Anadromous rainbow smelt (Osmerus mordax Mitchill) from the Gulf of St. Lawrence update of fishery and preliminary status of stock
by

G. Chaput and C. LeBlanc<br>Dept. of Fisheries and Oceans<br>Science Branch<br>P.O. Box 5030<br>Moncton, NB<br>E1C 9B6

${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte atlantique du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

#### Abstract

Anadromous rainbow smelt (Osmerus mordax) is extensively fished commercially in Gulf New Brunswick, Gulf Nova Scotia and Prince Edward Island. The smelt fishery is a low capital investment, high return fishery which is localized in importance. The commercial fishery is regulated by season, gear, and license restrictions. The Gulf New Brunswick fishery is the largest, representing $76 \%$ of the total landings in the statistical districts of the Gulf of St. Lawrence. The maximum landing was recorded in 1932 at 3840 t and the long-term median landing is just over 2000 t annually. The fishery occurs in the fall (Oct. to Dec.) and winter (Jan. to March). The winter fishery is more important. The fishery is dependent upon two age-classes, age 2 and 3 years. Reduced abundance can not be directly inferred from the historical trend of decreased landings. Commercial fishers have indicated that the landings data are inaccurate and severely underestimate the harvests. Fishers attributed the poor fishery in the fall of 1994 to unusually warm water temperatures. Under current season restrictions, there is a substantial portion of the smelt stock which is not available to the fishery. It is unlikely that the present fishing levels in Miramichi Bay are over-exploiting the resource but the stocks in smaller bays may currently be exploited at substantially higher levels.

## RÉSUMÉ

L'éperlan arc-en-ciel (Osmerus mordax Mitchill) a fait l'objet d'un exploitation commercialà travers les régions du Golfe Nouveau-Brunswick, Golfe Nouvelle-Écosse et l'île du Prince-Edouard. Cette pêcherie nécessite un investissement capital minimal mais produit un rendement élevé d'une importance localisée. La pêche commerciale est réglementée par des restrictions de saisons, d'engin de pêche et de quantité de permis issus. La pêcherie du Golfe Nouveau-Brunswick est la plus importante et représente $76 \%$ des débarquements du sud du Golfe du Saint-Laurent. Le débarquement annuel maximum de 3840 t a été enregistré en 1932 et la médiane des débarquements annuels depuis 1917 se situe à juste au-dessus de 2000 t . La pêche se poursuit à l'automne (octobre à décembre) ainsi que durant l'hiver (janvier à mars) mais la pêcherie d'hiver est la plus importante. Les captures sont composés principalement de poissons âgés de deux et trois ans. On ne peut pas conclure que la tendance à la diminution des débarquements représente une diminution de l'abondance de l'espèce. Les pêcheurs ont indiqué que la base de données statistiques est incomplète et les débarquements sont sévèrement sous-estimés. Les pêcheurs étaient de l'opinion que des températures d'eaux supérieures à la normale ont contribué aux faibles débarquements enregistrée à l'automne 1994. Une grande proportion de la population d'éperlan n'est pas exploitée due à la présente réglementation qui limite la saison de pêche. Il est peux probable que le présent niveau de pêche dans la Baie de Miramichi surexploite la ressource mais les populations dans les estuaires de tailles inférieures à la Miramichi sont sans doute exploitées à des niveaux élevés.

## INTRODUCTION

Anadromous rainbow smelt (Osmerus mordax), abundant throughout the Atlantic provinces and Quebec (Scott and Scott 1989), has been extensively fished commercially and recreationally throughout Gulf New Brunswick (Gulf NB) and Gulf Nova Scotia (Gulf NS) and Prince Edward Island (PEI) since the turn of the century (McKenzie 1964). Until the mid 1960's, the commercial fishery of Miramichi Bay was the largest smelt fishery in eastern Canada (Chaput 1995). The smelt population and the fishery of Miramichi Bay was studied and described in detail by McKenzie (1964) and the following points are particularly important:

- smelt spawn in the early spring in the low gradient tributaries of both branches and the main stem of the Miramichi,
- smelt leave the estuary and are found outside the bay in the summer and early fall,
- smelt do not migrate far from their natal streams and distinct populations may be found in individual bays (Fréchette et al. 1983),
- the fishery only exploited part of the stock because a large component of the population only moved into the inner bay after the fishery closed,
- there was a decreased fishing effort, $-85 \%$ in the Miramichi Bay fishery between 1931 and 1963, and
- smelt are not long lived, maximum age recorded in the Miramichi samples was 7 years while the modal age in the fishery was 2 and 3 years.
Smelt are a comparatively small fish with modal fork lengths of about 13 to 15 cm in the spawning population (McKenzie 1964, Chaput 1995). In the Miramichi River, smelt have been estimated to make up the largest part of the anadromous fish spawning biomass (more than $50 \%$ and in the order of $10,000 \mathrm{t}$ ) and are the most abundant anadromous fish ( 100 to 300 million individuals) migrating into the river (Chaput 1995). Smelt larvae were the most abundant species in the Miramichi estuary in 1992 (Locke and Courtenay 1995).

The smelt fishery is a low capital investment, high return fishery which is localized in importance (McKenzie 1964, Chaput and LeBlanc 1991). Because of this, it has not attracted a large amount of research or assessment - for the most part, there have not been any requests from the industry to provide a stock assessment of this resource. With recent significant declines in the major groundfish stocks throughout eastern Canada, these coastal fisheries have the potential to become more heavily exploited.

The objectives of this document are:
1 - to present the landings of the smelt fishery from the Gulf of St. Lawrence, maritime provinces with emphasis on the Miramichi River and southeast Gulf New Brunswick districts,
2 - to present updated information on the size and age of smelt in the 1989 to 1991 fishery and compare it to the early 1960's data (McKenzic 1964), and
3 - to determine with industry the information and knowledge gaps which exist in the current databases and recommend how these problems can be remedied.
This document addresses in particular the smelt populations and fishery of Miramichi Bay and southeast New Brunswick (Fig. 1). Data from the Chaleur Bay smelt fishery and smelt populations are presented in d'Amours et al. (1994).

## DESCRIPTION OF FISHERIES

## Management:

The commercial smelt fisheries are regulated by season, gear and license restrictions. In Gulf New Brunswick, the commercial smelt fishery opens October 15 and closes at the end of February. Variation orders have been used to prolong the fishery into March. In recent years, when season extensions have not been granted, it was because of poor markets, and/or poor landings.

Effort is restricted by license. In Gulf NB, there were 859 smelt licenses issued in 1988, Gulf NS had 150 licenses and PEI had 419 licenses for fishing with boxnets, bagnets and gillnets (Cairns 1989, McKenzie 1964). Almost half of the licenses in Gulf NB are issued in districts 66 to 73 (Fig. 1), $25 \%$ are for the Miramichi Bay districts (70 to 73).

## Landings

Landings, summarized from purchase slip data, for the statistical districts in Gulf NB, Gulf NS and PEI for 1917 to 1994 are summarized in Table 1. During 1989 to 1993, smelt landings from the Miramichi River districts (70-73) averaged 304 t with the highest catch since 1917 occurring in 1924 at 1624 t (Table 1).

The fishery occurs in the fall (open water) and winter (under the ice) and although these are recorded as having occurred in different calendar years, the winter and preceding fall fishery is the more appropriate aggregation of the data. The winter fishery contributes the largest share of the season's catch in the central and southeast New Brunswick districts but the fall fishery is a significant proportion ( $>25 \%$ ) of the catch in the southeast New Brunswick districts (Fig. 2). In Miramichi Bay, the fall fishery was generally less than $10 \%$ of the catch before 1980 but since 1981, there have been large fluctuations and the fall fishery now contributes between 15 to $20 \%$ of the landings (Fig. 3).

The fall 1994 fishery in Gulf NB was poor; landings were $50 \%$ below the previous five-year average and $34 \%$ of the previous ten-year average (Table 2). A poor fishery in the fall of 1994 was attributed to unusually warm water temperatures although poor fall fisheries had occurred in the past as well (Appendix 1).

## TARGET

A conservation target exploitation rate or spawning stock biomass has not been defined for smelt.

## FISHERIES DATA

Samples from the commercial catches were obtained twice per month in the 1989 to 1991 fisheries. Selected fishermen kept samples of between 25 and 50 fish every 15 days in three main areas of the province: Northeast - Tracadie River, Central - Neguac and Loggieville area, and southeast - Richibucto and Shediac Bay. All fish were measured for fork length, and a subsample by length was sampled in detail for length, weight, sex, gonad weight, and scales were collected for ageing.

A catch-at-age was determined using age-length keys (one per area by fall and winter) and applied to the length frequency samples from the fishery. Length samples were not prorated by the
landings and the catch-at-age matrices were calculated as the proportion-at-age in each of the fisheries and seasons.

Logbooks were completed by a select group of volunteers in each of the three main areas during the 1989 to 1991 fisheries. Daily catches of smelt and the number and type of nets fished were recorded. The catch and effort data were used to calculate a catch per unit of effort ( kg of smelt per net day of fishing) assuming that this CPUE index would be representative of the stock size and/or availability in each area and season.

## RESEARCH DATA

Length and detail sample of post-spawning smelt were obtained at the Bartholomew River counting fence in May 1989. Incomplete counts of smelts passing downstream through the Bartholomew fence were obtained in 1988 and 1989. The counts are incomplete because the fence was installed in order to enumerate Atlantic salmon smolts and the spawning migration of smelt was occurring while the fence was being installed (R. Pickard, DFO, pers. comm.).

## ASSESSMENT RESULTS

## Age and size composition

In the Miramichi Bay (Loggieville and Neguac) samples, the fork length of smelt in the fishery increased from the fall to the winter in both 1989 to 1990 and 1990 to 1991 (Fig. 4). Only in the Tracadie River samples (district 68) did size decrease over the period of the fishery. The increased size of smelt in the Loggieville samples corresponded to higher catches of older smelt as the season evolved; in the fall of 1989, catches were mostly composed of 2 year old smelt, whereas in the winter of 1990, 2 and 3 year old smelt were abundant in the catch (Fig. 5). Females were significantly longer at age than males in both the fall and winter samples but size was similar between the two sampling seasons (Table 3). This was consistent for ages 2 to 5 years. These findings contrast with those of McKenzie (1964) who reported a noticeable decline in the size of the smelt during the course of the annual fishery, in part attributed to an increase in the proportion of younger fish but also from a decrease in the length and weight of fish within an age group.

In all the areas samples, age 2 and 3 year old smelt were dominant in the catches. The oldest smelt sampled were five years old (Fig. 5). Males were dominant in the younger age groups but sex ratios were more equilibrated or skewed towards females for the 4 and 5 year old smelt. This pattern was consistent in both the fall and winter samples.

|  | Age group (years) |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Season | 2 | 3 | 4 | 5 |  |
| Fall | $43(\mathrm{~N}=230)$ | $40(\mathrm{~N}=179)$ | $50(\mathrm{~N}=79)$ | $44(\mathrm{~N}=10)$ |  |
| Winter | $36(\mathrm{~N}=342)$ | $43(\mathrm{~N}=329)$ | $58(\mathrm{~N}=122)$ | $91(\mathrm{~N}=23)$ |  |

Skewed ratios towards males were also reported by McKenzie (1964) in sampling from the Miramichi River fishery, with females being predominant (54\%) in the age 5 years and older fish.

## Composition of the spawning run

In the samples of downstream migrating smelt at Bartholomew River counting fence in May of 1989 (Fig. 6) males outnumbered females by 3 to 1 . The female component was slightly older than the males with age 3 and 4 smelt being relatively more abundant in the female group than in the males.

|  | Age group (years) |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | 2 | 3 | 4 | 5 |  |
| \% female | $21(\mathrm{~N}=134)$ | $25(\mathrm{~N}=178)$ | $28(\mathrm{~N}=69)$ | $31(\mathrm{~N}=13)$ |  |

In samples of post-spawning smelt from the Black River counting fence (Kouchibouguac National Park, district 75), the modal length of smelt was 14 cm (1989 to 1992) and age 2 to 4 smelt were the most abundant (Delaney et al. 1993). Sex ratios of the spawning run of smelt were skewed towards males ( $66 \%$ to $78 \%$ ) in 3 of the 4 years sampled.

The predominance of males in the samples of downstream moving, post-spawning smelt, probably results from the extended duration of males relative to females on the spawning grounds (McKenzie 1964).

## Abundance indices of smelt

Catch rates of the commercial fisheries vary by month, season and area (Table 4). In the winter of 1991, the catch rates in the Miramichi were higher than in the other areas. Fall catch rates also tend to be higher in the Miramichi but were generally less than catch rates in the winter. For the Miramichi districts, the catch rates reported by the fishers in 1989 to 1991 ( 16.2 to 66.9 kg per net per day) are higher those reported by McKenzie for the 1951 to 1963 period ( 2.2 to 12.4 kg per net per day).

In 1988, the Bartholomew River counting fence was operational on May 5 and more than 260,000 smelts were counted through the downstream trap. In 1989, the fence was operational on May 20 and over 121,000 smelt were counted moving downstream. These counts are considered incomplete because smelt were observed moving downstream before the fence was operational in both years (Russell Pickard, DFO, pers. comm.). With more than 60 spawning brooks and streams in the Miramichi River (McKenzie 1964), we would expect the spawning stock of smelt to be in the order of 10 's to 100 's of million fish.

## Status of the stock

Reduced abundance can not be directly inferred from the trend of decreased landings since 1917. There have been large declines in licensed effort in Miramichi Bay since the 1940's (McKenzie 1964). Indications from the catch rates during 1989 to 1991 would suggest that abundance is higher
now than in the 1950 to 1960's. But high catch rates do not imply high abundance, especially if effort over the time series also varies. The fishery has been in the past and is presently dependent on two age-classes, 2 and 3 year old smelt.

During 1946-1947, there were more than 2400 trapnet licenses and the exploitation rate on the entire Miramichi stock was less than $5 \%$ (McKenzie 1964). The low overall exploitation rate was a consequence of a large component which remained outside the bay and moved upstream towards the spawning grounds after the fishery closed. At that time, the total stock of smelt in the Miramichi was estimated at more than 375 million fish (McKenzie 1964). The exploitation rate on fish available to the fishery was as high as $74 \%$ within Miramichi Bay (McKenzie 1964).

It is unlikely that the present fishing levels (jut over 220 licenses in Miramichi Bay) are overexploiting the overall resource: potential gear effort is about $10 \%$ of the effort during the first half of this century. Under current season restrictions, there is a substantial portion of the smelt stock which is not available to the fishery (McKenzie 1964) although the exploitation rate on smelt within the bay during the fishing season could conceivably also be very high. Commercial fishers feel that the fishing exploitation may be substantially higher in the smaller bays and rivers throughout the southern Gulf of St. Lawrence relative to that of Miramichi Bay.

## ECOLOGICAL CONSIDERATIONS

During the science workshop in January 1995, the fishers were concerned about changes in accessibility and water quality of the spawning streams. McKenzie (1964) had indicated that remedial measures should be taken to alleviate natural and artificial obstructions to migration thereby increasing the spawning habitat and post-spawning survival of spawners.

## FUTURE PROSPECTS

Forecasting future recruitment is difficult. McKenzie (1964) indicated that there was no apparent relationship between larval abundance and yield of the year-class since four of the five strong year-classes resulted from poor larval abundance estimates. Smelt have been frequently sampled during the annual (1988 to 1995) July juvenile groundfish survey in NAFO Division 4Tl (Shediac Valley, outside Miramichi Bay) (Mark Hanson, DFO Science, pers. comm.). The survey data could provide an indication of the age-classes, size and abundance of smelt which would be available to the fall and winter fisheries.

## RESEARCH RECOMMENDATIONS

1-The user groups expressed concern that the purchase slip landings data being used by DFO are inaccurate and severely underestimate the actual landings in all the statistical districts. There was also concern expressed that the district for which the landings are recorded are not necessarily the district where the smelt were caught. Although logbooks may provide an indication of the catch and effort of the participants, it was unlikely that all the fishers would complete these accurately. It was decided at the science workshop that a committee of fishers would meet monthly to collate the catches by all individuals in their area. These data should be a better indication of the true landings than the purchase slip and local sales estimates currently compiled by DFO. This was initiated in January 1995.

2 -The fishery should be sampled as was done in 1989 to 1991. Coverage should be extended to fishers fishing different locations within the same area because catches and sizes of smelt can vary spatially as well as temporally.

3 - The catch data from the 4 Tl juvenile groundfish surveys conducted in July should be analyzed and compared to landings in the Miramichi Bay, southeast New Brunswick areas to determine if abundance of smelt in the survey can be used to predict landings (i.e. abundance).

Minutes from the peer review conducted in February 1995 are presented in the report edited by Science Branch (1995).

Table 3. Analysis of season and sex effects by age (years) on fork length (mm) of smelt sampled from the commercial catches in October 1989 to March 1991 from the Miramichi Bay area. Fall represents the October to December samples, Winter represents the January to March samples. C.V. is the coefficient of variation, N is the sample size. P-values for the season effect, sex effect and the interaction between sex and season.

Table 4. Catch per effort in the smelt fisheries of northeast, central and southeast New Brunswick estimated from logbook reports, 1989 to 1991.

Figure 1. Statistical districts and locations referred to in text.

■- Dist 63-68 — Dist 70-73 — Dist 75-80

Figure 2. Proportion of the total fall (year i) and winter (year $i+1$ ) catch that was reported lanc during the winter fishery (January to March), within Gulf New Brunswick.

Figure 3. Landings by season (fall year i , winter year $\mathrm{i}+1$ ) and the proportion of the total landings reported from the winter season (January to March) in the Miramichi Bay smelt fishi 1968 to 1993.

Figure 4. Smelt fork length distributions by month and year sampled from three fishery locations in Gulf New Brunswick, 1989 to 1991. Vertical line represents the 5th to 95th percentile range, the rectangles are the interquartile range, and the solid lines join the median values. The sample size is indicated under each individual plot.

Figure 5. Length distribution and proportion at age of smelt sampled from the Loggieville fishery, 1989 to 1991. Box plots are interpreted as in Figure 4.

Figure 6. Size distribution by age of male and female smelt sampled from the downstream migrants at the Bartholomew River counting fence in May 1989.

## APPENDIX 1. STOCK STATUS WORKSHOP NOTES

Minutes of the science workshop on smelt of central and southeast New Brunswick, January 17, 1995.

## 1. Landings:

- Purchase Slips do not accurately reflect catch. Fish are often landed in one area and sold in another and sales are often not recorded on the day the catch occurs.
- Discussion on how to collect accurate catch statistics focused on the pros and cons of logbooks and other methods. It was decided that each assessment area would set up a committee of three participants in the fishery to collect and report on statistics once a month. Initially the reporting would be done at a meeting but once the system was in place it could be done by teleconference. Initial contact persons are Miramichi: Ken Clark and Alvin Scott, Richibucto: Jean-Guy Maillet, and Buctouche: Omer Duplessis.
- Logbooks could also be kept by interested individuals, but contact with the individuals should be done in person and on a one on one basis and not by mail or over the phone.

## 2. Fishery Data:

- In the winter fishery square box nets are used, in the fall fishery a mixture of bag nets and square box nets are used.
- It is important to collect samples, this could best be done by phoning individuals and asking them to keep part of their catch for samples.

## 3. Abundance:

- Exploitation rate may be lower than indicated by landings because many smelt move into the systems after the fishery is closed.
- It was decided that the major stock areas for abundance assessments from Miramichi south would be the Miramichi, Pt. Sapin to Richibucto, and Buctouche to the Border. Within these areas there could be subareas for sampling and gathering statistics. For example, the Miramichi would have four subareas, North Shore, Chatham, Loggieville, Neguac, and Baie Ste. Anne.
- Miramichi: North Shore Bay - fall fishery catches were down to lowest point but $90 \%$ of the fish were of large size. Water temperatures were high this fall and catches are not usually good when temperatures are high. Loggieville - Water temperature was too high in the fall, winter was stable but for the winter fishery catches in Chatham and Loggieville do not reflect abundance. Chatham - fall fishery was low. Baie Ste. Anne - winter was lowest since 1967.
- Richibucto: Dec. to mid. January there were few smelts and they were of a small size.
- Buctouche: catches are increasing and the size of the fish are increasing.
- Low catches in 1994 were the result of poor weather conditions and not low abundance. Fishing is poor right now because of bad ice conditions.

## 5. Multispecies Interactions

- Seals are increasing in all areas and often damage gear.
- It is difficult to release flounder in the winter and the reason for this measure needs further explanation.

## 6. Environment

- Cleaning the brooks to make smelt passage easier is needed in some areas.
- Pollution effects need to be considered and someone from MREAC or the Dept. of Environment, or Habitat Research should be invited to the workshop to address these issues next year.

## 7. Other Considerations

- The workshop should be held as soon as possible after the fishery is over. The first week in April would be suitable.

8: Participants:

Terry Comeau
Sterfing King
Brian Relly
Daryl G. Trevors
Allison Robichaud
Alvin Scott
Jean-Louis Gallant
Jean-Guy Maillet
Michel McIntyre Edmund Drysdale
Normand Allain
Gaetan Landry
Florence Albert
Bernard L. Dubee
Omer Duplessis
Gérald Poirier
Marc Gallant
