Aerial Surveys (Chapter 3)
The 1994 aerial survey provided frequent coverage of transects in both Trinity and Conception Bays because of excellent weather conditions. During last year's assessment, a new index was derived to supposedly correct for multimodal spawning which would result in underestimates of inshore abundance. This index was derived by summing total surface area ( \(\mathrm{m}^{2}\) ) along each transect by year, dividing the total area by the survey time (hr) and multiplying by the duration of the fishing season. However, the derivation of this estimate suffered from two problems: the time used in the calculation included transit time as well as actual survey time, and multiple counting of schools occurred using this method. For these reasons and because the fishery was inactive in 1994, this index was not recalculated. As a result, the original index, the sum of the peak estimate of school surface area along each transect, was again used. The 1994 estimate was approximately double line 1593 index and the second highest in the series (about 94\% of the highest, 1987). The 1994 index was heavily influenced by the high estimate in Trinity Bay. The Trinity Bay portion of the index was the highest in the Trinity Bay series and about four times higher than the 1988-93 average. The Conception Bay estimate was about the lowest in the series, comparable to estimates during the early 1980's and about one-half the 1988-93 average.

\section*{Offshore Acoustic Survey (Chapter 4)}

An acoustic survey for capelin in Div. 2J3KL was conducted from 12 September to 29 October 1994. This is the second year of a fall survey to cover the area from \(46^{\circ} \mathrm{N}\) to \(55^{\circ} \mathrm{N}\) and out to the 500 m depth contour. The total biomass estimate was \(102,700 \mathrm{t}\) which is an increase from the 1993 estimate of \(45,600 \mathrm{t}\). The Div. 2J3K component has shown a decline from 32,900 t in 1992 to \(17,900 \mathrm{t}\) in 1993 to \(10,300 \mathrm{t}\) in 1994. The Div. 3L portion increased from \(27,600 \mathrm{t}\) in 1993 to \(92,400 \mathrm{t}\) in 1994, largely as a result of increases in one- and two-year-olds. The biomass of one-year-olds in Div. 3L increased from \(24,000 \mathrm{t}\) in 1993 to \(82,000 \mathrm{t}\) in 1994 while the biomass of two-year-olds increased from 2,900 t to \(9,600 \mathrm{t}\). There were no capelin detected in Div. 2J. This is the fifth consecutive year of low biomass estimates in Div. 2J3K in the fall. There have been few or no capelin in Div. 2 J for the last four years. The average biomass estimate in Div. 2J3K, 1990-94, is about \(5 \%\) of the average biomass estimated during 1981-89 (no estimate for 1982). During the 1994 survey, ages 2 and 1 accounted for \(56 \%\) and \(33 \%\) of the total numbers in Div. 3K while in Div. 3L, age 1 accounted for \(97 \%\) of the numbers estimated. The distribution of capelin in bottom trawl catches during the stratified groundfish survey immediately following the acoustic survey generally agreed with the distribution of capelin in the acoustic survey. Few capelin were found in the groundfish
survey outside the area covered by the acoustic survey. (Details follow in the section describing bycatches in bottom trawl surveys in Div. 2J3KLNO).

Egg Deposition Studies (Chapter 5)
Six beaches along the northeast coast in Div. 3KL have been surveyed since 1991 and indices of egg deposition have been developed from these studies. On one beach (Chapel Cove, Conception Bay), egg deposition was the second highest in the series but on the remaining five beaches, egg deposition was the lowest observed. On one beach (Cape Freels), no egg deposition occurred. When the results for all beaches were combined, the egg deposition index was the lowest in the series, about \(15 \%\) of the next highest (1992) and about 8\% of the highest (1993).

Overall larval production was the lowest in the four years of the study, about one-quarter of next highest (1991) and about one-sixth the highest (1992).

Age-compositions derived from samples of spawning runs were dominated by three-year-olds (52\%) and four-year-olds (29\%). Two-year-olds accounted for 12\%, more than double the proportions observed during 1991-93. This proportion of two-year-olds is comparable to those observed in 1985 and 1988 when the strong 1983 and 1986 year-classes appeared in the mature population (and assuming that age-reading was comparable in the early to mid 1980's - see section on comparison of capelin ageing).

The peak beach spawning in 1994 was again delayed although it was not as late as 1991-93. The duration of beach spawning was also shorter on four of the six beaches. Only one beach (Hampden) supported a protracted spawning period.

The question of the relative amount of off-beach spawning came under scrutiny. Previous studies have shown that smaller fish and lower offshore temperatures during the maturation period resulted in later spawning. Both factors existed in 1994 and spawning was later. Furthermore, the weather conditions that developed in late June and persisted throughout the summer, were conducive to rapid warming of water temperatures near the beaches. The incidence of winds that would provide favourable capelin spawning temperatures was lower in 1994. This combination of factors provided the basis for a hypothesis that there was a higher than usual occurrence of off-beach spawning in 1994. This hypothesis was supported by three observations.
1) Apparently heavy concentrations of capelin eggs in deeper water adjacent to spawning beaches were observed in aerial photographs. Such concentrations had not been previously observed except in 1988.
2) In the questionnaire survey, 49\% of the fishers reported off-beach spawning during 1994. Of this group, 24\% reported that they had never observed it before and an additional \(24 \%\) reported it as rare.
3) Beach spawning duration was shorter in 1994. Spawning tended to be earlier and occurred over a shorter time period at beaches where water temperatures were warm. Conversely, the spawning duration was extended where water temperatures were cooler.

If off-beach spawning was common in 1994 relative to previous years, the result might be an underestimate of the egg deposition index for 1994. An off-beach spawning index was calculated using observed spawning dates of capelin and numbers of days each year when water temperatures near the beach fell in the preferred spawning temperatures of \(5-10^{\circ} \mathrm{C}\). In the time period for which data were available (1990-94) there was good agreement between the egg deposition index anu lise nüiber of days available for spanining. The committee agreed that the results from this analysis offered support for the hypothesis that off-beach spawning was more extensive in 1994, however, the proposal to use the off-beach index to correct the egg deposition index was not supported because of lack of validation through subtidal sampling.

\section*{Capelin Predators (Chapter 6)}

Since 1991, Atlantic puffins, black-legged kittiwakes, herring gulls, great black-backed gulls and common murres have bred later than usual on Great and Gull Islands in Witless Bay. Kittiwakes and gulls have experienced severe breeding failure. Kittiwake breeding failure was much more severe in 1991-93 than 1990 and 1994 and all years in the 1990's show lower breeding success than 1969-70. It was hypothesized that 1990 was a transition year from typical to atypical conditions. Puffins and common murres have experienced normal breeding success during the 1991-94 period. The failure of only surface-feeding piscivores suggests that forage fish were not as abundant at the surface. Preliminary data indicate that there has been a decline in mean size of individual capelin in the puffin diet but the overall food mass has not changed in recent years. More recent detailed feeding data for puffins suggest that while capelin are important components of the puffin diet, other foods are also taken without noticeable detrimental affects to the puffins.

Harp seal feeding data have, in the past, been described using prevalence of prey items. Now feeding data are available from 1982, 1986 and 1990-93, nearshore and offshore, using reconstructed wet weights derived from measurements of otoliths and squid beaks in the stomachs (Lawson and Stenson, in press). The most comprehensive data came from NE Newfoundland. In 1982, capelin
were predominant ( \(81 \%\) by weight) in the diet but in 1986 and 1990-93, they accounted for no more than \(8 \%\) by weight. On the other hand, Arctic cod increased from 3\% by weight in 1982 to 5386\% by weight in 1986, 1990-93. It is not known whether this change reflects a change in prey distribution, prey abundance or both although since 1985 Arctic cod have been caught in greater quantities during bottom trawl surveys. Arctic cod was the major prey consumed in both summer and winter but herring, capelin and squid gained importance during the summer.

Capelin occur frequently in the stomachs of cod caught in the offshore environment of Div. 2J3KL during the autumn and these occurrences have been used to describe distribution patterns of capelin. During the period 1980-88, the average quantity of capelin in cod stomachs, expressed as a stomach fullness index, was moderate to high in two broad regions: (1) northern and western Div. 2J3K (Hamilton Bank, western Belle Isle Bank, and the inner shelf off northeastern Newfoundland) and (2) northern Div. 3L (northern ani nuitheastern slopes of Grand Bank). In many years, such as 1984 and 1985, the capelin in Div. 2J3K were primarily on Hamilton Bank and along the coastal shelf off southern Labrador and northeastern Newfoundland, whereas in some other years, notably 1986 and 1987, they were more aggregated on the central Northeast Newfoundland Shelf. During the early 1990's, the capelin in Div. 2J3K experienced a pronounced shift from the northwest to the southeast. The apparent distinction between a Div. \(2 J 3 \mathrm{~K}\) group and a Div. 3L group became less clear in 1990 and disappeared in 1991 and 1992.

Catches of cod during autumn 1993 were very small with the exception of a few moderate catches near the shelf break just south of the Div. \(3 \mathrm{~K} / 3 \mathrm{~L}\) boundary. Capelin were found in greatest quantities in the stomachs of those cod caught in southeastern Div. 3K and in northern Div. 3L. The northern limit of moderately large partial fullness index values (middle of Funk Island Bank) was further south than in any previous year. The use of stomach content data as indices of capelin abundance is limited by the change of survey design in 1991 and the reduction in cod distribution which has been progressively more dramatic since 1989. An adjustment for survey design is possible but it is unlikely that a correction can be derived for the absence of the sampler (cod). It was recognized that turbot might be a better sampler and that existing data should be analyzed to evaluate the potential.

Bycatches in Other Surveys
Bottom Trawl Surveys in Div. 2J3KLNO (Chapters 7, 8)
Capelin are frequently caught during bottom trawl surveys directed towards groundfish off southern Labrador and Newfoundland. The distribution and magnitude of capelin catches from the surveys
in Div. \(2 J\) and 3 K during the autumns of 1978-93 have been compared with geographic coverage by acoustic surveys for capelin to help evaluate acoustic survey coverage. As a result of these comparisons, acoustic surveys were expanded temporally and spatially during the late 1980's and early 1990's. During the autumn 1994 random-stratified bottom trawl survey, very few capelin were caught on Hamilton and Belle Isle Banks and near the coast off southern Labrador and northeast Newfoundland. Largest catches were on the eastern flank of Funk Island Deep, on western Funk Island Bank, and south of Funk Island Bank. In general, the distribution in 1994 was similar to that observed in 1991-93. All of the large catches in Div. 2 J and 3 K occurred within the area covered by the acoustic survey, although several near the southern border of Div. 3 K were very close to the boundary of the survey.

During autumn 1994 in Div. 3L, capelin were caught in northern and northeastern Div. 3 L and in the Avalon Channel in western Div. 3L. There were no catches on the plateau of Grand Bank.
 where catches had been taken in 1992 and 1993.

The Committee also examined frequency of occurrence of capelin in bottom trawls and minimum biomass estimates of capelin from the same data as potential indices of abundance. In this assessment, frequency of occurrence was adjusted to take into account the high proportion of sets allocated to certain strata in each year beginning in 1991. The new adjusted estimates of frequency of occurrence were very similar to the original estimates. In Div. \(2 J 3 \mathrm{~K}\), capelin were recorded at \(46 \%\) of the 237 fishing stations ( \(<750 \mathrm{~m}\) depth) which is the third highest frequency of occurrence (1978-94). In Div. 3L, capelin were recorded at 42\% of the 200 stations which is the third highest frequency of occurrence (1985-94). The minimum trawlable biomass estimates for fall in Div. 2J3KL show highest estimates during 1979-81 and generally variable and lower estimates after that. The 1994 value is slightly lower than the 1979-94 mean but slightly higher than the 1982-94 mean (excluding the initial three years with highest estimates). Estimates of minimum trawlable biomass in Div. 2 J have been very low since 1990 consistent with the observations from the acoustic surveys of extremely low numbers (1990) or none at all (1991-94) in Div. 2J.

Unlike the surveys in Div. 2J3KL in the fall, the spring 3L bottom trawl surveys had not been examined to compare capelin bycatch distribution and abundance to that observed in acoustic surveys. Data were available for 1971-94. Long-term distribution patterns from the entire series indicated that capelin were distributed on the eastern, northern and northwestern slopes of Grand Bank and towards the shelf break along the southwestern and southeastern parts of the bank. Largest catches tended to occur in the eastern Avalon Channel and on the adjacent northwestern slope
of Grand Bank and in the Avalon Channel south of the Avalon Peninsula. Catches tended to be small in the deeper water of the Northeast Newfoundland Shelf north of Grand Bank. Only in a few years were moderate to large catches obtained on the plateau of Grand Bank. The distribution of capelin in any particular year may be compromised somewhat by the seasonal timing of the survey and the pattern of surveying, but the general distribution of capelin in western Div. 3 L during April-June is in agreement with previously described migration of maturing capelin from northern Div. 3L to southwestern Div. 3L and northwestern Div. 30. The moderate and large catches obtained on northeastern Grand Bank in some years, notably 1982 and 1985-90, occurred outside the area covered by the acoustic surveys in those years. Acoustic surveys were extended to the east in 1991 and 1992 but failed to detect sizeable concentrations of capelin. Bottom trawl catches of capelin on eastern Grand Bank were generally small in those years.

The frequency of occurrence of capelin during the surveys in Div. 3L ranged from \(8 \%\) in isio to \(80 \%\) in 1986. During the period 1991-94, the frequency of occurrence was consistent at an intermediate level (48-52\%). Minimum trawlable biomass estimates have been very variable with highest values since 1980 in 1986, 1987, and 1990. Estimates have been low during 1991-94.

The bycatch indices of \(\%\) frequency of occurrence and minimum trawlable biomass were considered for inclusion in later analysis. Neither are designed to measure abundance of pelagic species. Large catches, which might occasionally be expected for pelagic species, will heavily influence the biomass estimates. On the other hand, frequency of occurrence may better describe general abundance trends because for pelagic species the range of a species may be a direct function of stock biomass levels. Frequency of occurrence data were used in the subsequent multiplicative analysis although it was noted that during the 1990's in Div. 3L spring surveys the bycatch success rate has remained relatively constant while size of the catches has been small.

\section*{Other Surveys (Chapters 9, 10)}

Bycatch data were available from juvenile cod surveys in inshore and offshore areas of NAFO Div. 3 KL conducted during winter (December 1992, December 1993-January 1994, December 1994-January 1995). A Campelen 1800 shrimp trawl was towed on bottom at predetermined stations on line transects from the large northeast Newfoundland bays to the edge of the Continental Shelf. Capelin were widely distributed during the surveys and frequency of occurrence was \(89 \%, 82 \%\) and 92\% for 1992, 1993-94 and 1994-95, respectively. The mean catch rates (numbers per 30 min tow) of capelin decreased from 373 in 1992 to 83 in 1993-94 but increased to 652 in the 1994-95 survey. Catch rates (numbers) were highest offshore in Div. 3K in all years and in Div. 3L in 1992 and 1994.

Over \(85 \%\) of the capelin caught were one- and two-year-olds with about 55\% one-year-olds.

Using similar survey areas in Div. 3 K , estimates of capelin abundance from the acoustic survey, from the groundfish random-stratified survey and from the juvenile cod survey were calculated. The acoustic survey estimate was about \(10,000 \mathrm{t}\) (September-October), a minimum trawlable biomass from the random-stratified survey (November-December) was about \(2,000 \mathrm{t}\) and, a minimum trawlable biomass estimate from the juvenile cod survey (December 1994-January 1995) was about \(22,000 \mathrm{t}\) (using arithmetic mean of catch rate in the calculation) or about 3000 t (using geometric mean of catch rates).

Capelin have also been frequent bycatches in pelagic 0-group cod surveys conducted in Div. 3KLNO during autumn 1991-94. These surveys were about the same time during 1991-93 but about 40 days earlier during 1994. Different sampling gears resulted in catches of 0-group and one-year-old capelin: In 1991-93, c-group capelin occurred in both inshore and offshore samples but in 1994, most capelin were taken only inshore. The length distribution data also showed fewer larger fish in 1994. Both the distribution and length data reflect the much earlier sampling in 1994. One-year-old capelin were widely distributed over the northern Grand Banks during 1993 and 1994, reinforcing the general observation that this is an important nursery area. Although detailed comparisons of distribution of this age-group with that observed during the acoustic survey could not be made at the meeting because of differences in data presentation, the general predominance of one-year-old capelin in Div. 3L occurred in both surveys. The Committee noted that the 0 -group survey would likely be discontinued and therefore did not represent the beginning of a time-series of 0-group estimates. However, the biological data would be very valuable when linked with the detailed capelin early life history data collected on the beaches as part of NCSP.

\section*{Other Studies}

Capelin Distribution (Chapter 11)
Since 1981 systematic hydroacoustic surveys of capelin abundance have been conducted during October by Canada in NAFO Div. 2J3K. The biomass estimates from these surveys have shown large interannual variations which have not been reflected in subsequent inshore indices of mature fish which they were designed to measure. In particular, low biomass levels were observed offshore in 1983, 1986, 1987, and from 1990 onwards. Previous authors had reported that up to 1992, anomalously low acoustic estimates had been consistently associated with shifts in capelin distribution to the south and east towards the outer portions of the acoustic survey blocks. As a result of these observations, the
acoustic survey had been expanded both temporally and spatially until in 1993 and 1994, this survey had covered the area from \(55^{\circ} \mathrm{N}\) to \(46^{\circ} \mathrm{N}\) and from the headlands out to the 500 m contour. In the analysis reviewed by the committee, groundfish bycatch data and cod feeding data (partial fullness indices) were primary data sources to describe statistical associations between capelin distribution patterns and interannual variability in the Div. 2J3K capelin acoustic biomass estimates. Central to the analysis was a conceptual model of capelin distribution and migration in Div. 2J3KL. This model indicated that Div. 3L was an important nursery area for juvenile capelin. During late summer/early fall maturing capelin would begin a northward migration towards an autumn feeding area in Div. 2J. Later in the fall, these capelin would migrate southwards to southern Div. 3 K and northern Div. 3L where they would overwinter. In the spring, these maturing capelin would begin a feeding/spawning migration which would take most to southwestern Div. 3L/northern Div. 30. They would continue their spawning migration northward through the Avalon Channel and into east and northeast coast bays.

Because the capelin are migrating extensively during the autumn period and the timing of the migration is changeable depending on the hydrographic conditions (which may be a proxy for other factors, eg. food), then timing of the survey is critical. This was illustrated by a comparison of autumn Canadian and Russian acoustic surveys (Russian surveys are later) and spring Div. 3L surveys. This comparison suggested that differences in timing of only a month can have large and systematic effects on biomass estimates.

Bycatch rates in the groundfish surveys show a general southeastward shift in distribution during the 1990's which has been associated with a shift of bycatches into deeper water (300-350 m compared to 200-250 m in earlier years). There was also an association between acoustic estimates and mean depth with lower acoustic estimates in years when mean bycatch depths exceeded 300 m .

Furthermore, a statistical relationship was established that showed that high biomass levels were reported from the acoustic survey when the centroid of capelin distribution (described by frequency occurrence in groundfish surveys) was located in the north (in 2J) and inshore (western 3 K ). When the centroid was located to the south and east (in the deeper eastern areas of 2 J and 3 K ) the available biomass (as inferred from bycatch rates) was largely undetected, presumably because the major concentrations of capelin were to the east of the survey transects. The author noted that the acoustic abundance estimates contain an abundance component and a distribution component and the statistical relationships were used to remove the distributional component.

As a result of the statistical analyses, modifications to the conceptual distribution model were hypothesized. In cold years, capelin would penetrate less extensively into 2 J and the southern migration would begin earlier and be deflected more to the east. Thus, capelin would be unavailable to the October acoustic survey. By November, the capelin would begin their cross-shelf migration and be available to the groundfish survey. By January, demersal juvenile cod surveys suggest the capelin are widely distributed across the northeast Newfoundland shelf and into coastal bays.

The Committee noted that the statistical relationships agreed with the earlier interpretation of capelin distributions from bycatches in the groundfish surveys and which resulted in expansions in the acoustic survey coverages. Unfortunately, it did not provide a mechanism to explain why in 1993 and 1994 the acoustic surveys did not result in higher biomass estimates because they would have covered the migration routes hypothesized in the conceptual model. However, the analyses and concepts could prove very useful in develuping hypotheses that might be testeß during the modified 1995 acoustic survey (see research recommendations).

\section*{Mean Lengths Offshore and Inshore (Chapter 12)}

Sizes of female capelin have become important in the market since the late 1980's with the Japanese market demanding larger capelin. During the 1990's, capelin have been smaller-at-age and there have been relatively more two-year-olds in the population resulting in problems in the industry. The small size of capelin has been a concern to management because a market for predominantly large females when only small capelin occur provides a framework for extensive dumping. Consequently, provision was included in the 1994 management plan that prevented opening or allowed early closure of the fishery until a specific size was reached (50 count/kg).

The committee examined the results from a comparison of mean lengths from fall acoustic surveys and inshore mean lengths to determine whether the mean lengths from the acoustic surveys could be used to predict mean lengths in the following year. Mean lengths at age for both sexes from the acoustic -surveys were calculated from survey strata which contained high proportions of maturing fish. The relationships were positive but stronger for females. Since females are targeted by the market, females became the focus of the analysis. The relationships were statistically significant for all ages tested except age 2 fall-age 3 spring. There was a positive and significant relationship between the residuals from the acoustic length-inshore length relationship and \(0-20 \mathrm{~m}\) temperatures during the growing period (February-June), suggesting slower growth in colder years. Mean length of age 2 females in the 1994 acoustic survey (age 3 in 1995) were the smallest in the series and for age 3 females (age 4 in 1995) the
mean length was below average. Thus, even if temperatures during the February-June 1995 period are average, female capelin at ages 3 and 4 in 1995 will likely be smaller than capelin seen during the \(1980^{\prime} \mathrm{s}\).

Comparison of Capelin Ageing (Chapter 13)
Age-composition of capelin collected during different studies and aged by different readers have been different since 1991, even though both age-compositions were assumed to be indicative of the same population. A formal ageing comparison experiment was conducted to determine whether different ageing protocols were contributing to the differences.

Between reader comparisons indicated that the two readers were interpreting ages differently. Otoliths from several years were used and this comparison showed that the agreements were better in earlier years. This confirmed the general observations of the reauers that otoliths in recent years have been more difficult to read. Anomalous environmental conditions may be affecting growth which may be manifested in physical changes in the otoliths. The biases between readers were consistent for all comparisons with the reader who regularly ages commercial samples assigning younger ages. This meant that age-compositions from the commercial samples in the capelin database would tend to show more younger ages than otoliths collected from capelin spawning on beaches.

Both readers exhibited significant differences in age interpretation over time. For the reader who has had the responsibility of reading capelin otoliths during the 1980's and 1990's, differences over time were not consistent, that is, otoliths from some years were read the same as original readings while some were not. However, in all cases, most recent readings resulted in generally younger ages. Thus, given this tendency to read younger in some cases and the difficulty in reading otoliths during the last few years, the committee noted that the proportions of younger ages in the commercial samples (eg. age 2) should be viewed as upper estimates and the proportion of older ages as lower estimates. However, the committee also noted that even otoliths collected from the capelin on spawning beaches and read by the other reader, who tended to assign older ages, had resulted in relatively high proportions of two-year-olds especially in 1994.

\section*{Bayesian Analysis (Chapter 14)}

The committee evaluated a new approach to weighting and combining different indices of abundance of capelin. This approach was presented as an alternative to the approach used in the most recent assessments, when some of the indicators of capelin stock status diverged. In these assessments, the different pieces of evidence were, to a large extent, evaluated on a qualitative basis
and discussions continued until a reasonable level of consensus had been reached regarding stock status. The recommendations regarding TAC based on these assessments were only qualitatively linked with recognized uncertainty in the conclusions regarding stock status. Since there was no explicit trace of the procedure used to reach a conclusion regarding the status of the stock, there was no guarantee that the same conclusion would be drawn if the assessment were repeated with the same information.

In the new approach, indices and individual cohorts would be evaluated. These evaluations would involve defining how good each index was at measuring the strength of specific age-groups and then particular cohorts (in this case, 1990-92) would be evaluated as to their relative strengths. The evaluations would be considered subjective in nature but probabilities would be assigned that would describe the usefulness of the index and the strengths of the target year-classes. All of the probabilities would then be combined mathematically using Bayes rule. Each year-class would then have a fiñai calculated probability that cescribed its strength. These probabilities could then be compared to predetermined values which would automatically trigger a decision (eg. maintain TAC, reduce TAC, etc.).

This approach was tested with a small working group and found to be a useful framework to discuss individual indices and year-class strengths. It was agreed that the method would be considered experimental but could be useful in the final assessment only if an assessment could not be finalized using the multiplicative model.

\section*{Assessment of Stock Status (Chapter 15)}

The Committee used a multiplicative model to statistically integrate a variety of indices into a standardized timeseries. Some initial decisions whether to include or exclude potential indices in the final model were necessary. These decisions were based on knowledge of each index and required a judgement regarding the potential value of the index. Each index and each cohort was given equal weight in the multiplicative model.

\section*{Multiplicative Model}

Sixteen potential indices were identified for possible inclusion in the multiplicative model. Six were from inshore sources and ten were from offshore. Each index was broken down into age-classes (Appendix 3). The indices were highly variable in terms of historical length and availability of sampling data. Notes on origins of the data, possible deficiencies in each index, and reasons for retaining or not using the indices are given in Appendix 3.

Several indices were retained for inclusion in the model but not all were included in a single model formulation because the strengths of individual year-classes diverged in recent years. The following formulations of the multiplicative model were run with the noted data series from Appendix 3 (alphabetic codes as in computer database).
1) Acoustic formulation (Fig. 2) included:
a) Russian 3L spring acoustic index (C)
b) Canadian 3 L spring acoustic index (L)
c) Russian 2 J 3 K fall acoustic index (B)
d) Canadian 3L fall acoustic index (H)
e) Canadian \(2 J 3 \mathrm{~K}\) fall acoustic index (K)
2) Inshore formulation (Fig. 3) included:
a) Aerial survey index (A)
b) Purse seine catch rate index (M)
c) Trap catch rate index (T)
3) Offshore formulation (Fig. 4) included:
a) Groundfish 3L fall bycatch (F)
b) Groundfish 2 J 3 K fall bycatch (G)
c) Russian \(2 J 3 \mathrm{~K}\) fall commercial catch rate index (J)
4) The relative strengths of the 1990-92 year-classes were very different in formulation 1) above compared to formulation 2) and 3) above. The strengths of these year-classes in the last two formulations showed them to be relatively strong compared to earlier year-classes. As in last year's assessments, less weight was placed on the results from the acoustic survey. Thus this final formulation (Fig. 5) was developed to provide a possible representation of actual stock abundance by including a data series of absolute estimates for calibration. Data from formulations 2) and 3) were combined with the data from the Russian \(2 J 3 \mathrm{~K}\) fall acoustic index (B). The latter data were used as a source of absolute abundance to scale the year-class strengths. The trends in this acoustic series closely matched the Russian fall midwater catch rate series.

In all versions of the model, the historical perspective of year-class strengths, 1977-88, were similar. The 1983 and 1986 year-classes were more abundant than all other year-classes, with the 1983 year-class being the strongest. The 1984 year-class was weak.

The first run of the model using only acoustic indices showed all recent year-classes, 1987-92, to be low in abundance.

The second formulation using inshore indices showed the 1990 and 1991 year-classes stronger than the 1983 and 1986 year-classes. The 1992 year-class appeared as the strongest on record; this estimate resulted from only one data source, the aerial survey (no data for 1994 purse seine and trap catch rates).

The third formulation showed the 1990 year-class to be equal in abundance to the strong 1986 year-class. The 1991 year-class was the weakest of the three with the 1992 year-class almost as strong as the 1990 year-class.

In the final formulation, using seven indices including the fall Russian acoustic survey for calibration, the 1990-92 year-classes are strong. The 1990 and 1991 year-classes are approximately equal to the 1986 year-class and the 1992 year-class is about equal to the 1983 year-class. Confidence intervals are particularly large around the 1992 year-class, reflecting the statistical uncertainty in this estimate.

Three projections were made using different estimates of year-class abundance from the calibrated multiplicative model, survival at age and maturity at age. One projection used year-class abundance and survival from the multiplicative model and maturity for Div. 3L capelin from past assessments. A second projection used year-class abundance from the multiplicative model as in the first projection except the age 2 for the 1992 year-class from the aerial survey index was excluded. This run of the model was used to illustrate the effect of the estimate of the 1992 year-class from the aerial survey on the projection. Estimates of survival and maturity were the same as in the first projection. In the final projection, estimates of year-class abundance were the same as the second projection, but estimates of survival and maturity were from Shackell et al. (1994). The estimates of mature biomass in 1995 from these projections ranged from approximately 1 to 3 million tons. The 95\% confidence limits on the lowest projected biomass of 1.0 million tons were 0.3 to 3.1 million tons and on the highest projected biomass of 3 million tons, the 95\% confidence limits were 1.4 to 8.0 million tons.

Stock Status in 1994
Stock status has been difficult to determine in recent years because of the divergence between inshore indices and the offshore acoustic surveys. This continued to be the situation in this assessment with the added uncertainty regarding the appropriate interpretation of the 1994 inshore indices. Egg deposition in 1994 varied from low to average on monitored beaches. Although the aerial survey index for 1994 was high, it was largely a result of the presence of large schools only in Trinity Bay and not in Conception Bay. Capelin arrived late inshore again in 1994 and
acceptable inshore catch rates were unavailable because the fishery opened only sporadically.

The 1991 and 1990 year-classes contributed (about 80\% combined according to beach sampling) to the spawning population in 1994. These year-classes were estimated to be average and strong, respectively, in the multiplicative analysis suggesting a higher than average spawning stock abundance in 1994.

The results of the multiplicative model formulations rely in some cases on indices which have not been collected specifically to monitor capelin abundance nor have they been validated as reliable indicators of capelin abundance. In addition, the formulation of the multiplicative model combining different kinds of indices is not known to have been attempted in other fish stock assessments.

\section*{Prognosis for 1995}

The 1994 acousiic survey estimate was again low, even though this was the second year of such an extensive synoptic survey. These acoustic surveys have been designed to provide a recruitment index and therefore, were expected to provide a basis for prediction of the spawning biomass inshore the following year. In recent years, these expectations have not been met. Consistently low biomasses have been estimated offshore but there have been no decreases in catch rates or aerial survey indices inshore of the magnitude that would be expected from the low acoustic indices. Thus, similar to last year, the acoustic survey is not being relied upon although there continued to be concern about the trends in this survey. The reasons for these low biomass estimates in the acoustic survey as well as the concerns regarding the indices and the multiplicative model noted above require further research. Despite the concerns about the indices and the model, the Committee noted that the projected biomass in 1995 would support a catch of \(33,000 t\) as outlined in the Management Plan without exceeding the conservation level of \(10 \%\) of the spawning stock biomass.

Capelin captured in the 1994 acoustic survey were relatively small and based on historical trends in sizes in the acoustic survey and sizes inshore the following year, capelin in the 1995 spawning stock likely will be small. Even if spring water temperatures were average or above normal, growth would have to be exceptional for capelin to reach sizes attained in the late 1980's. The overall average size in the spawning stock will be dependent on the relative proportions of the year-classes present. Since the 1992 year-class is expected to be stronger than the 1991 and the latter should already be reduced by spawning mortality, the 1992 year-class would be expected to dominate. This will likely contribute to an overall smaller mean size. Although the abundance of the 1993 year-class could not be quantified, it dominated in some surveys and appeared widespread in the offshore. If it is a
strong year-class, it could also appear in the 1995 spawning population and contribute to a small overall mean size.

\section*{Research Recommendations}
1) The lack of correspondence between abundance in the offshore acoustic surveys and other indices in recent years has resulted in the suggestion that the acoustic surveys have not been detecting capelin. This has occurred in both the Canadian and Russian acoustic surveys. Acoustics is a widely accepted method of assessing the abundance of pelagic, schooling species. Acoustic surveys have been used successfully to assess capelin in the Northwest Atlantic in the past and they continue to be the sole method of assessing recruiting year-classes of capelin in Iceland and the Barents Sea. However, given the recent problems and the fact that it is likely that multispecies surveys will soon dominate survey activity in the Region, the Committee recommended that high pi-iciity be given to testing the most liknly hypotheses raised to explain the recent low biomass estimates. These include capelin too dispersed to be detected by the acoustic system especially near the depth limits of the system, capelin in the "acoustic dead zone" near bottom and capelin occurring outside the survey area. It may not be possible to test all possible hypotheses but those considered most likely and most tractable should be given highest priority. This testing should be done during the shiptime allocated for the autumn capelin acoustic survey.
2) Different indices were combined, unweighted, in the multiplicative cohort model. The Committee recommends that the question of appropriate methods of weighting different indices in this model be referred to the SSS Committee.
3) If the 1995 capelin fishery does not open or operates at a reduced level, commercial catch rate data will not be available nor will commercial sampling data. The Committee therefore recommends the following:
a) the aerial survey be conducted in 1995;
b) the egg deposition studies be continued (former NCSP project) see below;
c) capelin should be sampled on spawning beaches to provide age composition data;

Items a) and b) require immediate allocation of funds and extensive planning and represent continuation of valuable time series of data. Item c) should be planned as a contingency in the event a fishery does not develop. Funding of b) above would guarantee the collection of adult capelin on spawning beaches.
5) The aerial survey index using school areas assumes all capelin schools encountered are of uniform density. The committee recommends for 1996 that an inshore acoustic program be developed in coordination with the aerial survey to investigate the relationship between school area, colour as viewed by the imaging spectrometer and acoustic density for prespawning schools.
6) Greenland halibut are known to be important predators of capelin. There is an extensive database on Greenland halibut food and feeding and the committee recommends that this database be analyzed to augment our knowledge of predator-prey relationships and distribution patterns of capelin from predator stomachs.

\section*{Appendix 2}

\section*{Appendix 2}

\section*{1994 NEWFOUNDLAND CAPELIN MANAGEMENT PLAN}

\section*{I. MANAGEMENT OBJECTIVES:}
1) To protect and conserve capelin stocks.
2) To maximize the harvesting, processing and marketing returns from the capelin resource.

\section*{II. RESOURCE MANAGEMENT:}

\section*{A) Whole Frozen Females}

The Atlantic total allowable catch (TAC) has been established at 47,545 t . This TAC level is slightly higher than the 1993 level of \(45,390 t\) and reflects the cautious advice provided by scientists on the capelin stocks. The total TAC includes 450 t which has been provided to allow an experimental fixed gear fishery in the Hermitage/Harbour Breton area (3Ps).

This TAC level is sufficient to supply the estimated female capelin market. This is a maximum TAC level. Should capelin runs to the beaches be less than normal, further curtailment of quotas or cessation of fishing will occur.

Closure of the fishery will also occur if the size composition of the catch in an area falls below what is generally acceptable in the market, and dumping of fish could occur. Due to the expected market demands in 1994, the size criteria has been established at 50 count per kilogram. In addition, fishermen will be required to land capelin which are at least 30 percent female. Fishermen should sample their catches to ensure they meet these criteria before taking any capelin onboard their vessel.

The regional allocations are sub-divided on an area and gear type basis. The quotas for the province of Newfoundland and Labrador are detailed in the allocation table.

\section*{B) Area sub-divisions}

White Bay, north of Cape Fox, will be managed as a separate area for fixed gear. This area will be further sub-divided at Fischott Island.

Notre Dame Bay will be divided into three sections for fixed gear: Cape John to North Head; North Head to Dog Bay Point; Dog Bay Point to Cape Freels. Fogo Island and Change Islands will be included in the section from North Head to Dog Bay Point.

The Southern Shore area, including Trepassey Bay from Cape Pine to Cape Race, will be divided into three sections for fixed gear: Cape Pine to Cape Neddick; Cape Neddick to

Long Point; and Long Point to Cape St. Francis. The Southern Shore area for purse seine will be from Cape Race to Cape St. Francis.

The 4R3Pn area will be divided into five sections for fixed gear: 3Pn and Cape Ray to Broom Point; Broom Point to Point Riche; Point Riche to Big Brook; Big Brook to Cape Bauld; and Labrador.

\section*{C) Quota Transfers}

Once an area specific quota has been reached that quota area will be closed and processors will have to access areas where quota remains.

Reallocations of quotas will not be considered in 1994 as a precautionary measure to provide for resource conservation.

\section*{D) Other Markets:}
vünere possible, other market requirements are to be satiisfied within the allocations established for the frozen female quota. No additional quotas will be provided to supply capelin to these markets.

\section*{III. SEASONS:}

The capelin season will open on June 11 in 4R (mobile gear), 3P, St. Mary's Bay and the Southern Shore, June 15 in Conception Bay, Trinity Bay and 4R (fixed gear) south of Broom Point, June 20 in Bonavista Bay, Notre Dame Bay and 4R (fixed gear) from Broom Point to Big Brook, and June 25 in White Bay, Labrador and 4R (fixed gear) north of Big Brook. However, in some of these areas industry sampling programs will be implemented to determine when capelin are suitable for harvesting, and the opening date in these areas will be based on those results. In areas where fishermen and processors agree to open the season based upon an industry sampling program, industry must provide the department with the agreed criteria. Established opening dates will only be changed as a result of a unanimous request from all sectors of the industry or if gear is placed in the water in advance of capelin appearing in an area.

The season in each area will continue until the established quota has been reached or the fishery is no longer active. Each quota will be strictly enforced and closures will be based on the recorded landings and projected catch. Notice of closures will be as short as necessary to ensure quotas are not exceeded.
```

Appendix 2

```

\section*{IV. RESOURCE ACCESS:}

\section*{A. MOBILE GEAR (PURSE SEINES)}
1) No new capelin purse seine licences will be issued in 1994.
2) Fishermen who held a capelin purse seine licence in 1993 are eligible for a licence in 1994.
3) Capelin purse seine licences will be valid for Capelin Fishing Areas 1-11 or Capelin Fishing Areas 12-14.
4) Fishermen who hold a capelin purse seine licence may not hold a capelin fixed gear licence.
5) The holder of a capelin purse seine licence may exchange his purse seine licence for a fixed gear licence. The applicant may retain all other purse seine licences he holds. The capelin purse seine licence may not be transferred prior to applying for a fixed gear licence. The applicant gives up any rights to a capelin purse seine licence in the future.

\section*{B. FIXED GEAR (TRAPS AND BAR SEINES)}
1) No new capelin fixed gear licences will be issued in 1994.
2) Full-time fishermen who held a capelin fixed gear licence in 1993 are eligible for a licence in 1994.
3) Fixed gear licences will be valid only for the quota area in which the fisherman resides or has historically fished (one of fishing areas 1-14).
4) Fishermen who hold a capelin fixed gear licence may not hold a capelin purse seine licence.
5) Fishermen are permitted to fish a maximum of two traps and one bar seine per licence.
6) In the Hermitage/Harbour Breton area (3Ps) 50 experimental fixed gear licences will be made available to allow fishermen in that area to assess the potential for a capelin fishery.

\section*{Appendix 2}

\section*{C. OTHER LICENCING PROVISIONS}
1) The department will not issue any specific licences to transport capelin. The only vessels permitted to transport capelin are those which were used to catch capelin.
2) Licence holders who did not fish in one of the years 1991, 1992 or 1993 will not be permitted to lease a vessel to participate in the 1994 capelin fishery.
3) The transfer of capelin licences is currently not permitted, with the exception of fishers participating in early retirement programs.

\section*{V. TRIP LIMITS:}

The \(50,000 \mathrm{lb}\) trip limit implemented for capelin purse seine vessels in Capelin Fishing Areas \(1-11\) in 1990 will be continued in 1994. In addition, a 50,000 lb trip limit will be implemented for fixed gear vessels in 1994. Trip limits will not apply in Capelin Fishing Areas 12-14.

\section*{VI. BY-CATCH RESTRICTIONS:}

In accordance with the Atlantic Fishery Regulations and the Fishery (General) Regulations, only capelin may be retained from catches made in capelin gear. Any bycatch of other species must be released.

\section*{NOTES TO ALLOCATION TABLE:}
1. Sub-divisions of the fixed gear quota in White Bay, Notre Dame Bay, Southern Shore and 4R3Pn are detailed on the attached table.
2. Trepassey Bay from Cape Pine to Cape Race is included in the Southern Shore quota area for fixec gear only.
3. The fixed gear quota includes 450 t for an experimental fishery in the Hermitage/Harbour Breton area.
4. The purse seine quota in 4R3Pn is further sub-divided with \(3,500 \mathrm{t}\) for vessels over 65 feet and 2,500 \(t\) for vessels less than 65 feet.

Notes on indices available for multiplicative model.
- alphabetic codes in multiplicative model computer database
A) Aerial survey index
- age compositions up to 1990 from the commercial fishery
- 1991 survey too early and considered an underestimate
- age compositions 1992-94 from NCSP study
- retained for multiplicative model
D) Larval index
- from NCSP study
- relative year-class strengths have not been validated so it was not used
E) Egg deposition index (unadjusted)
- no. of eggs
- not in multiplicative model because has not been validated as an index of abundance
M) Purse seine catch rate index
- age compositions from purse seine samples
- retained in model - some concern about purse seine catch rate as indicator of abundance but consistent with trap catch rates
- no 1994 fishery
R) Egg deposition index (adjusted)
- age compositions from NCSP study
- egg deposition index adjusted for off-beach spawning
- adjustment not accepted and index not used
T) Trap catch rate index
- age compositions from trap catches
- retained index
- retained in multiplicative model
- no 1994 fishery
C) Russian 3L spring acoustic survey
- 1983, 1986 not used because survey conducted in June, others earlier
- retained and used with other acoustic indices
L) Canadian 3L spring acoustic index
- one-year-olds not used
- retained and used with other acoustic indices
N) Groundfish 3L spring bycatch index
- not used
B) Russian \(2 J 3 \mathrm{~K}\) fall acoustic index
- one- and five-year-olds not used
- used with other acoustic indices
F) Groundfish 3 L fall bycatch index
- four- and five-year-olds not used
- 1994 data not used because of small sample size
- used in model
G) Groundfish \(2 J 3 \mathrm{~K}\) fall bycatch index
- one- and five-year-olds not used
- used in model
H) Canadian 3 L fall acoustic index
- only two years data, not used
J) Russian 2 J 3 K fall commercial catch rate index
- one-year-olds not used
- kept in model
K) Canadian \(2 J 3 \mathrm{~K}\) fall acoustic index
- one- and five-year-olds not used
- used with other acoustic indices
0) Dalley \(3 \bar{L}\) iail Campelen index
- short series, not validated
- not used```
