## 1997 Assessment of Georges Bank (5Zjmnh)

 Yellowtail Flounder (Limanda ferruginea)John D. Neilson<br>Stratis Gavaris<br>J.J. Hunt<br>Department of Fisheries and Oceans<br>Biological Station<br>St. Andrews, New Brunswick<br>E0G 2X0

Research documents are produced in the official language in which they are provided to the Secretariat.

1 La présente série documente les bases scientifiques des évaluations des ressources halieutiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des enoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

#### Abstract

Yellowtail flounder (Limanda ferruginea) on Georges Bank is a transboundary resource which has supported a directed Canadian fishery since 1993. Removals of yellowtail flounder by the Canadian fishery peaked in 1994, when 2139 t were landed. Quota regulation commenced in 1995. Landings in 1996 were 483 t (including an estimated 11 t of regulatory discards from the scallop fishery) against a quota of 430 t . The fishery is prosecuted almost exclusively by vessels $<65$ ' fishing otter trawls.

Resource status was determined by virtual population and surplus production analyses. The latter approach, which does not require age structured input data, was included because of uncertainties in the catch at age information. Both methods indicated that biomass decreased to under 4000 t in the late 1980s' and has been recovering since then. In 1996, biomass was estimated as 10,365 and $13,495 \mathrm{t}$ from the surplus production and VPA models, respectively. Exploitation rate was well above the target level of 20\% during the 1983 to 1987 period, declined somewhat during the 1988 to 1994 period, and in 1995-1996 was at the lowest values observed in the series. The VPA indicates that the 1995 year-class is the weakest since 1986, but the observation is inconsistent with 1997 Canadian survey results. Status quo yield projections for 1997 range between 1053-2014 t for the VPA and surplus production models, respectively. Fishing at $\mathrm{F}_{0.1}$ in 1997 implies a yield of 2470 and 4526 t for the VPA and surplus production models, respectively. All yields are for combined Canada and USA landings.

## RÉSUMÉ

La limande à queue jaune (Limanda ferruginea) du banc Georges est une ressource transfrontalière qui alimente une pêche canadienne dirigée depuis 1993. Les prises canadiennes ont atteint un pic de 2139 t en 1994. Après l'établissement d'un quota en 1995, les débarquements ont chuté à 483 t en 1996 (y inclus environ 11 t rejetées légalement à la mer dans le cadre de la pêche du pétoncle), le quota annuel ayant été fixé à 430 t . La pêche est effectuée presque exclusivement par des chalutiers de moins de 65 pi.

Des analyses des populations virtuelles et de production excédentaire ont servi à déterminer l'état de la ressource. Cette dernière analyse, qui ne requiert pas de données sur les prises selon l'âge, a été utilisée à cause d'incertitudes à ce titre. Les deux analyses ont indiqué que, après avoir chuté à moins de 4000 t vers la fin des années 80 , la biomasse est maintenant en voie de rétablissement et qu'elle devrait atteindre 10365 t et 13495 t , respectivement, en 1996. De 1983 à 1987, le taux d'exploitation se situait bien au-dessus du pourcentage cible de $20 \%$; il a par la suite quelque peu diminué de 1988 à 1994 pour atteindre en 1995-1996 le plus faible niveau observé. L'analyse des populations virtuelles indique que la classe d'âge de 1995 est la moins abondante depuis 1986, bien que cette observation ne corresponde pas aux résultats des relevés canadiens de 1997. D'après les modèles obtenus de l'analyse des populations virtuelles et de l'analyse de production excédentaire, le rendement de statu quo en 1997 varie de 1053 t à 2014 t , respectivement, tandis que la pêche à $\mathrm{F}_{0,1}$ laisse supposer un rendement de 2470 t et de 4526 (débarquements canadiens et américains confondus) respectivement.

## INTRODUCTION

Yellowtail flounder (Limanda ferruginea) range from Labrador to Chesapeake Bay and are considered relatively sedentary. Yellowtail flounder are typically caught at depths between 37 and 73 m , and a major concentration occurs on Georges Bank to the east of the Great South Channel. Based on tagging investigations (Royce et al. 1959; Lux 1963), the management unit is considered to include Georges Bank east of the Great South Channel encompassing statistical areas $5 \mathrm{Zj}, 5 \mathrm{Zm}, 5 \mathrm{Zn}$ and 5 Zh (Fig. 1). Thus, the management unit is transboundary in nature. An earlier Canadian summary of stock status indicated that yellowtail flounder on the Canadian portion of Georges Bank could be the basis of a sustainable managed fishery (Anon. 1994a). This conclusion was based on several observations: yellowtail flounder are comparatively sedentary as adults more than one year-class was present in the Canadian landings and that spawning (which occurs in late spring) likely occurs in Canadian waters. However, the sources of recruitment and the degree of mixing across the international boundary are not clear.

A recent assessment conducted by the National Marine Fisheries Service (NMFS), USA concluded that the stock was at low biomass levels, overexploited and collapsed relative to historic abundance levels (Anon. 1994b). An updated analysis including both USA and Canadian landings confirmed the conclusions of the NMFS assessment, but also noted that based on updated landings and survey information, F had decreased in 1995 (Gavaris et al. 1996). The assessment presented here contains current information on landings and discards in 1996, and also revised estimates of USA landings and discards in 1994 and 1995.

## The Fisheries

The USA yellowtail fishery is almost exclusively conducted by vessels using otter trawl gear. USA landings were negligible prior to the mid-1930s, but landings increased to average 6,500 t in 1948-1949 (Anon. 1994b). After declining to $1,600 \mathrm{t}$ by 1955 , landings recovered to a peak of $18,300 \mathrm{t}$ in 1969. Between 1968 and 1974, landings averaged $15,600 \mathrm{t}$ but more recently, landings have averaged $2,060 \mathrm{t}$ between 1986 and 1996 (Table 1). The low landings since 1995 may be attributable, at least in part, to the recent expansion (both spatially and seasonally) of the haddock spawning closed area on eastern Georges Bank. Discarding of undersized yellowtail is considered a major contributor to overall mortality in the United States fishery.

Landings and discard estimates from the USA yellowtail fishery from 1994 to 1996 have been revised from those presented in Gavaris et al. (1996). Last year's estimates are compared with this year in the text table on the next page.

|  | Last Year's <br> Estimate of <br> USA landings <br> $(\mathrm{t})$ | Last Year's <br> Estimate of <br> USA discards | Current <br> Estimate of <br> (t) | USA landings <br> $(\mathrm{t})$ |
| :--- | :--- | :--- | :--- | :--- |
|  |  |  |  | Estimate of <br> USA discards |
| 1994 | 1500 | 2300 | 1589 |  |
| 1995 | 1000 | 700 | 292 | 153 |
| 1996 |  |  | 751 | 29 |
|  |  |  |  | 72 |

Thus, the estimates of total USA removals in 1994 and 1995 used in Gavaris et al. (1996) are considerably higher than the revised estimates. However, projections of fishing mortality and stock biomass assumed that 1996 removals by the USA fishery would be 385 t , the USA target TAC.

Prior to 1993, Canadian landings were small, typically less than 100 t (Table 1, Fig. 2). Peak landings of 1328 t of specified yellowtail occurred in 1994 in an unrestricted fishery, and after a TAC of 400 t was established, specified yellowtail landings dropped to 397 t in 1995. In 1996, landings of specified yellowtail flounder were 434 t against a quota of 430 t (Table 2).

Flatfish landed as "unspecified" flatfish in the Canadian fishery have been significant and generally consist of yellowtail on Georges Bank. To estimate the proportion of unspecified flatfish that were actually yellowtail, we calculated the ratio of known yellowtail to the sum of known winter flounder, American plaice and yellowtail flounder caught by month and unit area, from both otter trawls and scallop drags. For otter trawl landings, the ratio was relatively constant over the months of the fishery, and values of 0.61 and 1.00 were used for 5 Zj and 5 Zm , respectively. For scallop drags, however, the ratio varied on a seasonal basis, and monthly values were used. The unspecified flounder problem was less of a concern in 1995 and 1996 due to improved monitoring of the landings (Table 3). Table 4 shows the total Canadian yellowtail landings, which includes both the specified yellowtail flounder plus the assumed yellowtail flounder, calculated as described above.

Over the 1994-1995 period, there have also been some reports from industry of highgrading of landings by size to meet the 13 inch minimum size requirement for USA importation. Gavaris et al. (1996) compared the length-frequency composition of samples taken by observers at sea with those obtained by port samplers in 1994 and 1995, and no indication of discarding was detected. However, for 1996, there does appear to be an indication of discarding of smaller-sized fish (Fig. 3). This observation is inconsistent with industry reports, which indicated that discarding was insignificant in 1996.

The majority of Canadian landings of yellowtail flounder are made by otter trawl, from vessels less than 65 ft , tonnage classes 2 and 3 (Fig. 4). Peak months for fishing were August and September in 1994 and 1995. The number of vessels participating in the fishery was about 55 in 1994, and dropped to about 40 in 1995 because of a
requirement for participants to have a catch history of greater than $5 t$ of yellowtail flounder. About 45 vessels participated in the fishery in 1996. Industry representatives indicated that about half the fleet fished 140 mm square mesh gear in 1994, with one quarter fishing 130 mm square mesh and one quarter fishing 155 square mesh. By agreement among those participating in the 1995 and 1996 fishery, only 155 mm square mesh gear was used. The same rigging of the foot gear was used from 1994 to 1996.

There was also a trip limit of $17,000 \mathrm{lb}$. imposed by industry in 1995 to equitably share the reduced quota among eligible participants. In 1996, no trip limit was in place, and the quota of 430 t was allocated based on previous catch history.

Canadian yellowtail directed fishing activity was concentrated in the southern half of the Canadian fishing zone, in the portion of 5 Zm referred to as the "Yellowtail Hole" (Figs. 5, 6).The distribution of fishing activity changed somewhat from 1994 to 1996, with the total area fished being more constricted in 1995 and 1996.

Prior to 1996, some yellowtail flounder were landed in the scallop fishery. In 1996, there were no reported landings of yellowtail by the scallop fleet, with all yellowtail flounder caught required by regulation to be discarded at sea. Based on at sea observer records, the amount of yellowtail flounder discarded was estimated as 11 t .

## Age and Length Composition

We compiled the Canadian catch at age for 1993 to 1996. Samples for length and age composition were obtained by Canadian port technicians and at sea observers (Observer Program). Canada does not age yellowtail flounder at present, thus seasonal USA age-length keys were applied to the length composition of the Canadian catch. In the last assessment, we followed the USA convention of not providing a separate catch at age for males and females. However, since yellowtail flounder exhibit dimorphic growth typical of flatfish with females achieving a greater asymptotic length than males (Mosely 1988), we concluded that the approach of aggregating sexes might produce a bias. Thus, we elected to reconstruct the age and length composition of landings using a sexdisaggregated approach for the Canadian fishery from 1993 to 1996. The sampling data used to construct the Canadian catch at age are summarized below:

Number of length measurements used from:
A. Observer Program
B. Port Samples

| 1993 | 1821 | 1114 | $103(18)^{1}$ |
| :--- | :---: | :---: | :---: |
| 1994 | 6142 | 1644 | $175(21)$ |
| 1995 | 122 | 1831 | $240(40)$ |
| 1996 | 2444 | 1733 | $141(6)$ |

Number of Age
Determinations Available:

1. Numbers in parentheses refer to the number of ages which were assigned to lengths which did not have age at length information available. Such assignments were made from the inspection of age length keys.

The length-frequency samples from the OP were combined by trip, with samples from sets weighted according to weight caught in the set. The port samples and OP samples were then combined by month, gear type/tonnage class (OTB/TC1-3, $\mathrm{OTB} / \mathrm{TC} 4+$ and scallop drag) weighted according to trip caught weight, before being further combined by half-year and year. USA length-weight relationships by quarter were used for these calculations. In the case of miscellaneous gear (which included longline, gillnet, etc.) combinations were done on a half year basis rather than monthly. USA age length keys (available from surveys conducted in the spring and fall) were then applied by quarter and/or half-year to get catch at age.

The Canadian catch at age using the sex-disaggregated approach is compared with the sex-combined catch at age from last year's assessment in Fig. 7. Similar age compositions were obtained in 1993,1994 and 1996, but more substantial differences were noted for 1995. Of more concern, however, is the indication that the age composition is relatively stable and comprised generally of ages 3 and 4 (Fig. 8), while the catch at length and reports from the fishery indicate that the length composition of the landings is increasing (Fig. 9).

The USA catch at age for recent years is shown on Fig. 10. Again, the age composition appears to be largely ages 3 and 4 . Ages 2 and 5 are somewhat better represented in the USA catch at age than in the Canadian equivalent.

When trends in length at age are compared (Fig. 11), an increase in the mean length at age is noted for both the Canadian and USA data. These trends in the mean lengths at age are problematic, and are likely masking expected changes in age composition, given the increasing average length of the catch (Fig. 9).

While recognizing these difficulties with the catch at age, it was still considered desirable to include age structured catch information in a virtual population analysis. In the absence of sex-disaggregated USA landings, the sex-combined catch at age from Gavaris et al. (1996) was updated for the 1996 Canadian fishery and combined with the USA sex-combined catch at age. The resultant catch and weight at age data are shown in Table 5 and 6, respectively.

## ABUNDANCE INDICES

## Commercial Fishery Catch Rates

Catch ( t ) and effort ( h ) for less than 65 ft Canadian otter trawlers fishing for yellowtail flounder in 1993-96 were summarized on a trip basis. Initial examination of the trip records showed a large proportion of trips with very small amounts of yellowtail in the total catch. These trips were not considered to be representative of yellowtail directed effort, and therefore only trips with reported landings of more than 500 kg ( 1100
lb.) were considered. As well, only vessels with reported landings in two or more years in 1993-96 were included in the analysis. Examination of the spatial distribution of effort showed highest concentrations in the area described by fishermen as the "Yellowtail Hole" located in the southeast part of the bank and adjacent to the Canada-USA boundary (Fig. 6). Therefore, only landings and effort from the Yellowtail Hole were included in the analysis.

Yellowtail landings and effort for trips were aggregated by month and year and monthly catch rates ( $\mathrm{t} / \mathrm{h}$ ) are shown in Fig. 12. The catch rate decreased between 1993 and 1994 but increased by a factor of over two between 1994 and 1995 and increased further in 1996. This is consistent with industry observations of increasing catch rates in the last two years.

Substantial gear changes occurred in the fishery between 1993 and 1994 with the introduction of 'flounder gear' which uses a small diameter footgear. Changes in mesh size also occurred, as described earlier. However, fishing practices have been relatively constant since 1994. While catch rates may prove to be useful as an index of abundance for this resource, the time series is too short to be included directly in the assessment at present.

## Research Vessel Surveys

Bottom trawl surveys are conducted annually on Georges Bank by the Canadian Department of Fisheries and Oceans (DFO) in spring and by the NMFS in spring and fall. Both agencies use a stratified random design, though different strata boundaries are defined (Fig. 13).

Aging of DFO survey samples has not been done and therefore age sampling from the corresponding NMFS spring survey was used to obtain abundance indices by age. Males and females were treated separately and then combined for the index at age. However, the small number of fish aged in some years and the further partitioning of the age length key by sex resulted in low precision for the estimates. In general, the use of age and sex-specific age length keys results in higher abundance at ages $3+$ when compared to unsexed keys.

Results from the Canadian survey and trends over time are shown in Fig. 14 (also Tables 7-10 for all surveys). USA age sampling was not available at the time of writing to apply against the 1997 DFO results. In 1997, the Canadian survey index was at the highest value recorded in the series. However, when the numbers caught at length in 1997 were compared with 1996, it was noted that the increase in the index, while driven partially by new recruitment, might also be caused by interannual variation in survey catchability. The sex-combined index for all ages from Gavaris et al. (1996) was updated, along with the biomass index from Canadian surveys from 1987 to 1997 (Table 10 a and b , respectively).

The overall trend for the NMFS spring survey is shown in Fig. 15. Similar to the Canadian spring series, the series has followed an increasing trend since 1988. However, during the late 1960s and early 1970s the index was considerably higher. The NMFS fall series shows a similar trend to the NMFS spring index and has followed a generally declining trend since 1963. It has remained at low levels since 1989. (Fig. 16).

The spatial distribution of the 1997 Canadian spring survey catch compared with the average of the five preceding years is shown on Fig. 17. Over the past five years, the highest catch of yellowtail flounder was found in 5 Zm , near the Yellowtail Hole, corresponding well with the distribution of the commercial fishery shown on Fig. 6. The 1997 results indicate that the population density has increased relative to the past five years.

Figures 18 and 19 are similar to Fig. 17, and contain comparisons of the USA spring and fall survey results contrasted to the five year average. In general, recent catches have not revealed the concentration of yellowtail seen in the Canadian survey, but sampling intensities in key yellowtail habitats have been low, particularly during the fall survey.

The resource distribution in 1997 is compared with the abundant years 1971-1973 as indicated in the NMFS spring survey (Fig. 20). The Canadian catches were downweighted by a factor of 2.4 to account for observed differences in catchability among the surveys. Differences in sampling intensity between the two surveys make comparisons difficult, but it appears as though the resource was more broadly distributed during the earlier period.

Most of the catch of yellowtail flounder seen during Canadian surveys occurs in the 5 Zm area. In the past five years, the average proportion of biomass in Canadian waters has been 38,67 and $59 \%$, as indicated in the Canadian and USA spring and fall surveys, respectively (Table 11). There is, however, considerable interannual variation in the proportion of biomass in Canadian waters.

The length composition of yellowtail flounder caught in the past three Canadian spring surveys is shown on Fig. 21, disaggregated by sex. An increase in modal length from 1995 to 1997 is apparent for both males and females. Consistent with observations from the fishery, the average length of fish has increased, as has the overall size range. There are also above average numbers of smaller fish (mode of about 25 cm ) found in the 1997 survey results.

## ESTIMATION OF STOCK PARAMETERS

Concerns were noted with the catch at age data, including the observation that few age groups were present in the population making results more dependent on assumptions for the fishing mortality at the oldest age group, and also whether recent low levels of
sampling has had deleterious effects. Surplus production models which employ aggregate biomass data and do not rely on age structure, could circumvent these concerns. It is recognized however, that where VPA can be applied satisfactorily, it provides better information for stock projections. Consequently, two methods of analysis were used, the traditional age-structured VPA and the aggregate biomass surplus production model.

The aggregate biomass method used was a non-equilibrium surplus production model, as implemented in the software ASPIC (A Stock-Production model Incorporating Covariates) (Prager 1995). The method requires total landings along with one or more abundance indices (including CPUE or RV indices) as input. In our case, the DFO spring survey (1987 to 1996) and the NMFS spring survey (1968 to 1996) were considered beginning of year biomass indices and the NMFS fall survey (1963 to 1996) was treated as a midyear index. The error in the survey abundance indices was assumed to be independent and identically distributed after taking natural logarithms of the values. The following model parameters were defined:

$$
\begin{aligned}
& r=\text { population intrinsic rate of increase } \\
& K=\text { maximum population size } \\
& q_{s}=\text { survey catchability } \\
& B_{1}=\text { population biomass }(\mathrm{t}) \text { at the start of the first year }
\end{aligned}
$$

ASPIC was used to solve for the parameters by minimizing the sum of squared differences between the ln observed survey catch rate and the ln predicted survey catch rate. The objective function for minimization was defined as

$$
\underset{s, t}{\Psi}\left(r, K, q, B_{1}\right)=\sum_{s, t}\left(\ln I_{s, t}-\ln \left(Y_{t} / \hat{f}_{t}\right)\right)^{2}
$$

where

$$
\begin{aligned}
& Y_{t}=\text { observed yield in year } t \\
& \hat{f}_{t}=\text { predicted effort in year } t
\end{aligned}
$$

and

$$
\begin{aligned}
I_{s, t} & =\text { bottom trawl survey biomass index } \\
\text { for } s & =\text { DFO spring survey, time } t=1987 \text { to } 1996 \\
s & =\text { NMFS spring survey, time } t=1968 \text { to } 1996 \\
s & =\text { NMFS fall survey, time } t=1963 \text { to } 1996
\end{aligned}
$$

A solution for $\hat{f}_{t}$ is obtained from

$$
q f_{t}=\frac{(r / K) Y_{t}}{\ln \left[\frac{(r / K) B_{i}\left(e^{\left(r-q f_{t}\right)-1}\right)}{r-q f_{t}}+1\right]} \text { when } r \neq q f_{t}
$$

or

$$
q f_{t}=\frac{(r / K) Y_{t}}{\ln \left[1+(r / K) B_{t}\right]} \text { when } r=q f_{t}
$$

using an iterative procedure. A solution for $B_{t}$ is obtained from

$$
B_{t+\Delta t}=\frac{\left(r-q f_{t}\right) B_{t} e^{\left(r-q f_{t}\right) \Delta t}}{\left(r-q f_{t}\right)+(r / K) B_{t}\left(e^{\left(r-q f_{t}\right) \Delta t}-1\right)} \text { when } r \neq q f_{t}
$$

or

$$
B_{t+\Delta t}=\frac{B_{t}}{1+(r / K) B_{t} \Delta t} \text { when } r=q f_{t}
$$

The adaptive framework, ADAPT, (Gavaris 1988) was used to calibrate the VPA with the research survey abundance trend results. The model formulation employed assumed that the error in the catch at age was negligible. The error in the survey abundance indices was assumed to be independent and identically distributed after taking natural logarithms of the values. The annual natural mortality rate, M, was assumed constant and equal to 0.2 . A model formulation using as parameters the $\ln$ population abundance at the beginning of the year following the terminal year for which catch at age is available was considered (Gavaris 1993). The following model parameters were defined:

$$
\theta_{a, 1997}=\ln \text { population abundance }
$$

for ages $a=1$ to 6 at the beginning of year 1997

$$
\kappa_{s, a}=\ln \text { calibration constants }
$$

for each survey source $s$ and relevant ages $a$

ADAPT was used to solve for the parameters by minimizing the sum of squared differences between the $\ln$ observed abundance indices and the $\ln$ population abundance adjusted for catchability by the calibration constants. The objective function for minimization was defined as

$$
\underset{s, a, t}{\Psi}(\theta, \kappa)=\sum_{s, a, t}\left(\ln I_{s, a, t}-\kappa_{s, a}+\ln N_{a, 1}(\theta)\right)^{2}
$$

for time $t$

For convenience, the population abundance $N_{a, 1}(\theta)$ is abbreviated by $N_{a, 1}$. At the beginning of the year 1997, i.e. $t=1997$, the population abundance for ages $2-5$ was obtained directly from the parameter estimates, $N_{a, 1997}=e^{\theta_{0,1997}}$. The population abundance for ages 6 and 7 were calculated assuming that the fishing mortality for these was equal to the average fishing mortality on ages 4 and 5 . The abundance at age 1 was set to 20 million. For all other times, the population abundance was computed using the virtual population analysis algorithm which incorporates the exponential decay model

$$
N_{a+\Delta, r, t+\Delta}=N_{a, r} e^{-\left(F_{a, t}+M_{a}\right) \Delta}
$$

Year was used as the unit of time, therefore ages were expessed as years and the fishing and natural mortality rates were annual instantaneous rates. The fishing mortality rate exerted during the time interval $t$ to $t+\Delta t, F_{a, t}$, was obtained by solving the catch equation using a Newton-Raphson algorithm

$$
C_{a, t}=\frac{F_{a, t} \Delta t N_{a, t}\left(1-e^{-\left(F_{a, t}+M_{a}\right) \Delta t}\right)}{\left(F_{a, t}+M_{a}\right) \Delta t}
$$

for $C_{a, t}=$ the catch at age $a$ during the time interval $t$ to $t+\Delta t$

The fishing mortality rate for age 6 in the last time interval of each year was assumed equal to the population weighted arithmetic average for ages 4 to 5 during that time interval,

$$
F_{6, t}=\sum_{a=4}^{5} N_{a, t} F_{a, t} / \sum_{a=4}^{5} N_{a, t}
$$

The data used were annual catch at age ,

$$
C_{a, t}=\text { catch }
$$

$$
\text { for ages } a=1,2 \ldots 7 \text { and for } t=1973 \text { to } 1996
$$

and bottom trawl survey abundance indices

$$
I_{s, a, t}=\text { abundance index }
$$

$$
\text { for } \begin{aligned}
s & =\text { DFO spring survey, ages } a=2,3 \ldots 6, \text { time } t=1987,1988, \ldots 1996 \\
s & =\text { NMFS spring survey, ages } a=1,2 \ldots 7, \text { time } t=1973,1974 \ldots 1996 \\
s & =\text { NMFS fall survey, ages } a=1,2 \ldots 7, \text { time } t=1973.5,1974.5 \ldots 1996.5 \\
s & =\text { NMFS spring scallop survey, ages } a=1,2,3,5,6,7, \text { time } t=1971,1972 \ldots 1996
\end{aligned}
$$

All available data were used except when the indices were 0 (logarithm not defined).

Myers and Cadigan (1995) reported that correlated errors among ages within a survey can be sufficiently large to produce model mis-specification biases in estimates of population parameters from standard assessment methods. Their simulation however, showed that maximum likelihood estimators from models which ignored correlation performed similar to those from models which incorporated correlation when the correlated errors were small. An estimate of the correlation among ages within a survey was computed using the standard sample estimator for the coefficient of linear correlation where the pairs of observations were the residuals from each abundance index source: $\left(e_{i,}, e_{j, 1}\right)$ for all ages $i \neq j$ and all times $t$. For the three survey sources used in this assessment, the correlation was found to be small; DFO spring survey $\hat{\rho}=-0.12$, NMFS spring survey $\hat{\rho}=0.06$, NMFS fall survey $\hat{\rho}=0.27$, and NMFS scallop survey $\hat{\rho}=0.32$. Accordingly, no correction was made for this type of model mis-specification.

The statistical properties of population estimates from the VPA are given in Table 12. The model formulation employed this year provided less biased and more precise estimates than those provided in the last Canadian assessment (Gavaris et al. 1996). Cadrin et al. (1997) completed a detailed examination of the statistical properties of a very closely related VPA model for this stock, and concluded that on average, bootstrap analyses indicated that results from the VPA calibration were insensitive to the effects of minor statistical problems, including trended residuals, correlated errors and outliers.

## ASSESSMENT RESULTS

The initial surplus production model fit is shown in Appendix One. In general, the overall fit of the observations to the model appear good ( $\mathrm{r}^{2}$ of $0.692,0.564$ and 0.706 for NMFS fall, spring and DFO spring, respectively). There are some runs of either positive or negative residuals, but the overall magnitude of the residuals appears small. In plotting the results, we have elected not to show the first five years, as Prager (1974) notes that initial biomass values are poorly estimated for the first 3-5 years of the series.

Bootstrapped estimates of model parameters (based on 500 trials) are provided in Appendix Two.

Results from the VPA are summarized in Tables 13 through 16.
Population abundance estimates (total biomass) provided from both assessment models show good concurrence (Fig. 22). Both models indicate a steady decline in population biomass from the early 1970's, an increase in the early 1980's attributable to the strong 1980 year class, then a decrease to under 4000 t in 1988. Biomass has been recovering since then, and in 1996 was estimated as 10,365 and $13,495 \mathrm{t}$ from the surplus production and VPA models, respectively. However, biomass remains low compared to the biomass at maximum sustainable yield, as indicated from the surplus production model ( $37,540 \mathrm{t}$ ).

The VPA and surplus production models produce similar patterns of exploitation rate over time (Fig. 23). Exploitation rate was well above the target level of $20 \%$ during the 1983 to 1987 period, declined somewhat during the 1988 to 1994 period, and in 19951996 was at the lowest of the values observed in the series.

Recruitment as indicated from the VPA is shown on Fig. 24. Recruitment during the 1980s was considerably poorer than that experienced during the 1970s. Recruitment in the 1990s has generally improved, but no exceptional year-classes were noted, such as those in 1974 and 1980. The strength of the 1995 year-class is uncertain at this point. The VPA indicates that the 1995 year-class is the weakest since the 1986 cohort. However, the 1997 Canadian survey indicated above average numbers of fish at a mode of 25 cm , which probably represents the 1995 year-class. The current VPA also indicates that the 1992 year-class is not as strong as previously estimated.

## OUTLOOK

Since two assessment models were used, two projections are provided, with scenarios illustrating exploitation rates equivalent to the status quo $\mathrm{F}_{96}$ and for $\mathrm{F}_{0.1}$. In the $\mathrm{F}_{96}$ option, the fishing mortality in 1997 is equal to that in 1996. The $\mathrm{F}_{0.1}$ option implies an exploitation rate of $20 \%$ in 1997. The $\mathrm{F}_{2 / 3 \mathrm{MSY}}$ is the exploitation rate corresponding to two-thirds of the exploitation rate observed at MSY from the surplus production model (see Appendix Three) and is comparable to the $\mathrm{F}_{0.1}$ option from the VPA.

|  |  | Yield <br>  | Biomass | Biomass |
| :--- | :--- | :--- | :--- | :--- |
| $\mathrm{F}_{96}$ | VPA | 1097 | 1997 | 1998 |
| $\mathrm{~F}_{0.1}$ | Production | 2014 | 12268 | 14013 |
| $\mathrm{~F}_{23 \mathrm{MSY}}$ | PPA | Production | 2470 | 12268 |

Status quo yield estimates for 1997 range between 1053-2014 t. Fishing at $\mathrm{F}_{0.1}$ in 1997 implies a yield of 2470-4526 t .

Projection results differ because the production model assumes an average longterm population growth rate, while the age-based VPA model use estimated abundance at age and average 1994-1996 stock conditions (partial recruitment, mean weight, maturation).

The assessment of Georges Bank yellowtail flounder is complicated by low levels of sampling. The changing spatial patterns of fishing and low levels of sampling, particularly in 1994 and 1995, contribute to the uncertainty in estimates of recent age composition of both the USA and Canadian catch. In particular, the size of the 1995 year-class is a major source of concern.

Because of such uncertainties, two assessment approaches were employed, each with strengths and weaknesses. For example, the VPA should generate more precise projections, since age structure in the current year is known. However, as indicated earlier, there are significant uncertainties in the age composition of the landings in 1996 which will impact the reliability of the projections. The uncertainty in the size of the 1995 year-class is not a concern in the short-term, as that year-class will not be recruited to the 1997 fishery.

The projections of biomass and fishing mortality from the VPA relative to $\mathrm{F}_{0.1}$ also have some uncertainty (Fig. 25). For example, compared with other groundfish resources, a large decrease in yield in 1997 is required to achieve a modest increase in the probability of not exceeding the target mortality or reducing population biomass in 1997. The uncertainty reflected in Fig. 25 does not include other sources such as recent age composition, catch information and variation in natural mortality.

The surplus production approach attempts to capture separate elements of stock dynamics such as growth and recruitment in a simplified model but may have limited ability to project stock status. The model indicator of stock growth is obtained from observations throughout the entire survey series, and may not reflect the most recent stock conditions. In particular, current relatively low biomass levels may be unlikely to produce adequate recruitment, and estimates of yield from the surplus production model may be optimistic. However, use of all available survey information in the surplus production model does allow a description of resource productivity during the entire period, which the VPA does not, due to problems in reconstructing the fishery catch at age prior to 1973 .

## ACKNOWLEDGMENTS

We thank Dr. Mike Prager for his assistance in the initial setup of the ASPIC model, and his helpfulness in resolving any difficulties we encountered. The VPA model described here is closely related to one developed by S.X. Cadrin and coworkers at the 24th Northeast Regional Stock Assessment Workshop, April, 1997. We thank Steve and our USA NMFS colleagues for their excellent collaboration throughout the assessment process. We also thank Peter Perley and Mike Strong for assistance in construction of the Canadian catch at age and development of the Canadian survey indices, respectively. Heath Stone provided a helpful review of an earlier draft of this document.

${ }^{2}$ Yellowtail landings included known yellowtail flounder, plus unspecified flounder. The proportion of unspecified flounder which was considered to be yellowtail was determined by the proportion of known yellowtail flounder in proportion to the landings of yellowtail, winter flounder and American plaice.

Fig. 1. Canadian fisheries statistical unit areas in NAFO Subdivision 5Ze.

Fig. 2. Landings of Georges Bank yellowtail flounder by Canada and the United States, 1973 to 1996.

Fig. 3. Comparison of length frequency distributions of samples observed in 1996 by port technicians with those at sea samples collected with the Observer Program, 1996, Georges Bank.

Fig. 4. Canadian landings by gear type, Georges Bank yellowtail flounder.

Fig. 5. Canadian landings by NAFO unit area, yellowtail flounder on Georges Bank.

Fig 6. Distribution of Canadian mobile gear (TC 2 \& 3) effort for 1993-96 where trip landings of yellowtail were $>500 \mathrm{lb}$, summarized by 10 min squares.

Fig. 7. Comparison of age composition obtained when using the sex aggregated method of reconstructing the Canadian catch at age (labelled "old") and that obtained using the sexes separate approach (labelled "new").

Fig. 8. Comparison of yellowtail flounder fishery age composition, 1993 to 1996, for Canadian catches on Georges Bank.

Fig. 9. Comparison of the yellowtail flouunder length frequency composition taken in the Canadian Georges Bank fishery from 1994 to 1996.

Fig. 10. USA yellowtail fishery age composition (including discards), 1993-1996, Georges Bank.

Fig. 11. Comparison of mean lengths at age of Georges Bank yellowtail flounder from the Canadian and USA catch at age matrices, 1993 to 1996.

Fig. 12. Monthly catch rates of stern otter trawlers (TC 2-3), Georges Bank yellowtail flounder, 1993 to 1996.

Fig. 13. USA (top) and Canadian (bottom) strata used to derive research survey abundance indices for Georges Bank groundfish surveys.

Fig. 14. Canadian spring survey results for yellowtail flounder (Strata 5Z1-4), 1987-1997.

Fig. 15. USA spring survey results for yellowtail flounder on Georges Bank, 1968-1996.

Fig. 16. USA fall survey results for yellowtail flounder on Georges Bank, 1963-1996.

Fig. 17. The distribution of catches of yellowtail flounder (solid circles) in the Canadian Georges Bank spring survey in 1997, compared with the average distribution in the previous five years (shaded rectangles), averaged by 3 ' squares.

Fig. 18. The distribution of catches of yellowtail flounder in the USA Georges Bank spring survey in 1996 (solid circles), compared with the average distribution in the previous five years (shaded rectangles), averaged by 3 ' squares.

Fig. 19. The distribution of catches of yellowtail flounder in the USA Georges Bank fall survey in 1996 (solid circles), compared with the average distribution in the previous five years (shaded rectangles), averaged by 3 ' squares.

Fig. 20. Comparison of the distribution of yellowtail flounder as indicated in the Canadian 1997 spring survey compared with the abundant years 1971-1973 as indicated from the USA spring surveys.

Fig. 21. Comparison of yellowtail flounder length composition in Canadian spring surveys, 1995 1997, Georges Bank.

Total Biomass (t)

Fig. 22. Trends in biomass for Georges Bank Yellowtail Flounder as indicated from a virtual population analysis and a surplus production model.

## Exploitation Rate

Fig. 23. Trends in exploitation rate for Georges Bank Yellowtail Flounder as indicated from a virtual population analysis and a surplus production model.

Fig. 24. Recruitment of Age 1 Georges Bank yellowtail flounder, as indicated from virtual population analysis.

Fig. 25. Probability of exceeding $\mathrm{F}_{0.1}$ in 1997 and of the 1998 biomass decreasing compared with 1997 for Georges Bank yellowtail flounder.

[^0]:    The bootstrapped results shown were computed from 500 trials.

    - These results are conditional on the constraints placed upon MSY and $r$ in the input file (ASPIC. INP)
    - All bootstrapped intervals are approximate. The statistical literature recommends using at least 1000 trials for accurate $95 \%$ intervals. The $80 \%$ intervals used by ASPIC should require fewer trials for equivalent
    accuracy. Using at least 500 trials is recommended
    - The bias corrections used here are based on medians. This is an accepted statistical procedure, but may

[^1]:    ${ }^{1}$ Yellowtail landings from scallop drags were calculated as the ratio of yellowtail flounder to the landings of scallops in observed trips, raised by the total scallop landings in 1996.
