# Assessment of Georges Bank Yellowtail Flounder 

by

S. Gavaris, J.J. Hunt, J.D. Neilson and F. Page<br>Department of Fisheries and Oceans<br>Biological Station<br>St. Andrews, New Brunswick

${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte atlantique du Canada. Elle traite des problèmes. courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche-sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

#### Abstract

Yellowtail flounder (Limanda ferruginea) on Georges Bank is a transboundary resource which has supported a directed Canadian fishery since 1993. Removals of flatfish specified as yellowtail flounder peak $\in d$ in 1994, when 1328 t were landed. Under a newly introduced quota in 1995 , landings were 397 t . The fishery is mainly prosecuted by mobile gear. Landings of unidentified flounder were substantial in 1993 and 1994 and are thought to be mainly comprised of yellowtail flounder. There have also been reports of discarding in th s fishery.

To assess stock status, the most recent published US catch at age was used which included removals through 1993. Using US values for partial recruitment and estimated US total landings in 1994 and 1995, the US removals at age was updated for those years. The Canadian catch at age was constructed using Canadia 1 lengthfrequency samples and by applying seasonal USA age-length keys.

Biomass decreased rapidly from 1973 to 1985, associated with a marked decline in recruitment, reac ing the lowest observed level and has since only increased moderately fluctuating at about $5,000 \mathrm{t}$. Recruitr ent during the 1980s has been considerably poorer than that experienced during the 1970s. Only the 1987, 1990 and 199:2 yearclasses have been near average in the past decade. The exploitation rate on ages 4 and older has been very high, often exceeding $60 \%$ since 1973. Since the mid 1980s, the exploitation rate shows a modest declining trend, reaching the lowest observed level of about $40 \%$ in 1995. The exploitation rate on age 3 is often as high and somitimes higher than that observed on ages 4 and older. Maintaining the 1996 Canadian catch at about the 1995 Canadian allovation of 400 t should, if the USA target TAC of 385 t is not exceeded, result in a fishing mortality rate in 199 f approximating the $\mathrm{F}_{0.1}=0.29$.

## Résumé

La limande à queuc jaune (Limanda ferruginea) du banc Georges constitue une ressource transfronlalière à l'origine d'une pêche sélective canadienne depuis 1993. Les prélèvements de poissons plats identifiés comme étant des limandes à queue jaune ont atteint un maximum en 1994 avec des débarquements de 1328 tonnes. Par suite de la mise en vigueur d'un nouveau quota en 1995, les débarquements sont plassés à 397 tonnes. Les captures se font surtout au moyen d'engins mobiles. Les débarquements de limandes non identifiées ont été importants en 1993 et 1994; on pense qu'il s'agissait principalement de limandes à queue jaune. Des rapports signalent le rejet de poissons dans cette pêcherie.

Afin d'évaluer l'état des stocks, on a eu recours aux relevés publiés les plus récents des prises selon l'âge aux États-Unis où figuraient les prélèvements jusqu'en 1993 inclusivement. En prenant des valeurs du recrutement partiel pour les États-Unis et des évaluations des débarquements totaux de 1794 et 1995 dans ce pays, il a été possible de calculer l'importance des prélèvements américains pour ces années-là. La prise canadienne selon l'âge a été déterminée à partir d'échantillons canadiens de la fréquence des longueurs et grâce à l'application de barèmes saisonniers américains de longueur selon l'âge.

Entre 1973 et 1985, la biomasse a diminué rapidement. Elle était associée à un recul marqué au plan du recrutement, atteignant la plus faible valeur jamais observéc; depuis, clle ne s'est redressée c|ue modérément pour atteindre environ 5000 tonnes. Au cours des années 1980 , le recrutement a été considérablement inférieur à celui des années 1970. Seules les classes annuelles de 1987, de 1990 et de 1992 se sont approchées de la moyenne au cours des dix dernières années. Le taux d'exploitation des classes d'âge de 4 ans et plus a été très élevé, pour dépasser souvent la marque de $60 \%$ depuis 1973. Depuis le milieu des années 1980 , il a tendance à s'abaisser un peu, atteignant sa plus basse valeur observée, soit environ $40 \%$, en 1995. Le taux d'exploitation de la classe de 3 ans est souvent aussi đlevé, parfois plus, que celui des classes d'âge de 4 ans et plus. Le maintien des prises canadiennes de 1995 sensiblement au niveau attribué au Canada en 1995, soit 400 tonnes, devrait conduire à un taux de mortalité par pêche au Canada, pour 1996, de l'ordre de $\mathrm{F}_{0,1}=0,29$ si le TPA visé par les États-Unis, soit 385 tonnes, n'est pas dépassé.

## INTRODUCTION

Yellowtail flounder (Limanda ferruginea) occur on both the Canadian and USA sides of the international maritime boundary on Georges Bank. Based on tagging investigations (Royce et al. 1959; Lux 1963), the management unit is considered to include Georges Bank east of the Great South Channel encompassing statistical areas $5 \mathrm{Zj}, 5 \mathrm{Zm}, 5 \mathrm{Zn}$ and 5 Zh (Fig. 1). An earlier Canadian summary of stock status indicated that yellowtail flounder on the Canadian portion of Georges Bank could be the basis of a sustainable managed fishery (Anon. 1994a). This conclusion was based on the observation that yellowtail flounder are comparatively sedentary as adults, the presence of more than one year-class in the Canadian landings and the observation that spawning (which occurs in late spring ) is likely occurring in Canadian waters. However, the sources of recruitment and the degree of mixing across the international boundary are not clear.

A recent assessment conducted by the National Marine Fisheries Service, USA concluded that the stock was at low biomass levels, overexploited and was considered collapsed relative to historic abundance levels (Anon. 1994b).

## The Fisheries

The USA yellowtail fishery is almost exclusively conducted by vessels using otter trawl gear. USA landings were negligible prior to the mid-1930s, but landings increased to average 6,500 t in 1948-1949 (Anon. 1994b). After declining to $1,600 \mathrm{t}$ by 1955, landings recovered to a peak of $18,300 \mathrm{t}$ in 1969. Between 1968 and 1974, landings averaged $15,600 \mathrm{t}$ but more recently landings have averaged $2,060 \mathrm{t}$ between 1986 and 1995 (Table 1). The low landings since 1995 may be attributable, at least in part, to the recent expansion (both spatially and seasonally) of the haddock spawning closed area on eastern Georges Bank. Discarding of undersized yellowtail is considered a major contributor to overall mortality in the United States fishery, but quantifying the extent of discarding in recent years has proved difficult (Anon. 1994b).

The Canadian yellowtail fishery is also conducted almost exclusively by vessels using otter trawl gear. Prior to 1993, Canadian landings were small, typically less than 100 t (Table 1, Fig. 2). Peak landings of 1328 t of specified yellowtail occurred in 1994 in an unrestricted fishery, and after a TAC of 400 t was established, specified yellowtail landings dropped to 397 t in 1995. There was also a trip limit of $17,000 \mathrm{lb}$. imposed by industry in 1995 to equitably share the reduced quota among eligible participants. Actual removals in 1994 were thought to be considerably higher (according to some industry reports, 1800 t would be a reasonable estimate), as flatfish landed as "unspecified" were actually largely comprised of yellowtail flounder, with smaller quantities of winter flounder and American plaice. The unspecified flounder problem was thought to be less of a concern in 1995 due to improved monitoring of the landings. Assuming that the unspecified flounder is comprised of yellowtail flounder in proportion to the landings of yellowtail, winter flounder and American plaice, the adjusted total landings for yellowtail are shown below:

|  | Yellowtail <br> Flounder | Winter <br> Flounder | American <br> Plaice | Unspecified <br> Flounder | Adjuste <br> Yellowtail |
| :---: | :---: | :---: | :---: | :---: | :---: |
| 1993 | 152 | 21.3 | 0 | 620.1 | 696.0 |
| 1994 | 1328 | 64.6 | 29.5 | 871.3 | 2141.6 |
| 1995 | 397 | 45.2 | 2.3 | 109.7 | 495.0 |

Over the 1994-1995 period, there have also been some reports from industry of highgrading of landings by size to meet the 13 in minimum size requirement for USA importation. However, when we compared the length-frequency composition of samples taken by observers at sea with those obtained by port samplers, no indication of discarding was detected (Fig. 3), although. few samples were available for such comparisons. While industry reports that some discarding occurred, it was not possible to quantify discarding rate or whether the discarding rate has varied over the three year duration of the fishery.

The majority of Canadian landings of yellowtail flounder are made by less than 65 ft otter trawlers of tonnage classes 2 and 3 (Table 2). Peak months for fishing were August and September in 1994 and 1995. The number of vessels participating in the fishery was $z$ bout 55 in 1994, and dropped to about 40 in 1995 because of a requirement for participants to have a catch history of greater than 5 t of flounders. About half the fleet fished 140 mm square me:h in 1994, with one quarter fishing 130 mm square mesh and one quarter fishing 155 square mesh. By agreement among those participating in the 1995 fishery, only 155 mm square mesh was used. The same rigging of the foot gear was used in 1994 and 1995. Some yellowtail flounder are: landed in the scallop fishery. Industry representatives suspected that the reported landings of yellowtail flounder underestimate the true landings by that sector considerably. However, offshore scallop vessels are subject to $100 \%$ dockside monitoring and statistics should accu rately reflect their catch.

Location information was available for 84,97 and $98 \%$ of reported landings in 19931995, respectively. Canadian yellowtail directed fishing activity was concentrated on the southern half of Canadian waters, in the area referred to as the "Yellowtail Hole" (Fig. 4).The distribution of fishing activity changed somewhat from 1994 to 1995, with the area fished being more constricted in 1995, probably due to the reduced quota.

## Catch at Age

The assessment provided here represents the first attempt by DFO, Canada to provide an analytic assessment of this resource. Previous assessments of yellowtail flounder by NMFS, USA have not considered Canadian removals explicitly. For this assessment we compriled. the Canadian catch at age for 1993 to 1995. Data sources included Canadian port samples, and Observer Program (OP). Canada does not age yellowtail flounder at present, thus seasonal USA age-length keys were applied to the length composition of the Canadian catch.

The available data are somewhat limited to reconstruct the Canadian catch at age, particularly in 1993. In all, the following samples were used:

Port samples included length frequencies on a trip basis, whereas OP samples are length samples from individual tows where an observer was present. The OP length samples were obtained from 3,11 , and 5 trips for 1993 to 1995 , respectively.

The length-frequency samples from the OP were combined by trip, samples being weighted according to tow caught weight. The port samples and OP samples were then combined by month, gear type/tonnage class (OTB/TC1-3, OTB/TC4+ and dredge/all) being weighted according to trip caught weight, before being further combined by half-year and year. USA length weight relationships by quarter for sexes combined were used to conduct these calculations. In the case of miscellaneous gear (which included longline, gillnet, etc.) combinations were done on a half year basis rather than monthly. USA age length keys for sexes combined (available from surveys conducted in the spring and fall) were then applied by quarter and/or half-year to get catch at age. The impact of using combined age keys for a species with known sexual dimorphism was not investigated. Since the fisheries typically take place during the latter half of the year, agelength keys from the fall surveys were used. However, in 1995, there were samples from the spring (scallop dredges) available and the age-length key from the spring survey was employed in that instance.

Fig. 5 and the text table below illustrate the Canadian catch at age results.

| Age | Catch (000s) |  |  | Weight at Age (kg) |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 1993 | 1994 | 1995 | 1993 | 1994 | 1995 |
| 1 | 7 | 121 | 1 | 0.150 | 0.199 | 0.200 |
| 2 | 70 | 263 | 49 | 0.242 | 0.222 | 0.247 |
| 3 | 831 | 2847 | 529 | 0.344 | 0.311 | 0.333 |
| 4 | 835 | 1907 | 579 | 0.427 | 0.381 | 0.435 |
| 5 |  | 574 | 48 |  | 0.527 | 0.538 |
| 6 |  | 39 | 9 |  | 0.785 | 0.658 |
| 7 | 5 | 26 | 0 | 0.685 | 0.494 |  |

The Canadian fishery is mainly on ages 3 and 4, and there is no indication of an usually strong or weak year-class in the three years of data available. These results for Canada were combined with USA catch at age (Table 3), which show that strong year-classes included 1973, 1974, and 1980. More recently, only the 1990 year-class appears relatively strong but not as strong as the earlier notable year-classes. .

## ABUNDANCE INDICES

## Commercial Fishery Catch Rates

Catch and effort, in hours, for less than 65 ft Canadian otter trawlers fishing for yellowtail flounder in 1993-95 were summarized on a trip basis. Initial examination of the trip records showed a large proportion of trips with very small amounts of yellowtail included in the total catch. These trips were not considered to be representative of effort directed towards ye:llowtail and therefore only trips with reported landings of more than 100 kg ( 225 lb .) were considered further. As well, only vessels with reported landings in the three years 1993, 1994 and 1995 were included in the analysis.

As noted above, landings of unspecified flounder in 1993 and 1994 were substartial and the ratio of yellowtail to other flounders (plaice and winter flounder) in specified landings wes used to estimate the weight of yellowtail flounder for the unspecified proportion. A small number of trips included both yellowtail and unspecified flounder. Therefore, the combined yellowtail plus the yellowtail proportion of unspecified flounder trips were used to derive an alternate catch rate series.

Catch and effort for trips were aggregated by month and year in Fig. 6. Catch rate series are given for both specified yellowtail flounder only, and yellowtail flounder plus prorated unspecified flounder. Catch rates in 1993 increased between June and October. In 1994, ca ch rates were marginally higher than 1993 but increased by a factor of over two between 1994 and 1995. This is consistent with industry observations that rates doubled from about $500-1500 \mathrm{lb} . / \mathrm{hr}$ in 1994 to about $1500-2500 \mathrm{lb} . / \mathrm{hr}$ in 1995.

Substantial gear changes occurred in the fishery between 1993 and 1994 with the introduction of 'flounder gear' which uses a small diameter footgear. Changes in mesh size also occurred, as described earlier.
Factors, other than stock abundance, which might have influenced catch rates include:

| Factor | Likely Impact Over Time |
| :---: | :---: |
| Relatively new fishery, so some learning and development of fishing practices expected | Catch rates would tend to increase |
| Differential rates of discarding from year to year | Catch rates would either increase or decrease |
| Mesh size increased | In the short term, catch rates could decrease |
| Changes in areas fished from 1994 to 1995 | Impact not known |
| Fewer vessels involved in 1995, but may include more yellowtail "specialists" | Catch rates would tend to be higher in 1995 |

The likely impact of each of these factors was discussed and industry representatives commented that apart from the change in mesh size (which, as noted, would deflate catch rates in the short term), all other factors would not impact catch rates. They noted that catch rates from the yellowtail commercial fishery may be among the most reliable available for any fishery given the lack of diversity of vessels exploiting the resource, the circumscribed nature of the fishing area, and the short fishing season.

## Research Vessel Surveys

Bottom trawl surveys are conducted annually on Georges Bank by Canada in spring and by the USA in spring and fall. Both Canada and USA use a stratified random design, though different boundaries are defined (Fig. 7). The spatial distribution of catches of yellowtail flounder (by numbers and weight) from the Canadian surveys conducted each spring since 1987 are shown in Fig. 8. The resource is distributed generally throughout Georges Bank, but since 1993, the major concentration appears to occur on the Canadian side of the international boundary. Further investigation of seasonal and size/age related distribution patterns and migration is warranted.

The age sampling from the USA spring survey was used to obtain abundance indices by age from the Canadian survey and trends over time are shown in Fig. 9 (also Tables 4-6) for all surveys. USA age sampling is not available yet to apply against the Canadian 1996 results. Based on examination of previous keys, we assumed that all fish of lengths $20-31 \mathrm{~cm}$ were 2 year olds, and fish equal to or greater than 32 cm were included in the 3-6 index. While approximate, this approach allowed us to use the most up to date information available.

The USA survey mean number per tow at ages 3-6 declined to a low in the mid 1980s and has since tended to increase somewhat. The 1995 USA spring index shows a substantial increase over the previous year. The Canadian survey results for ages 3-6 support the apparent increasing trend since the mid 1980s. The mean number per tow at age 2 from the USA spring and fall surveys and at age 1 from the USA fall survey (lagged ahead 1 year) show a generally declining trend since 1963. There is some moderate increase in recent years but it is almost imperceptible compared to historical levels. The trend for age 2 abundance from the Canadian survey also indicates some improved recruitment in recent years, but it lacks a historical perspective. The relative year-class strengths appear to be generally consistent between and within surveys at ages 1 and 2 but the pattern weakens considerably for ages 3 and older.

The most recent US indices diverge, with the spring survey giving a more optimistic view of the resource than does the fall survey. The 1996 values for the Canadian spring survey were the second highest and the highest for age 2 and for ages 3-6 respectively.

## ESTIMATION OF STOCK PARAMETERS

The adaptive framework, ADAPT, (Gavaris 1988) was used to calibrate the sequential population analysis with the research survey results using the following data :

$$
C_{\mathrm{a}, \mathrm{y}}=\mathrm{catch}
$$

for ages $\mathrm{a}=2$ to 6 and for years $\mathrm{y}=1973$ to 1995 and

$$
\begin{array}{ll}
\text { for } \quad I_{\mathrm{s}, \mathrm{a}, \mathrm{y}}=\text { abundance index } \\
\mathrm{s}= & \text { Canadian spring survey, age } \mathrm{a}=2 \text {, years } \mathrm{y}=1986 \text { to } 1995 \\
& \text { Canadian spring survey, ages aggregated for } \mathrm{a}=3 \text { to } 6 \text {, years } \mathrm{y}=1986 \text { to } 1 \text { c, } 95 \\
& \text { USA spring survey, ages } \mathrm{a}=2 \text { to } 3 \text {, years } \mathrm{y}=1973 \text { to } 1995 \\
& \text { USA spring survey, ages aggregated for } \mathrm{a}=4 \text { to } 6 \text {, years } \mathrm{y}=1973 \text { to } 1996 \\
& \text { USA fall survey, ages } \mathrm{a}=2 \text { to } 3 \text {, years } \mathrm{y}=1973 \text { to } 1995 \\
& \text { USA fall survey, ages aggregated for } a=4 \text { to } 6 \text {, years } \mathrm{y}=1973 \text { to } 1995 \\
& \text { USA fall survey, age } \mathrm{a}=1, \mathrm{y}=1972 \text { to } 1995 \text { lagged ahead }
\end{array}
$$

The spring survey results were compared to beginning of year population abundance in the same year while the fall survey results were compared to mid- year population abundance in the same year. The USA fall survey age 1 results were compared to the beginning of subsequent year at age 2. The age analyses for the Canadian surveys used the age length keys from the USA spring surveys in the same year. The model formulation employed assumed that the error in the catch at age was negligible. The error in the survey abundance indices was assumed to be independent and identically distributed after taking natural logarithms of the values. Natural mortality, $M$, was assumed constant and equal to 0.2 and fishing mortality, $F$, for age 6 was assumed equal to the arithmetic average for ages 4 to 5 .

Following Gavaris (1993), a model formulation using as parameters the ln population abundance at the beginning of the year following the terminal year for which catch at age is available was considered. Define the model parameters as

$$
\theta_{a, 1996}=\ln \text { population abundance }
$$

for $\mathrm{a}=2$ to 6 at the beginning of the year 1996,

$$
\kappa_{s, a}=\ln \text { calibration constants }
$$

for each survey source, denoted by s, and the relevant ages.
ADAPT was used to solve for the parameters by minimizing the sum of squared differences between the $\ln$ observed abundance indices and the $\ln$ population abundance adjusted for catchability. Define the objective function for minimization as

$$
\underset{s, a, y}{\Psi}(\theta, \kappa)=\sum_{s, a, y}\left(\ln I_{s, a, y}-\kappa_{s, a}+\ln N_{a, y}(\theta)\right)^{2}
$$

For convenience, the beginning of year population abundance $N_{a, y}(\theta)$ is abbreviated by $N_{a, y}$. For year $y=1996$, the population abundance was obtained directly from the parameter estimates, $N_{a, 1996}=e^{\theta_{a, 198}}$. For all other years, the population abundance was computed using the virtual population analysis algorithm which incorporates the exponential decay model

$$
N_{a, y}=N_{a+1, y+1} e^{F_{a, y}+M}
$$

where the natural mortality $M$ is assumed and the fishing mortality $F_{a, y}$, for ages a $=2$ to 5 , is obtained by solving the catch equation using a Newton-Raphson algorithm

$$
N_{a, y}=\frac{C_{a, y}\left(F_{a, y}+M\right)}{F_{a, y}\left(1-e^{-\left(F_{a, y}+M\right)}\right)}
$$

The fishing mortality rate for age 6 was assumed equal to the average for ages 4 to 5 .
The magnitude of the residuals is large and there are some time trends for some indices which warrant further examination (Fig. 10). The USA spring ages 4-6 aggregated, USA age 2 fall and Canadian age 2 would be of particular concern. The residuals for the most recent year of observation are somewhat large, and are amongst the largest observed for 4 of the 9 series. The age 1 USA fall survey observation in 1989 resulted in a very large residual but that data point does not appear to be unduly influential. The variance and bias of population abundance estimates, survey calibration constants and corresponding projected yield were derived using an analytical approximation (Gavaris 1993). The population abundance estimates show a large relative error and substantial bias at ages 1 and 2 reflecting the variability in the abundance indices (Table 7).

The 1996 Canadian survey was not used in the assessment because an age length key from the USA survey for 1996 was not yet available. As an approximation, it was assumed that yellowtail between 20 and 32 cm were age 2 and those over 32 cm were age 3 or older and an exploratory calibration was attempted. The population abundance estimates for 1996 from this analyses were similar to those above except for the 1994 year-class which was estimated to be considerably greater.

|  | Age Group |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | 2 | 3 | 4 | 5 | 6 | 7 |
| without CAN 1996 | 3491 | 4628 | 3778 | 329 | 791 | 152 |
| with CAN 1996 | 14221 | 5151 | 4125 | 319 | 815 | 151 |

Given the poor fit for the Canadian age 2 series (Fig. 10), the results with the Canadian 1996 data included were not considered further.

## ASSESSMENT RESULTS

For each cohort, the terminal population abundance estimates from ADAPT were adjusted for bias and used to construct the history of stock status (Tables 8-10). In the absence of an unbiased point estimator with optimal statistical properties, this approach for bias adjustment was considered preferable to using the biased point estimates. The fishery catch weights at age were used to derive beginning of year weights at age for calculating beginning of year population biomass.

Biomass decreased rapidly from 1973 to 1985 , associated with a marked declire in recruitment, reaching the lowest observed level and has since only increased moderately fluctuating at about 5,000 t (Fig. 11). Recruitment during the 1980s has been considerably poorer than that experienced during the 1970s (Fig. 12). Only the 1987, 1990 and 1992 year-classes have been near average in the past decade. The biomass increased temporarily to abou: $10,000 \mathrm{t}$ in 1992 when the 1990 year-class recruited. The strength of the 1992 year class was estimaled to be about 10 million, making it amongst the highest since the 1980 year-class. The exp.oitation rate on ages 4 and older has been very high, often exceeding $60 \%$ since 1973 (Fig. 13). Since the mid 1980s, the exploitation rate shows a modest declining trend, reaching the lowest cbserved level of about $40 \%$ in 1995. The exploitation rate on age 3 is often as high and sometimes higher than that observed on ages 4 and older.

The assumptions regarding 1994 and 1995 USA catches, the low level of sampling for ages, uncertainties about discarding by USA and species mis-reporting by Canada, potential for unaccounted differences in growth between males and females and poor fit of the data in relationships between indices and population abundance, suggest that these assessment results should only be considered as rough indicators.

## PROGNOSIS

Commercial catch rates and the most recent survey observations suggest that a jundance increased between 1995 and 1996. The assessment results also reflect this trend but indicate that biomass is very low compared to historic levels. Recent recruitment has generally been pocr and exploitation rates have greatly exceeded common reference levels. The truncated age structure suggests that a rebuilding strategy should be followed. Though it was not considered appropriate to conduct formal yield projections, an illustrative calculation at $\mathrm{F}_{0.1}=0.29$ was done asing the 1995 beginning of year population numbers as estimated from ADAPT. The partial recruitment to the fishery for ages 2 and 3 was 0.15 and 0.5 respectively. The projected yield at $F_{0.1}=0.29$ in 1996 would be about $1,000 \mathrm{t}$ and the biomass was projected to increase. Maintaining the 1096 Canadian catch at about the 1995 Canadian allocation of 400 t should, if the USA target TAC of 385 t is not exceeded, result in a fishing mortality rate in 1996 approximating the $\mathrm{F}_{0.1}:=0.29$.

The uncertainty associated with model assumptions has been noted but the uncertainty arising from imprecision of the observed data is also considerable for this resource. To reduce the chances to less than $20 \%$ that the $\mathrm{F}_{0.1}$ reference is not exceeded, the combined Canada and USA
yield would have to be reduced to less than 700 t (Fig. 14). On the other hand, the chances are better than $50 \%$ that the biomass will increase in 1997 for yields up to about 1600t. For yields greater than 1600 t, the 1997 biomass is more likely to decrease.

The apparent relationship between abundance at age 2 and beginning of year biomass for ages 3 and older suggests that recruitment could be improved by rebuilding the spawning biomass. High levels of recruits were only observed when the biomass exceeded about 8,000 tons (Fig. 15).

Discarding of small yellowtail results in lost potential yield and contributes to the reduction of spawning biomass. Measures to avoid the capture of small yellowtail could considerably enhance the benefits from this fishery.

The reported quantity of unspecified flounder landings decreased in 1995, improving the quality of data. Further progress in this regard is strongly encouraged.

## ACKNOWLEDGMENTS

We thank the staff at NMFS in Woods Hole, Mass., in particular P. Rago, R. Mayo, L. O'Brien and R. Brown for their assistance in providing information from the USA surveys and fishery and for their participation in the review process. We are grateful to members of the fishing industry who took the time to discuss with us their experiences in the fishery.
