'This series documents the scientific basis for the evaluation of fisheries resources in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques sur la côte atlantique du Canada.
Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

#### Abstract

Herring in western Newfoundland are mainly caught by large and small purse seiners, and fixed gillnetters, although since 1988, the proportion of the total catch taken by the purse seines has ranged from 90 to $98 \%$. In 1994 and 1995, total landings were below $14,600 t$ due to the restrictions imposed on the capture of spring-spawning herring. The spring-spawner catch-rate and questionnaire data indicated that the mature biomass in the southern spawning grounds had dropped steadily since between 1987 and 1994, primarily due to poor recruitment over the last decade. The 1995 acoustic survey estimated a minimum biomass of $84,000 \mathrm{t}$ ( $38,000 \mathrm{t}$ of spring spawners and $46,000 \mathrm{t}$ of autumn spawners) with $64 \%$ of the herring biomass being surveyed in the two northern most strata. Both the spring- and autumn-spawning herring found along the coast were dominated by younger year-classes which have recruited to these stocks over the past five years. In 1995, the 1987 year-class was for the first time as important on the southern spawning beds as the 1980 and 1982 year-classes. Comments from inshore fishermen indicated a slight improvement in spring-spawning activity in Port-au-Port. The delayed opening of St. George's Bay and Port-au-Port Bay in 1995 had the desired effect of concentrating fishing on the autumn spawners, of decreasing the quantity of spring spawners in the total catch and of allowing the remaining fish to spawn undisturbed. Fishing effort must continue to be restricted in these areas until there are indications of significant improvement in this local component. We conclude that in general the 4R herring stocks are healthy, and a TAC of $22,000 \mathrm{t}$ of spring- and autumn-spawning herring outside closed areas would not be excessive.

## Résumé

Le hareng de la Côte Ouest de Terre-Neuve est principalement capturé par les grands et les petits senneurs, et les filets maillants, quoique depuis 1988, la proportion des captures totales prises par les senneurs (senne-bourse) se situait entre 90 et $98 \%$. En 1994 et en 1995, les débarquements totaux furent inférieurs à $14,600 \mathrm{t}$ dû aux restrictions imposées sur la capture des frayeurs de printemps. Le taux de capture des frayeurs de printemps et les données de questionnaires indiquent que la biomasse des géniteurs des frayères du sud a constamment décliné entre 1987 et 1994, principalement dû au pauvre recrutement des dix dernières années. Le relevé acoustique de 1995 a estimé une biomasse minimale de $84,000 \mathrm{t}$ ( $38,000 \mathrm{t}$ de frayeurs de printemps et $46,000 \mathrm{t}$ de frayeurs d'automne avec $64 \%$ de la biomasse de hareng se retrouvant dans les deux strates les plus septentrionales. Les deux groupes de fraie printemps et automne retrouvés le long de la Côte étaient dominés par de jeunes cohortes qui se sont jointes à ces stocks durant les cinq dernières années. En 1995, la classe d'âge 1987 fut pour la première fois aussi importante sur les frayères du sud que les classes d'âge 1980 et 1982 . Des commentaires des pêcheurs côtiers indiquent une légère amélioration de la fraie du printemps dans la région de Port-auPort. Le délai dans l'ouverture des baies St-Georges et Port-au-Port en 1995 ont eu l'effet désiré en concentrant la pêche sur les frayeurs d'automne, en diminuant la quantité de frayeurs de printemps dans la capture totale et en permettant aux poissons qui restent de frayer en paix. L'effort de pêche doit continuer d'être restreint dans ces zones jusqu'à ce qu'il y ait des indications d'une amélioration significative de cette composante locale. Nous concluons qu'en général les stocks de hareng de 4 R sont en santé, et qu'un TPA de $22,000 t$ de frayeurs de printemps et d'automne à l'extérieur des zones fermées ne devrait pas être excessif.

## Introduction

Atlantic herring (Clupea harengus L.) are found throughout the waters of the northwest Atlantic Ocean from Labrador to Cape Hatteras. In Canada, they are fished mainly within the Gulf of St. Lawrence, in eastern and southern Newfoundland, and in southwestern Nova Scotia and the Bay of Fundy. The herring is a migratory species which, over the course of a year, will travel extensively throughout its stock range from spawning grounds, to feeding and overwintering areas. These migration patterns are repeated year after year with considerable regularity. They are found nearshore in the spring and fall where they congregate around traditional spawning beds to reproduce. They also typically assemble in large concentrations in the late fall in preparation for their departure to over-wintering areas where the water temperatures are more stable.

Within most of the distributional range of northwest Atlantic herring, including the west coast of Newfoundland (NAFO Division 4R) we can find populations which spawn either in the spring (April to June) or in the autumn (July to October). Each seasonal-spawning population is considered to be a separate stock for fisheries management. In addition, within each seasonalspawning stock, there are local spawning components associated with specific spawning areas. Examples of spring-spawning components can be found in St. George's Bay, Port-au-Port Bay and St. Paul's Inlet (Figure 1). The interrelationship between these local components has yet to be clearly established, although most evidence suggests that once an individual spawns in a given area, it will return to spawn in that area year after year (Blaxter 1985). Therefore, the repeat spawners of a local spawning component are subject to over-exploitation if fishing effort is concentrated on them disproportionately to the rest of the stock. Furthermore, a local component may not rebuild at the same rate as the overall stock if the recruitment to that component is not in proportion to the overall recruitment to the stock.

The major spring-spawning areas are located at the southern end of the coast in and around St. George's Bay (4Rd) and Port-au-Port Bay (4Rc) although several other spawning sites are known along the coast towards the north. Mature herring arrive and spawn in these areas from the end of April to the middle of June before dispersing. Autumn spawning is concentrated mainly north of Point Riche (4Ra) from mid-July to mid-September (Figure 1). At other times of the year, these two spawning stocks are mostly found in mixed schools in either feeding or overwintering areas. The major feeding areas, i.e. off St. George's Bay in the spring, north of Point Riche and in the Strait of Belle Isle in the summer and off Bonne Bay in the fall, are associated with concentrations of copepods (red-feed) and/or euphausiids (krill) which are their main food items. They are believed to overwinter in the deeper waters of the Esquiman Channel (Figure 2).

## Description of the Fishery

## Management Plan

Total allowable catches (TAC) have been in effect since 1977. Since 1981, 45\% of the TAC has been allocated to the fixed gear sector and $55 \%$ to the mobile gear sector. In addition, the purse
seine quota has been allocated proportionately among the half-dozen active vessels and the gillnet allocation has been divided evenly between the regions north and south of Cape St. Gregory. Since 1989, an additional inshore allocation has been made for the small-purse-seine fishery. The allocation for this gear sector has come from the inshore (fixed gear) quota and was increased from 2,000 to 4,800 t from 1989 to 1994.

Since 1987, the advised target fishing level has been exceeded only in 1991 (Table 1; Figure 3). In 1994, a cap of $5,400 \mathrm{t}$ of spring spawners was imposed as a conservation measure for the spring-spawning stock. In 1995, this spring-spawner cap was lifted, in favour of a delayed opening (June 1) of St. George's Bay and Port-au-Port Bay to fishing to protect these local springspawning components in accordance with the recommendations of-the west coast Herring Comanagement Group (McQuinn and Lefebvre, 1995a).

## Total Catches

Herring catches in western Newfoundland are mainly taken by large purse seiners ( $>85^{\prime}$ ), by small purse seiners ( $<65^{\prime}$ ) and to a much lesser extent by fixed gillnetters from April to December on both spawning and overwintering concentrations. Since 1988, the proportion of the total catch taken by the purse seines has ranged from 90 to $98 \%$ (Figure 4).

Over the past decade, total 4 R herring landings have increased from a low of $10,500 \mathrm{t}$ in 1984 to a peak of $21,400 \mathrm{t}$ in 1986 (Figure 3, Table 1) and have ranged between $15,300 \mathrm{t}$ and $26,400 \mathrm{t}$ from 1987 to 1993. In 1994 and 1995, total landings were below $14,600 \mathrm{t}$ due to the restrictions imposed on the capture of spring-spawning herring.

## The Purse Seine Fleet

From 1984 to 1987 , up to $80 \%$ of the purse seine catches were taken in areas 4 Rb and 4 Rc from October to December from over-wintering concentrations of herring (Figure 5a). From 1988 to 1993, the purse seine fleet had redirected its fishing effort towards the spring fishery in St. George's Bay and Port-au-Port Bay, leading to a considerable increase in landings from 4Rc and 4Rd (Table 2a), from approximately $2,000 \mathrm{t}$ in 1987 to $16,000 \mathrm{t}$ in 1991. This spring fishery in the St. George's Bay/Port-au-Port area accounted for $71 \%$ of the total purse seine catch in 1993 (Figure 6). This proportion dropped to $20 \%$ in 1994 due to a cap of $5,400 \mathrm{t}$ on spring-spawning herring but increased again to $40 \%$ in 1995 when the cap was lifted.

Concurrent with changes to the fishing pattern of the large purse seiners has been an increase in the activity of the small ( $<65^{\prime}$ ) purse seiners along the west coast since 1989. Annual landings from this gear sector had not exceeded $800 t$ until 1992, when they landed 2,200 t. From 1993 to 1995, this fleet has landed from $3,100 \mathrm{t}$ to $3,800 \mathrm{t}$ per year.

In 1995, purse seine fishing was concentrated around Cape St. George and northwest of Cape Anguille in May (Figure 7). Fishing activity then moved towards the Bay of Islands in June as in 1994 (McQuinn and Lefebvre 1995a). In the late fall herring schools were less concentrated than in previous years and fishing was much more spread out along the southern part of the coast. As in 1994, relatively good catches were again recorded in St. George's Bay in October, as well as in St. John Bay in November.

## The Gillnet Fleet

The inshore gillnet fishery is predominantly oriented toward supplying bait for the active lobster fishery. This has meant that recorded landings from 1990 to 1994 have ranged between only 140 and 840 t (Table 2b). There was a slight improvement in 1995 as landings increased to $1,250 \mathrm{t}$.

From 1979 to 1989, almost equal proportions of the total gillnet catch were taken from the south ( 4 Rd and 4 Rc ), and from the north ( 4 Ra and 4 Rb , Figure 5 b ). A late fall fishery has also occurred sporadically in areas 4Ra to 4Rc throughout this period. Since 1990, gillnet landings in St. George's Bay and Port-au-Port Bay have been minimal (Table 2b). In 1994 and 1995, there was a slight resurgence in landings from the summer 4Ra fishery.

## Biological Characteristics

## Data collection and Analysis

Random samples covering most of the major commercial landings were collected by port samplers and by index gillnet fishermen (Annex 1). These samples were frozen and sent to the Maurice Lamontagne Institute (MLI) in Mont-Joli, Quebec for analyses (i.e. length, weight, gonad weight, maturity stage and age determination).

Individual herring were assigned as either spring or autumn spawners by relating the maturity stage, estimated from a gonadosomatic index model (McQuinn 1989), to the date of capture, using the 4R maturity cycle chart (McQuinn 1987a). In the case of immature fish, otolith characteristics were used as described by Cleary et al. (1982). Ages were determined from the otoliths by counting the number of winter rings for spring spawners and the number of winter rings plus one for autumn spawners (Cleary et al. 1982). All herring aged 11 years or more were aggregated into an 11+ age-group. As in previous years, the 1995 catch at age was generated (CATDAGE vl.0, Anon 1986) for spring and autumn spawners as described by McQuinn (1987b), weighing the age compositions by the corresponding landing as grouped in Annex 1.

## Spawning Stock Proportions

The proportion of each spawning stock in the catches varies among areas and seasons, as well as between the inshore and the offshore, as shown by differences between the gillnet and purse seine samples. In the spring (May and June), herring schools fished by gillnets in and around the major bays in the south near the spawning beds are typically dominated by spring spawners (Table 3). The autumn spawners are more prevalent in deeper waters outside of St. George's Bay or north of Cape St. George in 4Rc as seen in the purse seine catches (Figure 8, McQuinn and Lefebvre 1994, McQuinn and Lefebvre 1995b). In the summer and fall (July to September), catches are mostly autumn spawners towards the north around the major autumnspawning grounds (Table 3) and are mixed in the southern regions (Table 4). In the late-fall purse seine fishery (October to December), catches are a mix of spring and autumn spawners, although again there is a predominance of autumn spawners towards the north (Figure 8).

Spring spawners have dominated the catch in every year since at least 1973 (Table 5), averaging $72 \%$ in numbers. This percentage increased to over $80 \%$ between 1988 and 1990 due to the active spring fishery in St. George's Bay, which exploited mainly spring spawners nearshore (Table 4). With the 5,400 $t$ cap on the TAC of spring spawners in 1994 and the delayed opening of St. George's Bay to commercial fishing in 1995, the percentage of spring spawners in the total catch has decreased to under $60 \%$.

## Age Composition

Since the mid-1980's, the 1980 and 1982 spring-spawner year-classes have been important contributors to the total catch (Table 5, Figure 9). In 1991, the 1987 year-class recruited strongly to the purse seine fishery (Table 6a). Since 1993, the 1989 year-class has increased in importance in the overall spring-spawner catch. However since 1994, it has become more and more difficult to distinguish these latter year-classes in the catch at age (Table 6a). This has lead us to suspect an error in the age attribution in the past couple of years. The distinction of the winter annuli seems to have degraded since 1992 or 1993 when these herring stocks were exposed to colder annual temperatures (Gilbert et al., 1996). In this respect, the length frequency data appear more reliable, and it is easier to follow the major year-class with these data (Figure $9)$.

McQuinn and Lefebvre (1995b) noted that the 1987, 1989 and 1991 spring-spawning year-classes were more abundant in the fall fishery in the more northerly areas and were of only minor importance on the southern spawning grounds in the spring. In 1995, these recruiting yearclasses were seen in the purse seine catches outside of St. George's Bay in the spring and all along the coast in the fall. Biological samples supplied by the index fishermen in St. George's Bay (4Rd) and Port-au-Port Bay (4Rc) showed that in 1995, the 1987 year-class was for the first time as important on the spawning beds as the 1980 and 1982 year-classes (Figure 10).

Since 1983, the 1979 autumn-spawning year-class has been the most important contributor to the fishery from this stock and is still dominant in some areas (Figure 11). Since 1990, the 1986 year-class has strongly recruited to the autumn-spawner purse-seine catch (Table 6b), but only became a significant contributor to the gillnet fishery in 1992 (Table 7). Since 1992, the 1988 year-class has also contributed significantly to the total autumn-spawner catch, with the 1990 year-class also appearing to be above average in recent years. These three year-classes have gradually increased in importance in the gillnet fishery since 1992.

## Abundance Indices

## Acoustic Surveys

Fall acoustic surveys have been conducted biannually since 1989. The 1995 survey was undertaken in close collaboration with the west coast large seiner fleet (McQuinn and Lefebvre, 1996). A scientific staff was invited aboard each of four purse seiners over a two week period to take temperature and salinity profiles and to collect biological samples while our research vessel, the Frederick G. Creed, collected the acoustic data.

The 1995 acoustic survey estimated a minimum biomass of $84,000 \mathrm{t}(38,000 \mathrm{t}$ of spring spawners and $46,000 t$ of autumn spawners) with $64 \%$ of the herring biomass being surveyed in the two northern most strata (Strata 9 and 10). The distribution of herring in the remaining strata was similar between 1993 and 1995, even though the survey was conducted three weeks earlier in 1995.

An additional acoustic survey was conducted in the first week of May, 1995 aboard the CSS Teleost (Figure 12). This survey was undertaken during a single night to locate schools of autumn-spawning herring outside of St. George's Bay (the bay itself was closed to commercial fishing). The survey area was defined from information supplied to us by purse seine operators fishing in this area as well as from our own explorations. In addition, a purse seine captain, Mr. John Hackett, was aboard the Teleost to assist in the design of the survey. This survey estimated the presence of approximately $12,400 \mathrm{t}$ of herring ( $8,000 \mathrm{t}$ of autumn spawners and $4,400 \mathrm{t}$ of spring spawners) within a $390 \mathrm{~km}^{2}$ area (Table 8). These herring were concentrated into schools in the mid-water ( $160-200 \mathrm{~m}$ ) and were dominated by older ( 1979 year-class) fish. Most of the spring purse seine fishery was localised on these schools. Other herring schools were seen northward along the coast during that same week, although their abundance and composition were not estimated.

## Index-Fisherman Logbook Data

Abundance indices were estimated for both spring and autumn spawners from detailed logbooks of daily catch and effort compiled by index gillnet fishermen since 1984 (Table 9 and 10) and standardized using a multiplicative model (Gavaris 1980). The categorical variables for this model were year, month and fishing site, and were chosen to account for spatial and temporal variability (Table 11 and 12). Prior to these analyses, catches were proportionately allocated to spring and autumn spawners using the percent spawning-stock composition as determined from the commercial samples (Table 4). Most of these fishermen set their nets in the vicinity of either the major spring-spawning sites in the St. George's Bay/Port-au-Port area (McQuinn and Lefebvre 1995a) or the autumn-spawning areas north of Point Riche.

The standardized spring-spawner catch rates indicated that the 1987 year-class was above average, but not sufficiently abundant in the southern bays to rebuild this local spawning component given the heavy fishing effort exercised on it in the early 1990s. This catch-rate index declined again in 1995 to its lowest historical level (Figure 13a; Table 13).

The 1986 autumn-spawning cohort appeared quite strong in the index-fisherman catch rates in 1992 and seemed at that time to be well above the 10 -year average (Figure 13b). However, it declined sharply in 1992 and 1993 and has now stabilised at a low level. Although this catch-rate index seemed to reflect the strong recruitment of the 1986 year-class, its sharp decline was unexpected given the low fishing effort on the autumn-spawning stock. In addition, the recent recruitment of the 1988 year-class has not been reflected in the index, which puts in doubt its usefulness as a measure of abundance. It is possible that this index is more a reflection of a change in availability, since it is known that autumn herring spawn farther offshore and are less available to inshore fixed gear than are the spring spawners.

## Industry Input

Comments collected from written questionnaires sent to all licensed inshore herring fishermen in 4R (Table 14) as well as from our index fishermen indicated a slight improvement in spring-spawning activity in 4Rc. The index fishermen noted that in several areas, notably around Port-au-Port Bay, the main spawning period was again later than usual this year, i.e. first of June. This period corresponds to when the 1987 year-class was dominant in the samples and when the catch rates were the highest for the season. However, in St. George's Bay, spawning activity was again quite weak this year, and consisted mainly of a mixture of older (1980 and 1982 year-classes) and younger (1987 year-class) fish (Figure 10). This suggests that the 1987 year-class has not replaced the 1980 and 1982 year-classes in St. George's Bay, as it has done elsewhere, and therefore cannot be counted upon to rebuild this spawning component. The 1989 year-class, which has been captured in the fall gillnet fishery since 1994, has yet to be seen in large numbers in these southern bays. These observations are consistent with the catch rate data from index-fishermen in these areas.

North of Point Riche in 4 Ra , the general opinion is that the abundance of herring is average to good especially in the summer and fall (Table 14). Spawning in the fall was noted mainly around Ferolle Point, but was not considered by our index fishermen to be extensive in this area nor around Forresters Point. They suggested that unfavourable winds from the southwest which dominated the season had moved the autumn herring offshore into deeper water, where they were less available to their gear.

Comments from the purse seine logbooks suggested that there was an abundance of herring along the coast throughout the year, but that they were often difficult to catch (Figure 14). In the spring, the herring outside of St. George's Bay were assembled into schools but were often too deep to fish ( $160-200 \mathrm{~m}$ ). In the fall, the herring were found in shallower water, but were generally too thinly aggregated and too close to the bottom for purse seining. Both of these observations were confirmed during our two acoustic surveys.

## Discussion

## Spring Spawners

The minimum spring-spawning stock biomass of approximately $38,000 \mathrm{t}$ from the 1995 fall acoustic survey was an increase over the 1993 estimate of $31,000 \mathrm{t}$ of spring spawners. However, McQuinn and Lefebvre (1995c) considered the 1993 estimate to be low since two northern strata were not surveyed due to bad weather, and fishing activity at that time confirmed the presence of herring schools in these strata.

The spring-spawner catch-rate data indicated that the mature biomass in the southern spawning grounds had dropped dramatically in 1993, primarily due to (1) the lack of strong recruiting year-classes to this area over the past 10 years combined with (2) the concentration of fishing effort on this local spawning component between 1989 and 1993. In 1995, this catch-rate
index suggested that this major component of the spring-spawning stock continued to be at a very low level.

Comments received from index fishermen and from the written questionnaires suggest little improvement over 1994 in St. George's Bay, although there are signs of more intensive spawning by the 1987 year-class around Port-au-Port Bay.

The present analyses support last years' conclusion (McQuinn and Lefebvre 1995a) that special measures must be taken to protect the spring spawners components in St. George's Bay and Port-au-Port Bay. The delayed opening of these bays in 1995 had the desired affect of concentrating fishing on the autumn spawners, of decreasing the quantity of spring spawners in the total catch and of allowing the remaining fish to spawn undisturbed.

## Autumn Spawners

The 1995 acoustic survey results placed the minimum autumn-stock biomass at $46,000 \mathrm{t}$, the majority of which were located in the northern strata, and are normally not heavily fished. These herring were not formed into schools, but rather were in a relatively thick, dense layer close to the bottom (McQuinn and Lefebvre 1996). Although the 1993 estimate was considerably lower ( $35,000 \mathrm{t}$ ), as stated earlier, this survey undoubtedly underestimated a significant portion of the stock since commercial catch data showed that herring were in the two unsurveyed northern strata in 1993.

The logbook catch-rate data indicated strong recruitment by the 1986 year-class in 1992, although the index has declined sharply since then. This trend is in contradiction with other indices which show this stock to be in relatively good condition (1) the fall acoustic survey estimate of at least $46,000 \mathrm{t}$, (2) the light exploitation of this stock over the past decade, i.e. less than $28 \%$ of the total catch and (3) responses to a written questionnaire indicating that the situation with this spawning component north of Point Riche is relatively good but that the market for gillnetted herring is very limited. It is quite possible that the index-fisherman catchrate series has become less reliable due to (1) a decrease in participation in the program (only three logbooks per year in 1992, 1994 and 1995) and (2) the decrease in availability to inshore gillnets as the herring have moved farther offshore (McQuinn and Lefebvre 1994).

## Prognoses

## Northern Gulf Herring Stock Status

The present analyses of the available commercial and research data has allowed us to confirm last years' assessment that the status of these herring stocks is generally healthy. Relatively young year-classes continue to dominate among both the spring- and autumnspawning herring in both the purse seine fishery and in the research surveys. The 1995 fall acoustic survey estimated the minimum abundance of spring and autumn-spawning herring available along the west coast at that time at approximately $84,000 \mathrm{t}$.

## St. George's Bay/Port-au-Port Bay

Although the status of the northern Gulf herring is generally good, the fishing effort had been high on the spring spawners in St. George's Bay and Port-au-Port Bay between 1988 and 1993 and, at present, the biomass of this local component is low. Without a strong recruitment pulse, the abundance of the spring-spawning herring in the St. George's Bay/Port-au-Port area will continue to decline in the short term. Since the 1987 and 1989 year-classes are now fully recruited in other areas, it is unlikely that they will contribute significantly to this local spawning component.

The 1994 closure of the spring commercial fishery (January 1- June 15) in St. George's Bay and Port-au-Port Bay has limited the targeting of these spawners and has increased the proportion of fall spawners in the total catch. Although covering a very small area ( $390 \mathrm{~km}^{2}$ ), the spring survey, undertaken in co-operation with the large purse seine fleet, showed that a good quantity ( $12,400 \mathrm{t}$ ) of mainly autumn-spawning herring ( $65 \%$ ) were present in May at the mouth of St. George's Bay. This confirmed the observations made by both commercial and research fishing in 1993 and 1994 that St. George's Bay spring spawners can be avoided to a large extent by restricting fishing to outside of the bay in the spring.

The situation in St. George's Bay must be watched closely. Fishing effort must continue to be restricted in these areas until there are indications of improvement in this local component. The continuation of the index-fisherman program in this area is essential for the monitoring of spawning activity and as a local abundance index.

Given that the spring closure of St. George's Bay and Port-au-Port Bay has effectively limited directed catches of this spring-spawning component, and that several recruiting yearclasses have entered the fishery elsewhere along the coast, the current TAC of $22,000 \mathrm{t}$ of springand autumn-spawning herring outside the closed area would not appear to be excessive.

## Acknowledgements

We would like to thank Jocelyne Hudon and Karine Kabasha for their diligent and expert assistance with the collection and compilation of much of the raw data. We would like to acknowledge the contributions made by the fisherman and port samplers (Jerry Lavers and Phil West) of the west coast of Newfoundland who provided us with biological samples, logbook and questionnaire information and many useful insights regarding the population dynamics of 4 R herring.
