Assessment of the Southern Gulf of St. Lawrence Cod Stock, March 1996

Alan Sinclair, Ghislain Chouinard, Linda Currie<br>Department of Fisheries and Oceans, Gulf Fisheries Centre, P.O. Box 5030, Moncton, N.B., E1C 9B6

${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte atlantique du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

#### Abstract

Directed cod fishing in the southern Gulf of St. Lawrence was closed in September, 1993. Stock size had reached an historic low level because of high fishing mortality, reduced recruitment, and low growth rates. The results of the 1995 research vessel survey and data from other sources including sentinel surveys, indicate that the adult biomass has increased slightly since the closure due mainly to the growth of adult fish, but that the abundance of young fish is well below average. There are signs that the abundance of age 0,1 , and 2 cod may be improving, however the indications are highly variable and uncertain at this time. Stock production continues to be low and catches of as little as 6,000 t could prevent any increase in spawning stock biomass. Continued low levels of fishing, similar to that in 1994-95, and improved recruitment are required for stock recovery.

Résumé
La pêche dirigée de la morue dans le sud du golfe du Saint-Laurent a été fermée en septembre 1993. Le niveau du stock était tombé à la valeur la plus faible jamais notée à cause d'une forte mortalité par pêche, d'une baisse du recrutement et de faibles taux de croissance. Le relevé par bateau de recherche de 1995 et des données d'autres sources, dont ceux de pêches de contrôle, indiquent qu'il y a eu une légère augmentation de la biomasse des adultes depuis la fermeture, surtout à cause de la croissance des individus adultes, mais que l'abondance des jeunes poissons est toujours bien en deçà de la moyenne. Il y a certains indices d'un accroissement de l'abondance des morues d'âges 0,1 et 2 , mais ceux-ci sont très variables et encore incertains. La production du stock continue d'être faible et un volume de captures d'aussi peu que 6000 t pourrait interdire toute augmentation de la biomasse des géniteurs. Le rétablissement du stock exige le maintien de faibles niveaux de capture, semblables à celui de 1994-95, et une amélioration du recrutement.

## 1. Description of the 1994 Fishery

Directed commercial cod fishing continued to be prohibited in 1995. Other fisheries which normally produce some cod by-catch were also closed in 1995, including Unit 1 redfish and 4 T white hake. Fisheries for American plaice, witch flounder, winter flounder and dogfish were permitted. However, these fisheries were subject to a number of management measures designed to limit cod by-catch. A recreational fishery using hook and line gear was allowed. A sentinel survey conducted under a scientific protocol and designed to obtain additional indices of abundance of the stock was conducted. In this section, a summary of landings, management measures and input from industry about the status of the southern Gulf of St. Lawrence cod stock in 1995 is provided.

### 1.1. Landings by gear, area, season, fishery type

The total reported landings of southern Gulf cod was 1075t in 1995 (Table 1). This is slightly lower than landings for 1994 (1334 t) and represents the third consecutive lowest catch on record for this stock (Figure 1). The catches were entirely from NAFO Division 4T except for 6 tonnes caught in 4 Vn in the period of November-December.

Landings decreased for all gear types except miscellaneous gears (mainly unspecified gear) which increased from 154 t to 371 t (Table 2). This component was composed primarily of catches from the recreational fishery ( 318 t ). Fixed gear (gillnets, handlines, longlines) catches declined from 554 to 139 t .

Monthly landings peaked in October mainly due to the sentinel surveys. This trend is contrary to the traditional pattern with peaks in January (in 4Vn), April and November (in 4T) (Figure 3 in Sinclair et al. 1994). Landings by fixed gears occurred predominantly in the period of August to October while the recreational fishery peaked in August.

### 1.2. Management measures

Management measures in 1995 were similar to those of 1994. With the continued closure of the fishery in 1995, DFO maintained the by-catch limits of $10 \%$ (by weight) of cod in fisheries directed toward other species. The cod by-catch protocol in existence in 1994 was continued whereby if a given fleet sector exceeded the limit of $10 \%$ in an area, the groundfish fishery would be closed for at least 10 consecutive days. The closure would be followed by a test fishery to determine if the cod by-catch level in the area was less than $10 \%$. There was no redfish fishery in 4 Vn in November, 1994 - April, 1995 because of the Unit 1 redfish closure. Flatfish fisheries were not permitted in 4Vn during the winter months (January-April).

In addition to the by-catch protocol, DFO implemented a small fish protocol whereby fisheries were closed if the percentage of small fish caught exceeded specific thresholds. The minimum fish sizes agreed to by the industry were the following:

```
- }\quad30\textrm{cm}\mathrm{ for American plaice;
- }\quad45\textrm{cm}\mathrm{ for white hake;
- }\quad25\textrm{cm}\mathrm{ for winter flounder;
- }\quad41\textrm{cm}\mathrm{ for cod.
```

In 1995, there were 36 closures due to either high by-catches of cod or of small fish. The closures affected both fixed and mobile gear fleets.

In addition to these measures, DFO introduced monitoring of small fish through the dockside monitoring system. Fisheries management personnel compared samples collected by dockside monitors to those collected by observers at sea. On two occasions, the plaice fishery was closed when dockside samples suggested that discarding at sea was taking place on vessels not covered by observers. Increased monitoring was also put in place in the fixed gear fishery. This coupled with the closure of the white hake fishery contributed to the reduced catches by this fleet sector.

### 1.3. Input from industry

The views from industry on the status of the cod stock were expressed at a number of meetings during 1995. Following the release of the 1994 stock status report on June 29, 1995 in Charlottetown, staff from the Groundfish Section held a series of information meetings in Charlottetown (June 30), Caraquet (July 4), Port Hawkesbury (July 7), Gaspé (July 12) and Cap-aux-Meules (July 13). Views of fishers expressed during Fisheries Resource Conservation Council (FRCC) public meetings were also noted. These meetings were held on September 11 (Halifax Airport), September 12 (Sydney and Moncton) and on September 13 (Gaspé).

In general, the views of fishers from the western southern Gulf differed from those from the eastern area. In the western area (Gaspé and northeast N.B. in particular), there was no indication of a significant increase in cod abundance. In the Magdalen Islands, the views were mixed with some indicating that cod abundance had increased particularly in inshore waters. In the eastern area (P.E.I. and Gulf Nova Scotia), fishers indicated that they had made numerous incidental catches of cod in various gears (lobster traps, handlines, etc) which indicated that cod abundance had increased. Fishers in these areas had made the same observation in 1994.

The pre-assessment consultation was comprised of a series of Science Workshops, designed specifically to obtain the views of industry on the status of the stocks. These were held throughout the southern Gulf of St. Lawrence in late November and early December 1995. The meetings were held in Grande Rivière, Québec on November 21, in Caraquet, N.B. on November 22, in Charlottetown, P.E.I. on November 23, in Port Hawkesbury, N.S., on December 5 and in Cap-aux-Meules, Magdalen Islands, on December 7.

Scientists presented a preliminary description of the 1995 fishery including fishery distribution, the summary results of the September 1995 fall groundfish survey, and some sentinel survey results at these meetings. Fishers were then invited to provide comments on these data and indicate whether or not this was consistent with their view of the stocks. Generally, the opinions regarding stock status expressed during the Science

Workshops were similar to those of other meetings. In the western southern Gulf, abundance of cod was considered to be low while fishers in the eastern area indicated that they had perceived a significant increase in the abundance of cod. The following is a short summary of comments made at these Science Workshops.

In Grande-Rivière, only a few fishers attended the meeting. The only comment received regarding cod abundance was that it had not increased along the south Gaspé shore (e.g. off Newport). There were no indications of increased abundance of cod in the area. Fishers noted the lack of fixed gear coverage along the Gaspé Peninsula in the sentinel survey.

The meeting in Caraquet was attended by 15-20 fishers. Some indicated that they thought there had been a marginal increase in abundance of cod in 1995. A fisherman who had participated in the sentinel survey remarked that cod were in abundance in some areas but that generally, there had not been a significant increase. Other fishers also indicated that cod abundance may be higher in specific areas and this had been observed in the past. Several fishers reported that cod had migrated outside of the Gulf early in the fall, as in previous years. Many fishers indicated that the catches from the recreational fishery were underestimated.

In Charlottetown, the Science Workshop was attended by few fishers. In general, fishers considered that cod were far more abundant in shallows along the north shore of P.E.I. and in an area of hard bottom off North Point, P.E.I. They thought the survey had underestimated cod abundance because some inshore areas had few sets. Generally, fishers thought that there was sufficient cod abundance to open the fishery. Occurrence of cod in lobster traps continued to be important in 1995. Fishers were concerned that the sentinel survey did not include any fixed gear participants from P.E.I. because it was those fishers who reported increased cod abundance. Participants felt that recreational fishery catches were underestimated by DFO.

In Port Hawkesbury, about 30 fishers attended the workshop. In terms of abundance, fishers indicated that they thought there were far more cod in the western Cape Breton area in 1995 than indicated in the research survey. They reported that cod were caught much closer to the shore ( $<30$ fathoms) and that the survey does not cover the inshore areas adequately. Many participants interpreted the numerous closures in other fisheries as an indication that the cod abundance had increased. One participant indicated however that he had fished some longline gear where others were reporting cod concentrations but that he had failed to locate any. Another noted that it was difficult to compare cod abundance to past years because of the change in mesh sizes. A participant indicated that when the fishery closed in 1993, parasite abundance in cod had increased by $250-300 \%$ and that this was concomittant with the increasing seal population. Sentinel surveys were also discussed at length during the meeting, with many participants indicating that many more fishers should be involved.

The meeting in Cap-aux-Meules (Magdalen Islands) was attended by about 35 fishers. Participants were of a very strong opinion that seal predation is seriously affecting the abundance of cod and other fish species in the area. There were mixed opinions about the abundance of cod in the area. Some noted a decrease in abundance to the northwest of the Islands, while others noted an increase to the southwest and southeast. Many participants reported an increased incidence of cod in lobster traps. Many felt cod had migrated away
from the area earlier than usual, in early September. There was little fishing effort in the area, and it was therefore difficult to have a clear idea of cod abundance. Many indicated that they would have to be allowed to fish in order to find out if the abundance had changed recently. Many were disappointed that there were no sentinel survey projects involving fishers from the area. They felt that fishers from other areas would not know the best locations to fish around the Magdalen Islands.

## 2. Commercial Fisheries Data

### 2.1. Data Updates

Commercial landings statistics were updated according to revised Canadian data for 1994. An extra 34t were reported in 1994 compared to last year. This increase was spread among otter trawls, handlines and gillnets. The 1994 estimated catch at age was modified accordingly and the results are given in Annex 1.

### 2.2. Age Calibration

Consistency of age determinations was verified by regular blind readings of a reference otolith collection. Tests were performed after about 1000 fish had been aged. The level of agreement with the reference collection was high and no bias was detected (see below).
Date $\%$ agreement direction of bias
951109020
$951127 \quad 930$
951205 92 0
$951213 \quad 89 \quad 0$

### 2.3. Catch at Age

The calculation of the 1995 commercial catch at age was complicated by the limited fishery, as was the case in 1994. It was not possible to maintain the traditional quarterly stratification by gear due to limited sampling coverage. It was necessary to use ageing material collected during the July 1995 and September 1995 research vessel surveys to augment the commercial samples. We also included all observer length frequencies collected by the Gulf and Quebec region observer programs. Observer samples are collected on a set-by-set basis while commercial port samples are collected on a trip-by-trip basis. The set-by-set observer samples were weighted to the catch in the set, then combined within trips and weighted to the observer estimate of trip catch.

A summary of the sampling data used in constructing the 1995 catch at age is given in Table 3.

At this time, we have treated the observer and port samples separately in calculating the catch at age. Comparisons of observer and port sample combined length frequencies for similar areas and time periods indicate important differences (Figure 2). For example, the observer length frequency for seines in April - June included large numbers of cod greater than 70 cm in length, while the port samples did not. Where the seine length frequency covered a broad range of lengths, and predominantly in the upper length range, the port
samples had a more distinct mode in the smaller length range. A similar pattern was noted for seines in October - December. In previous assessments, these comparisons revealed a different pattern. The length distributions for observer and port samples were similar for commercial sized fish ( $>41 \mathrm{~cm}$ ), but the observer samples included more small fish, less than the commercial size. We have attributed these differences to discarding at sea. In 1995, discarding cannot explain the differences, and for the moment the cause is unresolved. For this reason, we calculated the catch at length of observed and unobserved fishing trips separately. The observer sampling was applied to observed trips only while the port sampling data were used to calculated the catch at length of unobserved trips. Further investigation is warranted.

The catch at length in the 1995 sentinel surveys was calculated exclusively from sea sampling data on sentinel vessels. Ageing material from these trips was not available in time for the assessment and the July and September RV otoliths were used instead. Sampling for length was extensive, with over 440000 fish measured. Details of the keys are given in Table 3.

The following length ( L , in cm )-weight ( W in grams) relationship was obtained from the September 1995 research vessel survey and was used to calculate mean weights at age

$$
\mathrm{W}=0.00608 * \mathrm{~L}^{3.1036}
$$

Landings numbers, mean weights at age, and mean lengths at age for each age-length key are presented in Tables 4 to 6 .

The total number of fish landed in 1995 was the second lowest on record (Table 7). The modal age in the 1995 landings was 7 ( 1988 year-class) but relatively large numbers of age 4-8 were landed. The larger numbers of age 4 and 5 fish came predominantly from the sentinel surveys, where liners were used on several trips. Commercial weights at ages 3-9 declined in 1995 probably due to the influence of the sentinel gear catches with liners on the total landings at age (Table 8 and Figure 3). Where in the past 2 years, the commercial weights at age have been increasing relative to those in the RV survey, this trend has stopped. In 1993 and 1994, the fixed gears made up a higher proportion of the total landings, and these gears tend to land larger fish at age.

## 3. Research Data

### 3.1. September 1995 Survey

The annual groundfish survey in the southern Gulf of St. Lawrence was conducted September 7-30 on board the research vessel Alfred Needler (Mission N230). A total of 226 standard sets ( 30 minutes at 3.5 knots) were attempted, of which 210 were successful. One hundred and eighty-three of these were in 4 T , and 27 stations were fished in 4 Vn . This is the second year the survey coverage was extended into 4 Vn to investigate the distribution of cod between the two areas in September. The location of the sets is shown in Figure 4.

The 1995 survey results were strongly affected by one large tow. The mean number per tow of cod of all ages ( $0+$ ) in the 1995 survey ( 98.9 fish/tow) is greater than the 1994
estimate ( 54.7 fish/tow) (Table 9). This increase is due mostly to one large set (\#127 - see Figure 4) near Miramichi Bay that yielded nearly 6600 juvenile fish ( 765 kg ). When this set was included in the estimations, the CV's on ages 1-3 were the highest in the series (Table 10 ). If this set is excluded from the analysis, there were 65.9 fish/tow and the CV's are within the range previously observed.

The cod length frequency distribution from the September survey may provide some encouragement in terms of improved recruitment, however the results must be interpreted with caution (Figure 5). The catch of age $0 \operatorname{cod}$ ( 10 cm and less) in 1995 was the highest seen in the survey and the catches were distributed in several areas including Chaleur Bay, the Shediac Valley, northern P.E.I., and eastern Northumberland Strait. Set 127 was dominated by age 1,2 , and 3 fish and this had a large influence on the total population estimate. However, the juvenile survey (see section 3.2) conducted in the same area in July failed to detect improved numbers of fish less than 3 years of age. Age 0 to 3 fish in 1995 will not be of commercial size for at least two more years and it would be prudent to reevaluate their abundance following the 1996 survey.

The estimated abundance of fish age 5 and over in the September 1995 survey was close to that predicted in last year's assessment (Sinclair et al. (1995) predicted 38.5 fish/tow, and the observed value was 36.2 fish/tow). The overall survey results since 1992 continue to be very low compared to those of previous years (Figure 6) and indicate that the southern Gulf cod stock has not yet recovered.

Weights at age estimated during the 1995 September survey are at the low end of the range observed since 1960 (Table 11, Figure 3). This indicates that individual growth rates remain very low and these have not increased despite low stock abundance and reduced fishing mortality.

The geographic distribution of catches indicates that the highest concentrations of cod were found close to shore in 1995 (Figure 7). Areas of higher concentrations include the Shediac Valley, inner Chaleur Bay, the north shore of P.E.I., and east of the Magdalen Islands. Few cod were caught in the central part of the survey area and along the edge of the Laurentian Channel. The density of cod in 4 Vn was markedly lower than that found inside 4 T (Figure 8). The distribution of cod catches was discontinuous between 4 T and 4 Vn .

Distributions of cod aged 0 to 8+ were mapped for September 1995 (Figures 9 and 10) using the methods outlined in Sinclair et al. (1994). Large catches of age-0 cod were made in Chaleur Bay and in the Miramichi area at the northwest end of Northumberland Strait (Figure 9). A smaller concentration of age-0 cod was also encountered at the southeast end of Northumberland Strait.

Catches of age-1 cod in the 1995 survey were greater and more widespread than in recent years. A large concentration of age-1 cod was encountered in the Miramichi area, with smaller catches also made southeast of the Magdalen Islands and along the north shore of PEI. Ages 2 and 3 showed a similar distribution, with the greatest concentration in the Miramichi area and smaller concentrations southeast of the Magdalen Islands and along the north shore of PEI. Densities of cod aged 4-6 were greatest in the southwest Gulf in the Miramichi-Miscou area, with a second less dense concentration between Cape Breton and the Magdalen Islands (Figure 10). Cod aged 7 and older were most dense in a band
extending from Chaleur Bay, through the Shediac Valley-Miramichi areas, along the coast of PEI and between Cape Breton and the Magdalen Islands. Densities of these older cod were greatest in the Miscou area with smaller concentrations in the Miramichi area and east of the Magdalen Islands.

Swain (1996) compared the September distribution of age-5 cod in recent years (1994 and 1995) to the distribution throughout the 1970s and 1980s. Cod distribution differed between the 1970s and the 1980s (Swain 1993; Swain and Wade 1993). In the mid1970s, when cod abundance was low, cod densities were highest in inshore areas of the western half of the southern Gulf, in Chaleur Bay and the Miramichi-Shediac Valley areas, and were relatively low in the central Magdalen Shallows and the eastern half of the southern Gulf. In the early to mid-1980s, when abundance was high, distribution expanded into the central Shallows and the eastern half of the southern Gulf, and the center of distribution shifted offshore to intermediate depths in areas off the Gaspé Peninsula and in the central Shallows. In 1994 and 1995, the distribution of age- 5 cod in the western part of the southern Gulf shifted back to the pattern seen in the mid-1970s. Cod densities in 1994 and 1995 were highest in shallow water in near-shore regions of Chaleur Bay and the Miramichi-Shediac Valley area, and were relatively low in the central Magdalen Shallows. This recent shift in distribution provides further support for the hypothesis that cod distribution is density-dependent during the summer feeding season in the southern Gulf, with distribution shifting from warm (high cost) shallow waters at low abundance to colder (low cost) deeper water at high abundance (Swain 1993).

Cod distribution differs between the current low abundance period and the previous low abundance period in the 1970s in terms of relative densities in the eastern and western halves of the southern Gulf (Swain 1996). The relative density of cod is clearly higher in the east in recent years compared to the low abundance period in the mid-1970s. Swain (1996) compared trawlable biomass of cod between western (415-429) and eastern (431439) strata. Declines in cod biomass in the late 1980s and early 1990s were steeper in the western strata than in the eastern strata. In recent years, biomass has fallen to levels similar to those of the early to mid-1970s in western strata but has remained above the earlier low levels in eastern strata.

### 3.2. July 1995 Juvenile Survey

The sixth annual juvenile cod survey was conducted in the Miramichi Bay - Shediac Valley area of the southern Gulf in July, 1995 on board the CSS Calanus II. The survey follows a stratified random design. The CSS Calanus II, which was also used in 1994, is the fourth vessel used in this survey. No comparative fishing experiments have been conducted among vessels, however, the same doors, bridles, and net have been used all years. A total of 42 valid sets were made.

The 1995 mean numbers per tow was the second lowest in the time series and less than half the 1994 value (Table 12). The highest catch was of age 7 (1988 year-class). The abundance of age 1-3 cod in the 1995 survey was low in comparison to other years, ranking 4,5 , and 6 respectively in the 6 year time series. The July survey is conducted in the same area that a large set of age 1-3 cod was made in the September 1995 groundfish survey. These fish were not seen in similar abundance in July.

The estimated mean numbers per tow in the July and September (all strata) surveys are quite similar in 4 of the 6 years available (Figure 11). The modal ages and relative abundance of other ages compare well in 1990, 1991, and 1993. There is also close agreement between the 1995 estimates, if set 127 is eliminated from the September survey results.

It is probable that the July survey is more susceptible to changes in cod distribution than is the September survey. One large set, comprised mainly of age 2-4 cod, was made during the July 1994 survey. Given the results in 1993 and 1995, this set now appears anomalous (Figure 11). In addition, the large numbers of cod observed at ages 4-7 in July 1994 did not appear at one year older in the July 1995 survey, nor did the large numbers of age 1-3 cod seen in the July 1992 survey appear as one year older in 1993. The July survey covers a relatively small portion of the total stock area and shifts in distribution have been noted in the September survey, which covers almost all of the stock area.

### 3.3. January 1996 Survey

A groundfish survey was conducted in Cabot Strait from January 3-25, 1996 on board the research vessel Wilfred Templeman. Similar surveys were conducted in January 1994 (Chouinard 1994) and in 1995 (Sinclair et al. 1995). The main objective of the 1994 and 1995 surveys was to determine the distribution and relative abundance of groundfish species and herring in Cabot Strait area during the winter. The 1996 survey was part of a project to identify the stock origin of cod concentrations in the area.

The survey design followed a grid pattern covering waters deeper than 50 m with increased sampling intensity between 200 and 400 m . The survey extended from about $45^{\circ} 15^{\prime}$ to $48^{\circ}$ North and from about $58^{\circ}$ to $61^{\circ}$ West. The survey proceeded in a north-south direction to minimize problems with ice. At each location, a standard 15 -minute tow (calculated from touchdown) using a Campelen 1800 trawl (with 19 mm liner in lengthening piece and codend), was conducted. Depth profiles of conductivity, temperature and oxygen concentrations were also made. A total of 139 sets were attempted, of which 138 were successful.

### 3.3.1. Spatial Distribution of catches

A contoured map of the cod catches in kg per tow (Figure 12) shows that the largest catches were made on the slope of the Laurentian Channel in 4Vn at depths of 200 to 300 m . Four large concentrations were detected : St. Paul's, Port-aux- Basques, Sydney and Burgeo Bank. Smaller concentrations were found off the Magdalen Islands, Codroy and Misaine Bank. Cod abundance appears to be lower in the middle of the Channel than on both sides. This is consistent with previous observations of the occurrence of the two stocks found in the area in winter (Halliday and Pinhorn 1982). The distribution of catches was relatively similar to that observed in previous years (Chouinard 1994; Sinclair et al. 1995) both in terms of area and depth. Abundance in the southern section of 4 Vn appeared to be lower than in 1995, not withstanding the difference in trawl and tow duration.

### 3.3.2. Length frequency distribution

The relative length frequency distribution for cod in area 4T and 4Vn in January 1996 indicates two modes ( 28 cm and 43 cm ) (Figure 13). It is compared with the length frequencies from January and September 1995. Most significantly, the first mode in the

January 1996 survey appears to correspond with the mode seen at 28 cm (set 127 included) in the September 1995 survey. However, the relative height of this mode should be treated with caution because the Campelam 1800 trawl, which was used for the first time in 1996, is thought to be more efficient for small cod.

The length frequency distributions were also examined for each of the seven concentrations identified above (Figure 14, refer to map on Figure 12). The results indicate that juvenile fish ( $<35 \mathrm{~cm}$ ) are found in the northern areas and that there is a north-south gradient in mean size with larger fish being found to the south. This observation is consistent with fishers' knowledge and previous studies of cod distribution in the area. This segregation between juvenile and adult cod may be useful as a management tool to avoid the capture of small fish in early winter.

### 3.4. Cod Condition

Both seasonal and annual conditon factors were examined. Two measures of condition were examined and compared. The first was Fulton's condition factor (K):

$$
\mathrm{K}=\alpha \frac{\mathrm{W}}{\mathrm{~L}^{3}}
$$

where $\quad W=$ fish weight $(\mathrm{g})$. The seasonal index used carcass weight (total weight less stomach and gonad), and the annual index used total weight.
$\mathrm{L}=$ fork length (cm)
$\alpha=100$, a scaling factor to control the number of decimals
In many cases, there can be a relationship between the Fulton condition index and length. Therefore it is not valid to use mean condition index over the full range of length to monitor changes in condition as changes in length composition will affect the trends. Previous analyses (Sinclair et al. 1994) indicated that there was no significant relationship between length and condition factor for fish in the 40 to 50 cm range calculated from using total weight collected during research vessel surveys (e.g. annual values). In the case of the seasonal condition indices which were calculated from total weight minus the weight of stomach and gonad, there was no relationship between condition index and length in all but three cases where the slope was marginally significant.

The second measure was the predicted weight of a 45 cm cod derived from least squares length-weight relationships:

$$
\mathrm{W}_{45}=\mathrm{aL}^{\mathrm{b}}
$$

where $\quad W_{45}=$ predicted weight for a 45 cm fish a and $\mathrm{b}=$ parameters of the length-weight relationship $\mathrm{L}=$ length of fish (here 45 cm )

The two condition indices were then compared.
3.4.1. Seasonal patterns in cod condition

Seasonal cod condition has been monitored since September 1991 in the southern Gulf of St. Lawrence. Originally, a monthly sampling regime was followed as closely as possible. Since the fishery was closed in September 1993, samples were not always available.

Samples were collected in the sentinel surveys and the groundfish surveys in June to October, 1995 as well as from the January 1995 and 1996 groundfish surveys. Because of the cod migration, samples originate from 4 Vn in January, western Cape Breton in early spring and late fall and the western southern Gulf in summer.

A distinct seasonal cycle is evident in the Fulton's condition index, being low in the spring, before and during spawning, and reaching a maximum in the late fall (Figure 15). The fall condition is about $40 \%$ higher than that in the spring. Condition was lowest in 1992 for the period examined. Condition in 1995 was similar to 1991, 1993, and 1994.

### 3.4.2. Annual Condition indices

Annual condition indices and weight of a 45 cm cod were calculated from the data collected during the September groundfish surveys. Trends in condition using the two measures are highly correlated ( $\mathrm{R}^{2}=0.83, \mathrm{p}<0.0001$, Figure 16). This index is similar in 1994 and 1995, and close to the average for the period.

As indicated last year, caution should be exercised when interpreting the annual condition indices as they do not appear to correspond well with the indications from the seasonal samples. For example, seasonal samples suggest that condition in 1992 was the lowest in the period 1991-1995, however, the annual samples do not suggest the same trends. The condition indices from the annual survey probably suffer from several potential deficiencies and biases. First, the condition indices from the annual survey are calculated using total weight which can be affected by the degree of feeding of the animals and gonadal development. Secondly, the samples are collected during the entire survey and could be affected both by temporal and areal differences. Finally, there may be 'aliasing' due to minor shifts in the physiological cycle. Seasonal monitoring of condition (somatic weight) is likely to provide a more meaningful index of changes in condition than the annual values.

### 3.5. Sentinel Surveys

### 3.5.1. Description of 1995 program

A sentinel survey (also referred to as sentinel fishery) program to monitor changes in abundance and obtain biological information on groundfish was conducted in the southern Gulf of St. Lawrence in the fall of 1994. In 1995, funding for the projects was announced in mid-June and projects started between mid-July and early September.

Seven sentinel survey projects were conducted in the southern Gulf of St. Lawrence in 1995. Three types of projects were conducted. In general, the projects were designed to provide indices of annual changes in abundance, detect patterns in seasonal distribution, and monitor the timing of the autumn migration for all sizes of Atlantic cod and white hake, covering the entire southern Gulf. The projects were as follows:

| Sponsoring Association | Province | Projects | Number <br> of <br> Vessels | Number of <br> fishermen <br> (inc. crew) |
| :--- | :---: | :--- | :---: | :---: |
| Association des pêcheurs <br> professionnels acadiens | N.B. | - Mobile gear abundance <br> - Distribution and <br> migration | $\mathbf{2}$ | $\mathbf{8}$ |
| Association des pêcheurs de <br> la MRC Pabok | Québec | - Mobile gear abundance | $\mathbf{2}$ | $\mathbf{8}$ |
| P.E.I. Groundfish Association | P.E.I. | - Mobile gear abundance | $\mathbf{2}$ | $\mathbf{8}$ |
| Chéticamp Development <br> Commission | N.S. | - Mobile gear abundance <br> - Fixed gear abundance | $\mathbf{2}$ | $\mathbf{4}$ |
| North of Smokey Fishermen <br> Association | N.S. | - Fixed gear abundance | $\mathbf{2}$ | $\mathbf{8}$ |
|  |  | Total | $\mathbf{1 6}$ | $\mathbf{5 7}$ |

The first type of project was designed to establish a mobile gear index of abundance of groundfish in the area. For the four projects in this category, two mobile gear vessels from each of the three Maritime provinces and Québec (total of eight vessels) fished at predetermined locations and times in traditional fishing areas (see Figure 17). These projects used the same design as in the one project conducted in 1994 (Sinclair et al. 1995). The fishing areas were identified in consultation with the fishermen involved in the projects. Prior to each trip, randomly selected fishing locations, within each area, were assigned to each vessel. Typically, 4 sets were assigned in each area. Each vessel conducted between 5 and 10 trips between July and the end of November. Vessels used a 145 mm square mesh trawl or seine, and 58 mm liners were used on some of the trips. Trawlers did a standard set of 30 minutes at 3.5 knots which is shorter than a regular fishing set, but seiners fished as they normally would in a fishery.

The second type of project was a distribution and migration study. In this project, two mobile gear vessels from N.B. conducted three snapshot surveys of the entire southern Gulf. The first survey was done at the end of July and early August, the second survey was conducted in September while the third survey started in mid-October. All sets were done using a 60 mm liner in the cod-end and lengthening piece.

The last type of project involved fixed gear fishermen fishing longlines to establish an abundance index. Ten lines of 250 hooks (Number 12 circle) were fished at predetermined fixed locations, once per week. Locations fished are also indicated in Figure 15.

### 3.5.2. Results

Total catches in the sentinel surveys amounted to 346 t . The mobile gear abundance projects caught 181 t , catches in the fixed gear abundance amounted to 44 t and the catches in the mobile gear migration and distribution project were 121 t .

As the abundance index projects were designed to show year-to-year changes, only the results from the N.B. project, which began in October, 1994, can be used to investigate changes from 1994-1995. A comparison of catch rates does not indicate a significant increase (Figure 18).

However, these results allowed us to make some observations in terms of distribution, since many of the vessels are fishing more than one area. Both the New Brunswick and Québec projects indicate that abundance was higher in Shédiac Valley than in the Baie des Chaleurs or along the Gaspé Shore. Abundance appeared to be low in the Souris-Cape George and the Mabou-North areas.

In terms of migration, catch rates declined along the Gaspé Shore in early October and in mid-October in the Shédiac Valley. Catches subsequently increased in the eastern section of the southern Gulf in late October consistent with the known migration patterns for this stock. A comparison of the length frequency of set 127 in the September 1995 groundfish survey and a set done by the sentinel survey in the same area and time (Wayne and Randy, set 1 , September 19) shows that the sentinel survey vessel also caught a significant quantity of small fish (Figure 19). Because of the different mesh size of the liners ( 58 mm in sentinel vs 19 mm in survey), only the larger fish were retained in the sentinel survey. This confirms that there were some small fish $(<35 \mathrm{~cm})$ in the area at that time.

Further analyses remain to be conducted on the data collected including more analysis of catch rates in both the mobile and fixed gear fisheries, length frequencies and spatial distribution. However, in general, the results of the 1995 sentinel survey corresponded to information from the research survey conducted in September.

## 4. Analysis Methods

### 4.1. Analysis of RV Data

### 4.1.1. Multiplicative Analyses

The RV mean numbers per tow at age were analyzed with a multiplicative model to obtain information on trends in recruitment and total mortality in the pre-recruit ages. The model was

$$
\ln \mathrm{A}_{\mathrm{ij}}=\beta_{0}+\beta_{1} \mathbf{I}+\beta_{2} \mathbf{J}+\varepsilon
$$

where
$A_{i j}=$ the RV index at age $i$ and year-class $j$
$I=$ a matrix of 0 and 1 indicating age
$\mathbf{J}=$ a matrix of 0 and 1 indicating year-class
Sinclair et al. (1995) reported that the southern Gulf RV survey gave consistent estimates of relative year-class strength for cod beginning at age 2 and continuing to age 12. Results for two groups of ages, 2-3 (pre-recruit ages) and 4-6 (recruiting ages) were analyzed separately. In addition, two analyses were performed for the ages 2-3 data, one including set 127 in 1995 and the second excluding this observation. The main effect vector for yearclass ( $\beta_{2}$ ) was interpreted as an index of relative year-class strength. The difference between the year-class effects estimated for the two age groups was interpreted as an index of total mortality of the respective year-classes. Inter-year-class differences in the mortality index were interpreted as differences in total mortality (see Sinclair et al. 1995 for details).

### 4.1.2. Analysis of covariance

An analysis of covariance of the RV survey results was used to investigate trends in total mortality of adult cod. In previous assessments, we used a multiplicative model similar to equation 1 to obtain this information. Analyses were conducted on data for ages 2-10 and on 5 -year moving windows of the dataset. The predicted least square mean catch at age from each analysis was taken to represent a catch curve for that period, with year-class effects removed. The slope of the catch curve from age 6-10 was used as an estimate of the mean total mortality for that time period. This year we have adopted a more parsimonious approach, in which only the fully recruited ages (6-12) are included in the analysis. The average total mortality for a time period is estimated as part of the model:

$$
\ln \mathrm{A}_{\mathrm{ij}}=\beta_{0}+\beta_{1} \mathrm{I}+\beta_{2} \mathbf{J}+\varepsilon
$$

where $\quad A_{i j}=$ the RV index at age $i$ and year-class $j$
$\mathrm{I}=$ a continuous variable indicating the age group
In this case the parameter $\beta_{1}$ is the slope of the catch curve, and is interpreted as the total mortality in the time period. This year we used a 4 -year moving window. The final time period included data from the 1992-95 RV surveys. The commercial fishery was greatly reduced in 1993, and closed in September of that year. Thus, the total mortality for this last time period should reflect a very low amount of fishing mortality.

### 4.2. Direct Estimates of Relative F

Sinclair et al. (1994, Section 7.2) described a new method for examining trends in fishing mortality using a relative estimate of fishing mortality obtained from the ratio of catch at age divided by the RV population estimates at age. The analysis was repeated here with the current data. The estimated relative $F$ at ages 4,7 , and 10 were plotted.

### 4.3. Sequential Population Analysis

This year we updated the SPA to include the years 1950 to 1970 in order investigate a longer time series of stock status. The last analysis of the data for this earlier period was by Maguire et al. (1983), and we used their data on catch and weight at age. While the 1971 to 1995 data include landings from the revised management unit (4TVn (Nov.-Apr.) and part of 4Vs (Jan.-Apr.)), the earlier data include landings only for 4TVn (Jan.-Apr.) and does not include $4 \mathrm{Vn}(\mathrm{N}-\mathrm{D})$. The sum of products of the earlier catch and weight at age matched the reported landings for this period in most years. However, they greatly exceeded the landings in 1954-55, 1958-59. The effect of these few years on the general patterns described below is minor. Nonetheless, these results are considered preliminary until the discrepencies can be resolved.

Two calibration methods were used for the SPA; ADAPT and Laurec Shepherd. Calibration affects terminal year population estimates and the estimates of the respective year-clases. Inclusion of earlier years (1950-70) in the SPA has no effect on the most recent population estimates since the SPA calibration includes only 1971-95.

### 4.3.1. ADAPT

The adaptive framework (ADAPT) (Gavaris 1988) was used as the basis for this year's SPA of southern Gulf cod. Two stock abundance indices were used, the RV results from 1971-95, and the commercial CPUE at age series for 1982-93 (see Sinclair et al. 1994). We used the same ADAPT formulation as last year (Sinclair et al. 1995). A temporal trend in the catchability of the CPUE indices was included in the following manner:

$$
\mathrm{U}_{\mathrm{ik}}=\left(\mathrm{q}_{\mathrm{i}}+\delta \mathrm{k}\right) \mathrm{N}_{\mathrm{ik}}
$$

where $\mathrm{U}_{\mathrm{ik}}=$ the CPUE at age i in year k
$q_{i}=$ the catchability at age I
$\mathrm{N}_{\mathrm{ik}}=$ the SPA estimate of numbers at age i in year k
$\delta=$ coefficient of a temporal trend in catchability
Secondly, the ADAPT formulation included a density-dependent catchability function for the RV survey indices in the form:

$$
A_{i k}=a_{i} N_{i k}^{b_{i}}
$$

where a and b are parameters describing the density dependent relationship. The ADAPT formulation is:

## Parameters

Terminal N estimates:
$\mathrm{N}_{\mathrm{i}, 1996}, \mathrm{i}=4$ to 13
Calibration coefficients:
$\mathrm{a}_{\mathrm{i}} \mathrm{i}=3$ to 10
$b_{i} i=3$ to 10
$q_{\mathrm{i}} \mathrm{i}=5$ to 12

Structure Imposed:
Error in catch at age assumed negligible
PR on ages 14 and 15 in $1994=1.0$
F on oldest age equal to average at ages $9-10$
$\mathrm{M}=0.2$
Input:
$C_{i k} \mathrm{i}=3$ to $15, \mathrm{k}=1971-1995$
$\mathrm{A}_{\mathrm{ik}} \mathrm{i}=3$ to $10, \mathrm{k}=1971-1995$
$\mathrm{U}_{\mathrm{ik}} \mathrm{i}=5$ to $12, \mathrm{k}=1982-93$
Objective function:
Minimize sum of squared residuals

Summary:

Number of observations:
200 from RV
96 from CPUE
Number of Parameters
35

### 4.3.2. Laurec Shepherd

The Laurec-Shephard calibration method was used for comparison with the ADAPT results. The method is implemented as part of the Lowestoft tuning package (Darby and Flatman 1994), and while the method is well suited for stocks with multiple tuning indices, it requires each index to have data for the terminal year. Consequently, only the RV results could be used here. The RV index from 1978-1994 and ages 3 to 12 was used. No special options (i.e. weighting, shrinking) were used. The fishing mortality on the oldest age was set at the arithmetic mean of the 5 previous age groups and full recruitment was assumed for ages 9 and over.

### 4.4. Yield Projections

Two types of yield projections were made. In the first, input parameters were assumed to have no errors and projections were made in a deterministic manner, similar to what has been done in previous assessments using the method described by Rivard (1982).

We incorporated information on the uncertainty of key projection parameters into a risk analysis in the second set of projections. By risk, we mean the probability of something undesirable happening as a result of a management action. The action is the catch in a given year. We have focused on two population state variables, F and spawning stock biomass (SSB, assumed to be age $5+$ ). F was chosen because the overall management strategy is to control fishing mortality. SSB is also important since low SSB was the main reason for closing the fishery for this stock. The Fisheries Resource Conservation Council (FRCC) has proposed criteria for re-opening fisheries which include an SSB level. In a recent discussion paper, they proposed re-opening the fishery when the SSB has increased to a level half way between the SSB when the fishery was closed and the long term average. We have estimated this to be approximtely 115,000 t and have included this in our analysis. It is important to note that this criterion is only a discussion point at present, we use it only for illustrative purposes. Risk was expressed as the probability that a) the SSB would decrease, $b$ ) that the SSB would be less than $115,000 \mathrm{t}$, and c ) that F would exceed 0.2 as a result of a range of yields in 1996 and 1997. The terminal year abundance estimates were assumed to be independent and lognormally distributed with mean and standard error corresponding to the analytical approximation results from ADAPT. This method was reviewed by the Statistics, Sampling and Surveys Committee in November, 1995 and is described by Sinclair and Gavaris (1996).

Two Monte Carlo simulations of a catch projection from the beginning of 1996 to the beginning of 1998 were performed. In the first, the 1996 and 1997 yields varied from $1,000 \mathrm{t}$ to $25,000 \mathrm{t}$ in $1,000 \mathrm{t}$ increments. Three hundred replicates were generated for each yield option and the frequency distributions of $F$ and biomass were used to quantify the probability that the reference $F$ and threshold biomass were exceeded. The same 300 initial 1996 population abundances were used for each yield level. In the second simulation, the

1996 yield was fixed at $2,000 t$ for all replicates while the 1997 yield varied from 1,000 to $25,000 \mathrm{t}$ in $1,000 \mathrm{t}$ increments.

## 5. Assessment Results

### 5.1. September RV Survey

The fit of the three multiplicative models was good. The total variance explained was between $87-91 \%$ (Table 13). The assumption of normal distribution of residuals was not violated.

Set 127 in 1995 had an important effect on the results of the age 2-3 analysis. If the set was included, the 1993 year-class was estimated to be above average in abundance, similar to the high values of the late-1970s and early 1980s (Figure 20). If this is the case, this year-class would make a significant contribution to the recovery of the stock. However, if set 127 was removed, the 1993 year-class was estimated to be of similar abundance to the below average year-classes of the late 1980s and early 1990s. If this is the case, the yearclass will not have a positive impact on stock recovery.

The age 4-6 RV mean numbers per tow in 1995 were virtually unaffected by the large catch in set 127, thus the inclusion or deletion of this set would have little effect on the results of this multiplicative analysis. The year-class effects from the analysis of the age 46 data indicate that the 1991 year-class is below average in abundance at these ages (Figure 21). The pattern for other year-classes is similar to that reported last year.

The trend in total mortality between ages 2-3 and 4-6 is similar to that reported last year. The estimate of relative Z for the 1991 year-class, the new observation this year, is similar to the three previous year-classes, and well below the estimates for the 1985-87 yearclasses (Figure 22). The difference in the relative Z indicates that the 1985-87 year-classes experienced, on average, a total mortality 0.75 greater than the three previous and four following year-classes. In the normal scale, this suggests that only half as many of them survived the recruitment phase as did the year-classes before and after.

The fit of the analyses of covariance to the age $6-12 \mathrm{RV}$ results were good. All analyses were highly significant and the slopes were all negative and significant (Table 14).

Total mortality peaked at about 0.8 in the early 1970s, then declined to 1979 to values less than 0.4 (Figure 23). Estimates increased to between 0.6-0.8 in the mid- to late- 1980s, then increased sharply to over 1.3 in the period 1989-92. Total mortality estimates have declined since then. The final analysis covered 1992-1995 and the estimated total mortality was about 0.5.

Provided the commercial fishery remains closed in 1996, this method may be used to estimate natural mortality for this stock. The September 1996 survey will be the fourth survey conducted in a period when fishing mortality will have been about as close to zero as possible.

This pattern in total mortality corresponds well with fishing mortality estimates and recent trends in fishing effort. Fishing mortality was low in the late-1970s when TAC's were
reduced on this stock. F was somewhat higher in the 1980 s, then increased substantially in the late-1980s to a maximum in 1991-92. With the closure of the fishery, F has declined substantially. We conclude that the pattern in total mortality shown in Figure 23 is driven largely by changes in fishing mortality.

### 5.2. Direct Estimates of Relative $F$

The relative fishing mortalities were very high in the early 1970s followed by a sharp decline at the time of extended fisheries jurisdiction in 1977 (Figure 24). The relative F was stable in most of the 1980s but increased sharply beginning in 1988 until a peak in 1992. With the closure of the cod fishery in September 1993 the relative $F$ dropped to the lowest level previously seen and with the continuance of the closure, the relative F declined further in 1994 and 1995.

### 5.3. Sequential Population Analysis

The fit of the ADAPT calibration was similar to that in last year's assessment. The exponents in the density dependent RV calibration model are greater than 1.0 for all ages except age 3 , suggesting that catchability is density dependent (Table 15). The linear trend in the CPUE calibration was positive and significantly greater than zero. The residuals for the RV observations were mainly negative for 1971-72, suggesting relatively low catchability in these years, the 1981 residuals were all positive suggesting catchability in this year was abnormally high, and there was a step increase in residuals in 1988 followed by a decline to 1993 (Figure 25). It is possible that the SPA results from the late 1980s and early 1990s are biased by under-reporting of catches and this could produce the residual pattern seen (Sinclair et al. 1995). The CPUE residuals increased from 1982 to 1992, the second last year in the series, then declined in 1993.

A retrospective analysis of the SPA F (ages 7-12) and N (ages $4+$ ) estimates from the ADAPT calibration indicated a relatively strong pattern where F's increased and $N$ decreased as more years are added to the analysis (Figure 26). However, the estimates in the last four years were much more consistent than those obtained for the late 1980s.

Fishing mortality, beginning of year population estimates, and beginning of year biomass estimates are given in Tables 16,17 , and 18 respectively. Beginning of year weights at age were estimated from the mid-year commercial weights (Table 8) using the approximations described by Rivard (1982).
.Diagnostics for the Laurec-Shepherd calibration indicate full recruitment to the survey at about age 5 (Table 19). The residual pattern is somewhat unbalanced with several negative residuals in the first few years (Table 20). Population numbers were the lowest in 1992 and appear to have only recovered slightly from this low level (Table 21). The estimates of year-classes produced in the 1990s are low, about $1 / 10$ of the 1980 year-class. The analysis suggests fishing mortalities in the range of 0.03 in 1995.

The 1996 population estimates from the Laurec Shepherd calibration were approximately $20 \%$ lower than the ADAPT calibration. This could be largely due to the use of a density dependent calibration relationship for the RV data in ADAPT, and a linear relationship in Laurec-Sheperd.
5.4. Abundance, Biomass, Fishing Mortality

Population abundance was relatively high in the 1950s, varying between 300 to 400 million (Figure 27). Abundance declined throughout the 1960s and reached a minimum in the mid-1970s of about 150 million. There was a sharp increase in abundance with the recruitment of strong year-classes born in 1974-75, and abundance reached a maximum of 500 million in 1983. This was followed by a continuous decline in abundance to 1993. The trend in total and spawning biomasses resembled that of abundance, except that the relative heights of the peaks in the 1950s and 1980s were reversed. Biomass was lower in the 1980s than the 1950s due to lower weights at age. With the closure of the fishery in 1993, the decline in abundance stopped and biomass is beginning to increase. Fishing mortality increased from about 0.3 in the early 1950 s to about 0.7 in the mid-1970s, with the exception of a value of 1.4 in 1959. F was low in 1977 and 1978, but increased again and averaged approximately 0.6 up to 1988 . Fishing mortality then increased to around 1.2 in 1992. Fishing effort was reduced markedly in 1993 with the closure of the fishery. The catch of slightly above $5,000 \mathrm{t}$ in 1993 resulted in a fishing mortality near the $\mathrm{F}_{0.1}=0.2$ reference level. The further decrease in effort in 1994 and 1995 resulted in declines in F to 0.03 and 0.01 respectively.

### 5.5. Recruitment

The increase in population abundance in the late 1970s was due to the appearance of the large 1974 and 1975 year-classes. These were followed by two more above average yearclasses, the 1979 and 1980, which supported the fishery through most of the 1980s.

The results of the RV analysis suggest that the 1985-87 year-classes experienced significantly higher total mortality than the three year-classes before and after. The most likely cause is increased exploitation in the late 1980s and early 1990s (Sinclair et al. 1995) and this significantly reduced their contribution to the commercial stock. It is important to note that SPA estimates of the sizes of these year-classes are probably biased in that they do not include discards (Figure 28). The close agreement between the age 2-3 index and the SPA recruitment estimates of more recent year-classes suggests that the discarding problem has been reduced. This corresponds with the period when minimum mesh sizes were increased (1992), and the reduction of fishing effort.

Year-classes produced in the late 1980s and early 1990s appear to be well below average in abundance. The September 1995 RV survey did find high numbers of age 0 cod, however, catches of this age group have never been used in a quantitative manner in this assessment. The survey also made one large set of age 1-3 cod in the Shediac Valley area. We recommend caution in interpreting this result because large numbers of similar aged cod were not found in other areas in September, or in the same area in the July juvenile survey. These fish will not be of a commercial size for another 2-3 years, and if they are indeed abundant, they should be found in future surveys.

### 5.6. Stock and Recruitment

A plot of the abundance of a year-class at age 3 vs the associated spawning biomass (age $5+$ ) from SPA indicates that the chances of having a poor year-class (less than 50 million) diminishes as the spawning biomass increases (Figure 29). The 1950-57 year-classes were all above 50 million, and the spawning biomass was over 200,000 t. The 1988-93 year-classes are all estimated to be below 50 million, and the spawning biomass has been below 200,000t. This relationship is not, however, without exceptions. The 1973-77 year-
classes were produced when the spawning biomass was relatively low, less than $120,000 \mathrm{t}$, and the 1979-80 year-classes came from moderate spawning biomasses.

Relative to the rest of the time series, the 1973-77, and 1979-80 year-classes were produced under particularily favorable conditions. The ratio of the number of recruits divided by spawning biomass has been used as an indication of the relative survival of a year-class during its juvenile period (Serebryakov 1990). We calculated the ratios from both the SPA and RV data. The latter were used as a check given the uncertainties of the SPA estimates of recruitment due to unaccounted for discarding. The RV ratios were calculated from the age 2-3 recruitment index (Figure 18) and the age $5+$ mean weight per tow. The latter was taken from the mean numbers per tow at age (Table 9) and the RV mean weights at age (Table 11). Both indices peaked in the mid-1970s (Figure 30).

### 5.7. Deterministic Projections

The input data for projections are given in Table 22 and were derived as follows. The begining of year 1996 population numbers at age were taken from the ADAPT calibration. The 1993 year-class age 3 abundance was set at 20 -million based on the recruitment index from the September survey. There is currently no information available on the abundance of the 1994 year-class, however its abundance was set at 20 million at age 3 since all recent year-classes have been in this range. These year-classes will contribute very little to catches and spawning biomass in 1996-97. Partial recruitment was derived from fishing mortalities in the period 1993 to 1995 from the ADAPT analysis with full recruitment at age 9. Beginning of year and mid-year weights at age in 1996-98 were calculated as the average from 1993 to 1995.

Deterministic catch projections were made for two yield scenarios. In the first, projections were made for a range of 1996 yields, and the spawning biomass in 1997 was calculated. The 1996 yield at $\mathrm{F}=0.2$ was approximately $16,000 \mathrm{t}$ (Figure 31). The resulting 1997 SSB was estimated to be $9 \%$ lower than the 1996. At a 1996 catch of 6000 t , the SSB remained the same. With no catch in 1996, the SSB was projected to increase by $5 \%$.

In the second scenario, the 1996 yield was assumed to be 2000 t . This level was chosen because there is a possibility that the 1996 yield will be higher than the 1995 yield due to expanded sentinel surveys. A 1996 yield of 2000t was estimated to generate a fishing mortality of 0.02 and the 1997 SSB was estimated to be $115,000 \mathrm{t}$, up from $111,000 \mathrm{t}$ in 1996 (Figure 32). The 1997 yield at $\mathrm{F}=0.2$ was $17,000 \mathrm{t}$, but the 1998 SSB would decline to $104,000 \mathrm{t}$ as a result. A 1997 yield of about $6,000 \mathrm{t}$ would result in no change in SSB between 1997 and 1998.

### 5.8. Risk Analysis

The standard errors for the 1996 population estimates were obtained from the ADAPT calibration, and the standard error for both the 1993 and 1994 year-classes was set at 20 million. When the 1996 yield was kept at $1,000 \mathrm{t}$, the probability that the 1997 SSB would be below the illustrative re-opening threshold was approximately $50 \%$ (Figure 33). The probability that the 1997 SSB would be less than the 1996 SSB increased from about $0 \%$ for a 1000 t 1996 catch to about $50 \%$ for a $6,000 \mathrm{t}$ catch, and to about $90 \%$ for a 12,000 t catch in 1996. The probability distribution for $F$ exceeding 0.2 was steeper than those for biomass, and it increased from $0 \%$ at a $13,000 \mathrm{t} 1996$ catch to almost $100 \%$ at an 18,000 t catch.

If the 1996 catch was held at 2000 t , and the 1997 catch varied, the probability was lower that the 1998 SSB would be below the threshold and that the 1998 SSB would decrease relative to 1996 than in the first simulation (Figure 34). The probability distribution of fishing mortality shifted to the left.

The choice of any particular catch level will reflect the risk tolerance of the decision maker. A risk neutral decision maker would choose the deterministic catch projection as the best strategy; there would be a $50 \%$ chance that the target F or threshold biomass would be exceeded, and they would not be interested in probabilistic catch projections. A risk averse decision maker would favor lower catches, wishing a lower probability of the target F being exceeded or of the biomass being below the threshold, for example $10 \%$. If such a decision maker wanted the SSB to exceed $115,000 \mathrm{t}$, they would not re-open the 1996 fishery, since at a 0 catch in 1996 there is a $50 \%$ probability that the biomass will be less than $115,000 \mathrm{t}$. A risk prone decision maker would favor a higher probability, let's say $90 \%$ for example. If such an individual was also interested in having the SSB $>115,000 \mathrm{t}$, but was willing to take a $90 \%$ risk that it wouldn't be, they would accept a 1996 TAC of about $14,000 \mathrm{t}$.

The probability distributions from these short term catch projections indicate a higher degree of certainty associated with statements about an F criterion in relation to catch than about a biomass criterion in relation to catch. The probability distributions of F are steeper and provide a relatively discrete range of catch to choose from. The probability distributions of biomass are shallower and cover a much larger range of catches. This is because F is much more sensitive to variations in catch than is stock biomass, especially in low F , short term projections.

This risk analysis is based on approximations and does not incude uncertainties in natural mortality, weight at age, and partial recruitment. However, it should provide rough guidelines.

### 5.9. Future Prospects

Prospects for a firm and steady stock recovery continue to be bleak. While some improvement in stock size has been noted in 1995, this was due mainly to a limited increase of adult cod biomass. This was only possible because of a very low level of fishing. Individual growth rates continue to be low and recruitment has not improved. Stock production continues to be low, even though the SPA estimates of spawning biomass are approximately $110,000 \mathrm{t}$, there is about a. $50 \%$ chance that a catch of $6,000 \mathrm{t}$ in 1996 would prevent any further increase in SSB.

## 6. Uncertainties

The main source of uncertainty in the assessment is the abundance of recruiting yearclasses, specifically the 1992-94 year-classes. The September RV estimate of these yearclasses was strongly influenced by one large set made in the Shediac Valley area, a known area of juvenile distribution. A sentinel survey vessel also made a large set of juveniles in the same area and time, but in both cases the area of distribution was restricted. The July juvenile survey did not find large numbers of these year-classes in the Shediac Valley area. The cod length frequency from the January, 1996 survey in the Cabot Strait had a mode
which corresponds to age 1-2 cod. However, this survey used the Campelen 1800 trawl which is thought to be more selective of small fish than the Western IIA trawl used on previous surveys in this area. Therefore it is difficult to interpret the January results. In any event, these year-classes will not be of commercial size for 2-3 years, and additional information on their abundance will be obtained on future surveys.

There are differences in opinion regarding stock status among fishers from the eastern and western portions of 4T. Fishers from P.E.I., Cape Breton, and from the Magdellan Islands indicated at several consultation meetings that cod are abundant and even increasing in abundance in their areas. They cite high incidence of cod by-catch in other fisheries, and high catches of cod in lobster traps. Fishers from Gaspé and northeast N.B. indicate that cod abundance is much lower than in the late 1980s and early 1990s, and they have not noticed increases in abundance. If one allows that fishers' perceptions of stock status may be more reflective of local conditions than of the total stock area, then the results from the September RV survey support the views of both the eastern and western area fishers. The surveys indicate that cod are distributed closer to shore in recent years, that cod are rarely found in the central part of the survey area, contrary to the early 1990s, and that the relative abundance of cod has increased in the eastern part of 4T (Swain 1996).

The difference in the length frequency distributions between observer and port samples is an important source of uncertainty in the assessment. The reason for the high abundance of larger cod in the observer samples relative to the port samples should be investigated.

## 7. Acknowledgements

We thank D. Swain for preparing the figures and text describing the spatial distribution of the RV catches of different aged cod in the 1995 September survey. We are grateful to G. Nielsen and C. LeBlanc for their comments on the manuscript.

10. Figures

Figure 1: Landings of southern Gulf cod, 1917-95.

Figure 2: Observer and port sampled length frequencies in 1995.

Figure 3: Trends in mean weights at age 5,7 , and $9(\mathrm{~kg})$ of southern Gulf cod from the commercial fishery (dashed lines) and the research vessel surveys (solid lines).

Figure 4. Set locations for the September 1995 groundfish survey (N230) conducted in the southern Gulf of St. Lawrence. The location of set 127 is indicated.

Figure 5: Annual length frequencies (mean numbers per tow at length) of southern Gulf cod from September groundfish surveys, 1971-95. In 1995, the dashed line includes set 127, the solid line does not.

Figure 6: Mean numbers per tow (ages $0+$ ) of southern Gulf cod from the September groundfish survey. Vertical bars give 2 standard errors.

Figure 7. Cod catches (kg) in the southern Gulf of St. Lawrence September groundfish surveys from 1990 to 1995.

Figure 8. Cod catches (kg) in 4 T and 4 Vn in the September 1995 groundfish survey

Figure 9: 1995 RV catches of age 0 cod.

Ages Ages 7,8+ 5,6
$5-10$

Figure 10: cont'd.

Figure 11: Comparison of mean numbers of cod per tow at age from the July juvenile cod survey and the September groundfish survey, 1990-1995. Two lines are shown for the 1994 juvenile survey, line 94 does not include a large set while 94 b does. Two lines are also shown for the 1995 September survey, 95 includes set 127, 95 a does not.

Figure 12: Cod catches (kg/set) in the January 1996 groundfish survey in Cabot Strait.
Open circles are set locations and dotted line is 200 m contours. Names refer to concentrations discussed in the text

Length (cm) / Longueur (cm)
Figure 13: Length frequencies of cod captured during the January 1995-1996 and September 1995 groundfish surveys.

Figure 14: Length frequencies of cod concentrations encountered during the January 1996 groundfish survey in Cabot Strait.

Figure 15: Seasonal change in condition index (carcass weight/length ${ }^{3}$ ) for southern Gulf of St. Lawrence cod of 40-50 cm between September 1991 and January 1996. Error bars give 2 standard errors.

Figure 16: Trends in annual condition factors for southern Gulf cod.

Figure 17: Areas fished by the abundance projects of the sentinel surveys program. Polygons are areas fished by the mobile gears and filled circles are areas fished by fixed gears. Areas fished by mobile gears were as follows: Quebec - Baie des Chaleurs, Gaspe Shore,Orphelins South and Shediac Valley; N.B. - Baie des Chaleurs and Shediac Valley; N.S. - Mabou North and Cheticamp; P.E.I. - Mabou north and Souris-Cape George.

Figure 18: Comparison of cod catch rates (kg/tow) for the one vessel involved in the 1994 and 1995 sentinel survey in the southern Gulf of St. Lawrence. Data are presented for sets with (L) and without (NL) a liner.

Figure 19: Comparison of length frequencies from the sentinel survey (Wayne and Randy, Set 1, September 19, 1995, Shediac Valley) and the groundfish survey (N230, set 127, September 20, 1995) in similar location and date.

Figure 20: Relative year-class strengths of southern Gulf cod shown as least square means from multiplicative analyses of September RV survey mean numbers per tow for ages 2 and 3. The solid line is from an analysis that excludes set 127 in 1995, the dashed line includes this set.

Figure 21: Relative year-class strengths of southern Gulf cod shown as least square means from multiplicative analyses of September RV survey mean numbers per tow for ages 4, 5, and 6. Vertical bars show 2 standard errors.

Figure 22: Trend in total mortality (relative) of the 1968-91 southern Gulf cod year-classes between the ages 2-3 and 4-6, estimated from September RV mean numbers per tow.

Figure 23: Total mortality ( Z ) estimates from separate multiplicative analyses of RV results which covered successive 4 -year intervals. Z was estimated for ages $6-12$. Vertical bars give 2 standard errors of the estimated slopes.

Figure 24: Estimates of relative fishing mortality for ages 4, 7, and 10 obtained directly from the ratio of catch at age divided by RV population estimates at age.

Figure 25: Residual patterns from ADAPT calibrations. The error bars indicate the 95\% confidence limits of the annual means.

Figure 26: Retrospective patterns in fishing mortality and population numbers from the ADAPT calibration.

Figure 27: Total (3+) and adult (5+) biomass ('000 t), total abundance (million) and fishing mortality (7-12) of southern Gulf of St. Lawrence cod. ADAPT was used for SPA calibration.

Figure 28: SPA (age 3) and research survey (age 2-3) estimates of recruitment. The solid squares are the research survey estimates.

Figure 29: Stock (SSB) and recruitment (age 3 numbers) plot for 4 TVn cod. The yearclass is labeled.

Figure 30: Juvenile survival rates, calculated as the ratio of year-class size (numbers) at age 3 and age 5+ SSB. Estimates from two independent sources are presented, SPA and RV results.

Figure 31: Deterministic catch projections for 1996 for southern Gulf of St. Lawrence cod. The graph presents the 1996 F (solid line) and the 1997 SSB as a function of the yield in 1996. The 1995 F and 1996 SSB are indicated by arrows.

Figure 32: Deterministic catch projections for 1997 for southern Gulf of St. Lawrence cod. The graph presents the 1997 F (solid line) and the 1998 SSB as a function of the yield in 1997. The 1996 F and 1997 SSB are indicated by arrows. The 1996 yield was assumed to be $2,000 \mathrm{t}$.

Figure 33: Risk analysis of a one year catch projection for southern Gulf cod. Three probability distributions are shown in relation to the catch in 1996: the probability that the 1997 spawning biomass is greater than 115000t; the probability that the 1997 spawning biomass will be greater than the 1996 level; and the probability that F will exceed 0.2 .

Figure 34: Risk analysis of a two year catch projection for southern Gulf cod. The 1996 catch was held constant at $2,000 \mathrm{t}$. Three probability distributions are shown in relation to the catch in 1997: the probability that the 1998 spawning biomass is greater than 115000 t; the probability that the 1998 spawning biomass will be greater than the 1996 level; and the probability that the 1997 F will exceed 0.2 .
