Abstract

Results obtained from a fish counting fence provided the basis for the assessment of the Conne River Atlantic salmon stock in 1995. Returns to home waters (river and estuary) were 3502 salmon < 63 cm in length and 110 salmon ≥ 63 cm in size. This represented an increase of 128% for small salmon in comparison with 1994. Large salmon returns increased by 10% from 1994. Sea survival increased to the highest level since 1989-90 (5.8%). Estimated egg deposition from small salmon was 5.952×10^6 eggs; 76% of the target requirement. The contribution from large salmon was 0.369×10^6 eggs and thus 81% of the required target egg deposition was achieved. An enhancement project was initiated at Conne River in 1994 resulted in the stocking of about 128 thousand fry in 1995. Brood stock was again removed in 1995 for fry stocking in 1996. A mark-recapture study suggested a smolt run in 1995 of 62749 (55300-70197). With survival similar to that of 1994-95, over 3300 fish would be expected to return in 1996. A sea survival of about 7% will be needed in order for total returns to homewaters to meet or exceed 4000 adult salmon.

Résumé

Les résultats obtenus à la barrière de dénombrement ont servi de base à l'évaluation du stock de saumon atlantique de la rivière Conne en 1995. Les retours dans les eaux d'origine (rivière et estuaire) se chiffrent à 3 502 saumons < 63 cm de longueur et 110 saumons ≥ 63 cm de longueur. Cela représente une augmentation de 128 % pour les petits saumons, par rapport à 1994. Les retours de gros saumons ont augmenté de 10 % par rapport à l'année précédente. La survie en mer a atteint le niveau le plus élevé depuis 1989-1990 (5,8 %). La ponte approximative des petits saumons était de $5,952 \times 10^6$ oeufs, soit 76 % des besoins. La contribution des gros saumons était de 0,369 $\times 10^6$ oeufs, ç'est-à-dire 81 % de l'objectif de ponte cible. Un projet de mise en valeur a été entrepris à la rivière Conne en 1994, et a donné lieu au déversement d'environ 128 000 alevins en 1995. Un stock de reproducteurs a été prélevé encore une fois en 1995 pour le repeuplement en alevins en 1996. Une étude par marquage-recapture prévoit une dévalaison de smolts en 1995 de l'ordre de 62 749 (55 300 - 70 197). Si le taux de survie est semblable à celui de 1994-1995, on s'attend à ce que plus de 3 300 poissons reviennent en 1996. Un taux de survie en mer d'environ 7 % serait nécessaire pour obtenir une remonte totale dans les eaux d'origine équivalente ou supérieure à 4 000 saumons adultes.

Introduction

Conne River, SFA 11 (Fig. 1) flows into Bay d'Espoir on the south coast of insular Newfoundland. It is a sixth-order river with a drainage area of 602 km^2 and a total length of 193 km. Since 1986, a fish counting fence has been operated to enumerate the upstream migrating population of Atlantic salmon (*Salmo salar*). Mark-recapture studies were initiated in 1987 to survey the number of migrating smolts. These operations continued in 1995. Previous estimates of the total return of small salmon have ranged from a low of 1533 in 1994 to 10155 in 1987. Target spawning requirements were met or exceeded from 1986-90, but declined to 40% of the target in 1994 (Dempson 1993; Dempson et al. 1994a; Dempson et al. 1995). Stocking of reared fry in 1995, from brood fish maintained in 1994, would have increased 'equivalent' egg deposition in 1994 to 58% of the target. Smolt production has varied from about 56000 to 75000.

A major change in the management of the Conne River Atlantic salmon stock for 1993 was the complete closure of the recreational fishery. In light of the forecast of low salmon returns in 1994 and 1995, this closure was continued and extended to the Indian Band Council's food fishery.

This paper summarizes smolt production and returns of adult salmon to Conne River in 1995. Biological characteristic data for Atlantic salmon are updated and information on the abundance of rainbow trout (*Oncorhynchus mykiss*) from test fishery surveys are summarized.

Noteworthy events or changes in 1995

The following summarizes noteworthy changes to fishery regulations and other observations/events occurring in 1995:

- recreational and native food fisheries closed for the entire season;
- increase in sea survival to the highest value recorded in five years (5.8%);
- estimated egg deposition double the previous year (1994) with 81% of the current target spawning requirement met;
- net-marked salmon continue to be observed at Conne River;
- first fry stocking (N = 128 thousand) from an enhancement program occurred in 1995.
- capture of Atlantic salmon smolts and adults of farmed (hatchery) origin documented again from Conne River in 1995;
- approximately 5,000 wild salmon smolts were removed from the river and transferred to sea cage holding facilities at Roti Bay.

Methods

1. Landings

In past years, information on recreational catch statistics were collected by Department of Fisheries and Oceans (DFO) Fisheries Officers and guardians and processed by DFO Science Branch personnel. Landings from the native food fishery were obtained from the Conne River Native Band Council.

2. Biological characteristics

Biological characteristic information on adult salmon, including fork length, whole weight, age and sex (internal examination), was obtained in 1995 largely from salmon captured at the fish counting fence and subsequently retained for brood stock use. In contrast with 1994, brood stock fish were captured over most of the main run of salmon. Biological data from Atlantic salmon smolts were again obtained from specimens sampled at the downstream counting fence trap.

Analyses of smolt 'condition' were updated following the general methods outlined in Dempson et al. (1994b). A general linear model was used to examine the response of fish weight, standardized to a common length as:

$$Y_{ij} = \mu + \alpha_i + b \bullet z_{ij} + \epsilon_{ij}$$

where,
Y_{ij} is the response variable, smolt weight,
α_i is a class variable, year,
z_{ij} is the covariate fork length, and
ϵ_{ij} is the error term associated with individual observations.

The model was used to calculate adjusted mean smolt weights by year standardized to the covariate. Additional details regarding the common slope (b) model used are in Dempson et al. (1994b). Weight and length variables were transformed to natural logarithms.

3. Rainbow trout

Rainbow trout, which stray into the Conne River as a result of incidental escapements from local fish farming activities in Bay d' Espoir, were again sampled in 1995. In addition, test fisheries were carried out at various locations in Bay d'Espoir from May 25-31, and again from September 12-18. Eight sets were made during the spring and four sets in September. Surface gill nets with mesh size varying from 76 (3") to 102 mm (4") were used. Effort was expressed in terms of mile-hours, defined as the product of the

length of nets (in international nautical miles) and the time in hours that the nets were fished following Reddin (1991). Thus catch per unit effort is expressed as the number of rainbow trout caught per mile-hour of gear fished.

4. Physical measurements

Water temperature information was obtained from a continuous recording Hugrun thermograph in the lower Conne River (April 28 – October 17). Information on air temperature, precipitation, and discharge were obtained from the Environment Canada, Atmospheric and Environment Service monitoring facility located on the main stem of Conne River, below Conne Pond.

5. Estimated returns and spawning escapement

Adult Atlantic salmon migrants were enumerated at a fish counting fence, located about 1 km upstream from the mouth of the Conne River (Fig. 1), which operated from May 30 to October 16, 1995 (Table 1). The counting fence was monitored as a cooperative project between DFO and the Conne River Indian Band.

During 1995, adult salmon were counted either as they: 1) passed through monitored openings in the fish counting fence; 2) entered the trap directly; or 3) passed through openings in the fish counting fence but were recorded on the video camera system. The video camera system utilized a positive image horizontally directed camera (Panasonic model WV-BD400) positioned on the substrate and angled to view an opening in the fish counting fence. A Panasonic Time Lapse Video Recorder (Model AG 6040) was used to record the video signal from the camera and could also superimpose the time and date thus providing a summary of actual fish passage times. The video system was operated each day generally from early evening until about 0900 hours from June 17 until July 31. Some adult small salmon caught in the fish counting fence trap were transferred to holding cages located about 50 m upstream and maintained as brood stock for artificial propagation.

Total returns (TR) of adult salmon were estimated from:

$$TR = Fc + Mb + Cn$$

where, Fc is the count of fish at the counting fence
  Mb is the known mortalities below the counting fence, and
  Cn is the estimated number of Conne River origin salmon
    caught in the native food fishery (0 in 1995).

Spawning escapement (SE) was estimated as:

$$SE = Fr - Ma - Br$$

where,   Fr is the number of fish released at the counting fence
           Ma is the known number of mortalities above the fence
           Br is the number of salmon removed for brood stock use.

Consistent with the practise established in 1991, estimated egg deposition refers to the 'potential' deposition relative to the current target. That is, no additional adjustments have been made to account for any unknown or assumed mortality of fish up to the time of spawning and thus the potential egg deposition probably overestimates the actual egg deposition.

As in past years, egg deposition was calculated separately for salmon < 63 cm and salmon ≥ 63 cm and then totaled.

Egg deposition = number of spawners x % female x fecundity at size.

An estimate of fecundity was obtained from the relationship derived in 1987 (October 27-30) from ripe salmon (Dempson et al. 1987):

$$Fecundity = 0.1988(fork\ length, cm)^{2.3942} \quad (r^2 = 0.48,\ P < 0.001)$$

where fork length was the mean length of female salmon < 63 cm in size sampled in 1995 ($\bar{x}$ = 49.7 cm, N = 83; includes repeat spawning females < 63 cm) and the percentage female was 77%.

An estimate of the egg deposition from salmon ≥ 63 cm in size was obtained using the same length-fecundity relationship for salmon < 63 cm, with the same data for mean length (67.8 cm) and percent females (71%) as used in past years (Dempson 1989, 1990).

The target spawning requirements have been maintained as in past years at 7.8 million eggs, equivalent to about 4000 salmon < 63 cm in size.

6.   Net-marked salmon

Surveys of net-marked salmon returning to Conne River were carried out from June 4 - July 21, 1995, but only on those fish clearly observed in the fish counting fence trap.

7.   Smolt production

A mark-recapture study was carried out to estimate the smolt production in 1995. The study was similar to those carried out in 1987-94, the design of which is summarized in Dempson and Stansbury (1991) and uses the estimator described in Schwarz and Dempson (1994). One exception, however, was that the downstream smolt trap was monitored 24 hours of the day. This was possible because of the cooperative project with the Conne River Indian Band.

During 1995, 2558 smolts were tagged and released at the upstream partial counting fence site (Fig. 1). At the downstream recapture site, 12260 smolts were caught including 545 tagged smolts.

Results and Discussion

1.   Landings

Landings in the recreational fishery are summarized in Table 2. As indicated above, no recreational fishing has been allowed since 1993. In past years, angling exploitation rates varied from 0.181 to 0.285 (Dempson et al. 1994a).

Native food fishery catches are also summarized in Table 2. No fishery occurred in 1994 or 1995 although in past years, the food fishery was estimated to have harvested from 5 to 16% of the total number of small salmon returning to Conne River.

2.   Biological characteristics

Tables 3 summarizes annual biological characteristic data for salmon sampled from Conne River (1986-95). Mean weight of 1SW salmon in 1994 and 1995 is lower by comparison with earlier years. During the past two years, length and weigh data have been obtained from fish maintained in cages for brood stock. Thus data are recorded in September and not in June or July as in past years. Biological characteristics of the native food fishery catch have been provided in past reports (see Dempson et al. 1995).

Figure 2 illustrates the run timing of smolts and adult small salmon at Conne River. Variability in run timing is apparent for both groups with up to a 15 day difference in the 25th percentile of the run of either life stage. Median dates of the smolt and adult run were typically later during the four years 1991-93 in comparison with the pre-1990 period. During 1995, median run timing for smolts was the earliest since 1990. Timing of the adult run was generally similar to the past three years (1992-94) but still later than the 1986-89 period when returns to home waters was considerably greater.

The analysis of smolt condition indicated significant differences among years (F = 34.82, P = 0.0) (Fig. 3). Lowest condition was in 1992 followed by 1994, 1990, and 1991. Previously, years in which smolts had a higher condition were those that were generally associated with warmer spring temperatures (Fig. 3). Also, there was an indication that smolt condition was associated with subsequent sea survival, as higher survival of smolts occurred in years where condition was greater (Fig. 3). This pattern was not consistent with results obtained in 1995. First, the temperature 'index' was the coldest recorded in 1995 yet run timing was earlier than in the past few years. Sea survival increased to 5.8%, the highest value in five years although condition in 1994 was among the lower values. We note that smolt condition in 1995 was the third highest recorded. Smolt run timing is still negatively associated with the percent survival to small salmon (r = -0.853).

The following text table summarizes the air temperature index, smolt run timing statistic (day of the year) and percent survival from smolt to small salmon.

Year	Air temperature index (April 1-May 15)	Median Day run timing	% Survival
1987	5.48	Day 131	10.2
1988	4.77	136	7.6
1989	4.08	138	7.3
1990	3.46	138	4.2
1991	2.87	141	3.4
1992	2.36	145	4.0
1993	2.34	143	2.7
1994	2.69	142	5.8
1995	1.80	139	

3. Rainbow trout

Records have been kept on the numbers of rainbow trout that have been encountered at Conne River during the course of field activities. This was because of the increased production of rainbow trout at sea farming sites in the Bay d'Espoir area, and the potential impact this could have on wild Atlantic salmon stocks in the vicinity. Summaries of known occurrences for past years are reported in Dempson et al. (1994a and 1995). Information for 1995 is updated in Table 4. Additional rainbow trout were observed during the course of periodic snorkling observations in the lower river or as they were identified from the video camera recordings.

Results of the spring and fall test fisheries are summarized in tables 5 and 6. A total of 33 trout were caught during the spring. No fish were captured in the 'inner bay' (inside of St. Joseph's). Trout were caught at sets outside of Morrisville

(entrance to Conne River estuary), between Tickle Head and Eads Point, northwest of St. Albans, and at Frenchmans Head, outside of St. Albans towards Roti Bay. Fish ranged in length from 285 to 445 mm (mean = 380 mm). Catch rates (CUE) varied from 0 to 6.395, with an overall average CUE of 1.575. Using only those sets where rainbow were caught, then the average CUE increased to 4.201.

Test fishery results during the fall differed considerably from those during the spring. No sets were made in the 'inside' areas. A total of 164 rainbow trout were caught. Lengths ranged from 290 to 480 mm (mean 350 mm). Corresponding whole weights varied from 0.3 to 1.8 kg. Fall catch rates varied from 8.231 to 29.639, with an overall mean CUE of 16.402.

No comparable studies have been carried out previously. However, these results may be interpreted in view of Reddin's (1991) results for postsmolts in the Labrador Sea. In 1987, postsmolt catch rates ranged from 0 to 1.53 (mean = 0.23) while older salmon captured had an average CUE of 0.81 (Reddin 1991). In 1988, catch rates for postsmolts ranged from 0-4.20 (mean = 1.55). Reddin concluded that *"The high catch rates compared with catch rates from Greenland suggest that the population of postsmolts in the Labrador Sea may be large."* Given the catch rates of rainbow trout in Bay d'Espoir, one may be tempted to conclude that they are quite abundant. Sticklebacks were the most common food item in the rainbow trout stomachs. No evidence for predation on salmon was found.

4.   Estimated returns and spawning escapement

There were 3500 salmon < 63 cm and 110 salmon ≥ 63 cm counted at the fish counting fence on Conne River in 1995 (Table 7 and 8). This represents an increase of 128% in the number of small salmon in comparison with 1994. Large salmon numbers increased by 10% from the previous year. The single largest daily run occurred on July 5 (295 fish). In past years, daily counts of over 1000 salmon have occurred (Fig. 4). Only 12 small salmon were enumerated after July 31.

Partitioning the count of salmon among the various ways fish were enumerated in 1995 is as follows:

	Small Salmon		Large Salmon	
	N	%	N	%
Fence opening	96	3	5	5
Counting fence trap	1647	47	61	55
Video camera chamber	1757	50	44	40
Total	3500	100	110	100

With respect to the video camera system, salmon generally migrated all night long. The period from 2230 to 0229 hours accounted for 54% of the total. This pattern of movement was consistent with that observed at Conne River in 1993 and 1994. A total of 1607 fish were associated with time of fish passage as follows:

Time (hours)	Number of fish	%
2030 - 2229	154	10
2230 - 0029	431	27
0030 - 0229	546	34
0230 - 0429	425	26
0430 - 0900	51	3

Total returns of adult salmon to Conne River in 1995 are summarized in Tables 7 and 8 for small and large salmon, respectively. Returns of salmon to Conne River in 1995 were forecast to be below target. Dempson and Reddin (1995) have examined various factors that may have been contributing to the low returns to Conne River.

Total returns of small salmon (3502) were 128% higher than in 1994 while large salmon returns (110) increased by 10%. Sea survival of smolts has changed from 2.7% (2.6-3.0%) in 1994 to 5.8% (5.2-6.5%) (Table 9). This represents the highest survival recorded in five years.

Potential spawning escapement in 1995 was estimated to be 3376 small salmon and 108 large salmon (Tables 7 and 8). Mean number of eggs per female was 2290 using size data from 1995. With 77% of the run estimated to have been female salmon, the number of eggs per fish is 1763. Estimated total number of eggs deposited was:

small salmon   = 5.952 million eggs

large salmon   = 0.369 million eggs

for a total natural egg deposition of 6.321 million, or 81% of the current target egg requirement and a 103% increase in egg deposition from 1994.

Salmon retained for brood stock in 1995 produced 143,436 eggs that were incubated at the Southwest Brook incubation facility by the community of Conne River. Egg-to-fry survival from an incubator is commonly about 85% while wild survival is 10% (V. Pepper, DFO St. John's, personal communication). By extrapolating to the fry stage, an 'equivalency' in terms of the number of wild eggs that would have had to have been spawned can be estimated

given the numbers of fry that were produced. In doing this, the estimated egg deposition at Conne River in 1995 would increase by approximately 1.219 million eggs [(143436 x 0.85)/0.10], that would correspondingly increase the egg requirement met to 97% of the target.

From eggs incubated over 1994-95, approximately 128 thousand fry were subsequently stocked back into Conne River (all into Twillick Brook). About 40,000 of these were stocked as fed fall fingerlings. All fall fingerlings were adipose fin clipped.

Relationships between estimated egg deposition and subsequent smolt output, and estimated smolt output with adult returns are based on limited data and as such, are not conclusive (Fig. 5). At best, higher egg depositions produced more smolt but the first complete (to river age 4) smolt output from a low egg deposition (4 million eggs in 1991) will not be apparent until 1996. Moderate to high numbers of returning adults corresponded with moderate to higher numbers of migrating smolts in the previous year (Fig. 5). Low returns of adults were obtained over the entire range of smolt migrants. We still caution, however, that it is premature to draw any conclusions from these limited data.

Estimates of egg-to-smolt survival are now available for five year-classes (1986 to 1990; the 1990 year-class complete only to age 4 smolts in 1995). These values, by year-class, are:

Year-class (eggs)	Estimated egg deposition	Smolt Production	Survival (%)	Eggs per 100 m^2
1986	11,340,000	56,873	0.50	860
1987	16,730,000	76,655	0.46	1269
1988	12,420,000	65,038	0.52	942
1989	8,040,000	55,335	0.68	610
1990	8,730,000	66,827	0.77	662
1991	3,980,000			302

Egg-to-smolt survival, while increasing, is still less than 1%. Egg deposition in 1991 was approximately 4 million eggs. Smolts produced to date from the 1991 year class are now complete only to age 3. However, egg-to-smolt survival is already 1.1% and could approach 1.5% if age 4 smolts in 1996 are comparable with the average production from 1989-1995 (15,504). We note that, relative to the estimated 13,180 units (1 unit = 100 m^2) of rearing habitat in the Conne River system, egg deposition rates per unit have ranged from 610 to 1269, coinciding with egg-to-smolt survivals of 0.50 to 0.77%. With the 1991 egg deposition and survival to age 3 smolts already at 1.1%, it is interesting to note that the egg deposition rate per 100 m^2 in this year was only 302.

5. Net-marked salmon

The following summarizes observations of net marked fish at Conne River during 1995.

Date	Number of fish observed	Number scarred	Percent Scarred
June 4-16	220	17	7.7
June 17-21	184	9	4.9
June 22-26	264	23	8.7
June 27-July 1	95	10	10.5
July 2-6	371	22	5.9
July 7-11	72	5	6.9
July 13-21	60	4	6.7
Total	1266	90	7.1

Numbers of net marked salmon varied on each occasion with no apparent increasing or decreasing trend. Results are comparable with those obtained in 1994.

6. Smolt production

The estimated number of smolts in 1995 was 62749 (95% confidence limit = 55300-70197) (Table 9); similar to the previous year. The estimated number of smolts in each age group is summarized in Table 10. Sixty-eight percent of the smolts were age 3+, from the 1991 spawning year when only 51% of the target was achieved.

Discounting the 5,000 smolt transferred to Roti Bay (see below), at 4% survival, the approximate average recorded during the past three years, no more than 2300 fish would be expected to return to home waters in 1996. With survival similar to that of 1994-95, over 3300 salmon could return to Conne River. A sea survival of approximately 7% would be required in order for total returns to meet or exceed the current target requirement of 4000 fish. Sea survivals of 7-10% have been recorded at Conne River in past years but it is stressed that so far, sea survival cannot be predicted with accuracy in advance. At present (March 1996), there is nothing to suggest that survivals approximating 7% will occur. However, early in-season monitoring could be used to advise managers on the status of the run as it progresses.

6.1 Transfer of wild smolt to sea cages at Roti Bay

Five thousand wild smolts were captured at the downstream partial fish counting fence and transferred to sea cages at Roti Bay (May 13-25). These fish were handled a minimum of three times. One hundred tagged smolts (streamer tags) were also included. Initial survival was high. To the end of June 1995, survival of the two groups was comparable (88% for the tagged fish, 85% for the untagged fish; G = 0.951, P = 0.329). Mortalities began to increase and by the end of July, tagged fish had a higher survival (58%) than untagged smolt (34%) (G = 24.117, P = 0.000). To the end of December 1995, survival of the untagged smolts was about 25%. Information on tagged fish was incomplete after the end of July given tag loss that was occurring.

* Total for 1990 does not include approximately 50 fish found dead and partially destroyed in traps.

Recreational fishery closed in 1993 and 1994. Quotas of 100 and 330 small salmon were in effect in 1991 and 1992, respectively.

Native food fishery closed in 1994 and 1995

Fig. 3. Index of Conne RIver smolt condition: varying over years (upper panel); in relation to the April-May air temperature index (middle panel); and as it relates to estimated sea survival of adult salmon returning in the following year (lower panel). Vertical lines in the upper panel represent ± one standard error.
Fig. 4. Daily count of Atlantic salmon smolt at the downstream partial fish counting fence trap (upper panel) and number of adult small salmon returning to the adult fish counting fence trap (lower panel). Mean daily river water temperature indicated on both graphs.

Recruits (Thousands of smolt)

Stock (Millions of eggs)

Recruits (Thousands of small salmon)

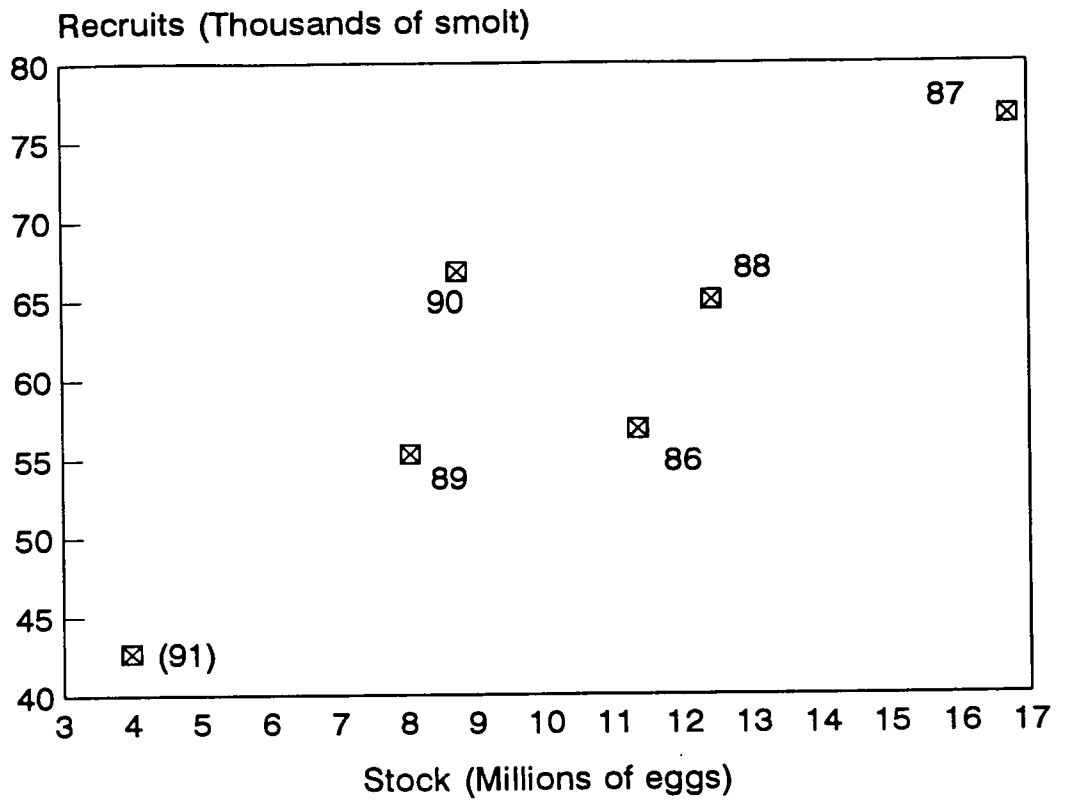

Stock (Thousands of smolt)

Fig. 5. Relationship between estimated egg deposition and subsequent smolt production, by year class (year of egg deposition indicated, upper panel), and smolt production (year of smolt run) and corresponding return of adult small salmon in the subsequent year (lower panel). Brackets around the 1991 year class in the upper panel indicate incomplete information on number of age 4 smolt which will migrate in 1996.

STOCK: Conne River (SFA 11)   **Drainage area:** 602 km²
TARGET: 7.8 million eggs (~4000 small salmon) calculated as fluvial area x 2.4 eggs/m² and
            egg/recruit applied to total population as derived from assumed commercial exploitation
            rates.

Year	1990	1991	1992	1993	1994	1995	MIN[1]	MAX[1]	Mean[1]

% Target eggs met:									
	112	51	51	61	40	81	51	214	131

[1] Minimum, maximum and mean recreational catch for period 1974-91; other mean data for
1986-91 to coincide with the pre-moratorium period. Angling catches are DFO statistics. First
Peoples' catch in salt water includes some salmon from other rivers. First Peoples' fishery quota
of 1200 fish has been in effect since 1986, but reduced to 500 fish for 1993. First Peoples'
fishery closed in 1994 and 1995.

Data and methodology: Smolts used in adult forecasts are surveyed by mark-recapture. Returning
adult salmon are enumerated at a fish counting fence. A video camera system was introduced in
1993.

State of the stock: Target requirements were met from 1986-90. Only 40-61% of the target was
achieved from 1991-1994. This increased to 81% in 1995. Sea survival increased to the highest
value in five years (5.8%), but is still low relative to the 1987-90 period. An enhancement project
was initiated in 1994 with approximately 128 thousand fry released in 1995. Note that these fry
have not been included in terms of the percentage target achieved in the above table.

Forecast: Estimated smolt output in 1995 was 62,749 (55,300-70,197); similar to 1994. At 4%
survival, the average recorded during 1990-92, no more than 2,500 fish would be expected to
return in 1996. A sea survival of 6.4% will be needed in order for total returns to meet or exceed
the 4,000 salmon necessary to reach the target egg deposition. Sea survival of 7-10% has been
recorded at Conne River in past years. Survival of salmon appears to be associated with timing of
the smolt run and smolt condition. At present, there is nothing to suggest that survivals
approximating 7% will occur. In-season monitoring could be used to update managers on changing
conditions as the 1996 run progresses.
