Abstract

Based on returns through 1997 and using methods previously approved by PSARC, the recommended forecast for the total terminal run of Robertson Creek Hatchery and Stamp River chinook (age 3,4, and 5) to Barkley Sound in 1998 is 58,800±20% (based on averaging the Prod2 and Prod3 forecasts). The age structure of the return is projected to be 8% Age 3, 72% Age 4, and 20% Age 5; with an expected sex ratio of 52% females. The number of chinook required to meet the minimum escapement goal is 31,900.

The detailed assessments and forecasts of the RCH/Stamp chinook are undertaken annually for management of that major stock plus as an indicator of the expected returns to the naturally spawning chinook populations along the west coast of Vancouver Island. Terminal run size and spawning escapements to the RCH/Stamp indicator stock have been similar over the past three years and are projected to be similar and relatively weak again in 1998. However, returns to some of the natural systems were better in 1997 than indicated by this stock. This is particularly true for returns to populations along the northern half of the Island (Areas 25 to 27); seven populations in these Areas are, in aggregate, used in the Pacific Salmon Commission (PSC) to indicate trends in escapement to naturally spawning chinook along the WCVI.

While this is positive indication that the conservation actions taken by Canada to protect these populations has been successful, there are two concerns which suggest caution when planning 1998 fisheries. First, the recovery in the northern population is not evident in the more southern naturally spawning populations (e.g., the Area 24 populations and Nahmint River). Secondly, the age structure of the 1997 returns was strongly age-4 chinook. Returns of Age-3 chinook to the natural systems did not appear as strong as the return to the RCH/Stamp indicator stock. Consequently, returns in 1998 may be reduced if survival of the 1994 brood year declined again. The only indication of brood survival for these northern populations is the return to Conuma Hatchery. Age-3 returns in 1997 to Conuma were only about 25% of the Age-4 returns observed in the sport fishery and in the escapement.

While the condition of most naturally-spawning chinook populations along the WCVI have improved during recent years, the above concerns and the relatively weak return forecasted for the RCH/Stamp stock indicate a continued need for conservative management plans in fisheries impacting these stocks during 1998.

Résumé

Suivant les retours observés tout au long de 1997 et les méthodes approuvées par le PSARC, la prévision recommandée pour la remontée terminale dans Barkley Sound du saumon quinnat (3, 4 et 5 ans) des piscicultures de Robertson Creek et de Stamp River est de 58 800 ±20 % pour 1998 (fondée sur la moyenne des prévisions pour les Prod2 et 3). On prévoit un retour composé à 52 % de femelles et comportant 8 %, 72 % et 20 % d'individus âgés respectivement de 3, 4 et 5 ans. Il faut 31 900 individus pour atteindre l'objectif minimal d'échappée du saumon quinnat.

Chaque année, le quinnat de Robertson Creek et de Stamp River fait l'objet d'estimations et de prévisions détaillées, utilisées d'abord dans la gestion de cet important stock, mais aussi comme indices de la remontée des populations sauvages le long de la côte ouest de l'île de Vancouver. La remontée terminale et l'échappée du stock des piscicultures de Robertson Creek et de Stamp River s'est maintenue au même niveau d'abondance au cours des trois dernières années et elle devrait être semblable et faible une fois de plus en 1998. Toutefois, la remontée de certains stocks sauvages a été supérieure en 1997 à celle du stock indicateur. C'est le cas, en particulier, des populations du secteur nord de l'île (zones 25 à 27). En concentration, sept populations de ces zones servent d'ailleurs d'indices à la Pacific Salmon Commission (PSC) pour suivre l'évolution de l'échappée des populations sauvages du saumon quinnat sur la côte ouest de l'île de Vancouver.

Même si ces données indiquent que les mesures de conservation prises par le Canada pour protéger ces populations semblent avoir porté fruit, deux préoccupations incitaient tout de même à la prudence lors de la planification des pêches pour 1998. En premier lieu, le rétablissement observé dans la population au nord ne semble pas s'être reproduit parmi les populations sauvages plus au sud, notamment dans celles de la zone 24 et de la rivière Nahmint. En second lieu, la composition par âge des remontées du quinnat en 1997 était fortement dominée par la classe de 4 ans. Les remontées de la classe de 3 ans dans la population sauvage ont semblé inférieures à celles du stock indicateur de Robertson Creek et de Stamp River. Par conséquent les remontées de 1998 pourraient être plus faibles si la génération de 1994 continuait à décliner. Le seul indice qui permet d'évaluer la survie des populations au nord est la remontée vers la pisciculture de Conuma. Or, en 1997, les remontées de la classe de 3 ans vers Conuma ne représentaient que 25 % environ de l'abondance de celles de la classe de 4 ans observée en pêche sportive et en échappée.

Quoique l'état des populations sauvages de saumon quinnat de la côte ouest de l'île de Vancouver se soit amélioré au cours des dernières années, les préoccupations susmentionnées, de même que les faibles remontées prévues pour les stocks des piscicultures de Robertson Creek et de Stamp River, plaident en faveur de la poursuite en 1998 des plans de gestion comportant des mesures de conservation pour les pêches ayant une influence sur ces stocks.

1. Introduction

This PSARC document uses methods previously reviewed in Riddell et al (PSARC X96-01) to forecast Somass River chinook salmon returns to Barkley Sound. This working paper includes a summary of data collection and accounting procedures used in 1997 and one forecast of the 1998 return. Historic data are not repeated but documented in PSARC X96-01.

Since the development of Robertson Creek Hatchery (RCH) in 1971, the Somass River system has become one of Canada's major producers of chinook salmon, with large contributions to ocean troll and sport fisheries, and stimulating the development of substantial terminal sport, native, and commercial fisheries.

CWT analyses for this stock indicate that during an average year (excluding 1995-1997) about 50% of the stock has returned to Barkley Sound, and over half of the ocean harvest has occurred in south east Alaska fisheries (SEAK). Recently, production of chinook salmon from the Somass River system, including total terminal run plus ocean catch of hatchery fish, has ranged as high as 400,000 chinook (1991 return year). This ocean catch is based on expanded coded-wire tag from the hatchery but does not account for incidental mortality in ocean fisheries, or the ocean catch of natural production from the Somass River system.

The Somass River system is located at the head of Alberni Inlet in Barkley Sound on the west coast Vancouver Island. Within this system, the Stamp River, which drains Great Central Lake, and the Sproat River, which drains Sproat Lake, combines to form the Somass River. Roughly half way up the Stamp River are a set of impassable falls, Stamp Falls. Fishways constructed to circumvent the falls are the basis for counting escapement into the upper Stamp River. Historically, naturally spawning chinook were present in the lower Stamp below Stamp Falls, the Sproat River, and the Somass River mainstem. These areas were generally poorly enumerated. However, since the development of RCH on the upper Stamp River, the majority of the spawners are now located in the upper Stamp River.

An interim spawning escapement goal was established in 1988 based on escapements immediately prior to the 1985 Pacific Salmon Treaty (PST), including:

- 70,000 naturally spawning chinook (or double the estimated 35,000 adult spawners),
- 15,000 chinook for 10 million eggs into RCH, plus a
- 20% increment to account for prespawn mortality.

Extreme conservation concerns due to poor marine survival brought on by an extreme El Nino event in the 1992-1995 period required formulation of a minimum escapement level. This level was based on escapement prior to 1985, and included:

- 50 million egg target for natural spawning,
- 9.3 million egg target for RCH, plus the
- 20% increment to account for prespawn mortality

2. Terminal Run Calculation

The Stamp River is a key indicator for exploitation rates and distribution patterns of WCVI chinook production systems. The accounting of the terminal return into Barkley Sound (DFO Statistical Area 23) is formulated in Appendix Table 1 and summarized in Table 1. The conduct of the monitoring programs and results in 1997 are described herein.

2.1 Sport Fishery Survey

All Somass River chinooks caught in the sport fishery in DFO Statistical Area 23 are included in the terminal run. A creel survey was conducted in Alberni Inlet and Barkley Sound from mid-June to the end of September. During this period 3,709 interviews (14% of the fishing effort) were conducted in Alberni Inlet and 2,489 interviews (9% of the fishing effort) were conducted in Barkley Sound. Approximately 40 effort counts were conducted in each area. Most chinooks observed during the interview process were also sampled for adipose fin clip, scales, and length.

The creel survey results are presented in Appendix Table 1. The total chinook catch in Alberni Inlet was estimated to be 10,900 chinook of all origins, and 15,100 in Barkley Sound (Aug.-Sept.). Effort was approximately 27,000 boat trips in Alberni Inlet, and the same in Barkley Sound.

For the purpose of this accounting, Alberni Inlet includes waters out as far as Pocahontas Point. The total chinook catch in Alberni Inlet, excluding expanded coded wire tag (CWT) recoveries of non-Somass River chinook, is included in the terminal run calculation. The catch of Somass River chinook in Barkley Sound was estimated as the expanded CWT in Barkley Sound / proportion RCH in the Alberni Inlet catch plus escapement (Table 1).

2.2 Native Fishery Monitoring

Under an agreement between DFO and the local First Nations, several Pilot Sales fisheries targeting chinook salmon were conducted in the lower Somass River below Papermill Dam (the tidal limit). Gear is limited to hand set gill nets, mainly using 7-inch mesh size. Fisheries were conducted starting September 2 until September 19. Total catch was estimated by a census of fishers as they landed at designated landing sites and assumed that all fishers were encountered. The total catch observed was 5,726 chinook.

Biological sampling was conducted on a portion of the catch as it was transferred to buyer's totes or as it was unloaded at the plant. In all, 2000 chinook (35% of the total catch) were sampled for mark incidence. Scales, sex, and length were taken from 315 chinook.

The sampled age composition of the native fishery indicates a selection for larger fish, with 64% of the catch being age 4 chinook.

2.3 Stamp Falls Fishway Observations of Total Escapement

Monitoring of salmonid migration through Stamp Falls fishway in 1997 was initiated September 3 and ended November 10. A snorkel survey was conducted above the falls on Sept. 3rd to determine the number of early migrants. Observations at Stamp Falls were conducted daily, except for the period September 30 to October 7, when observation was precluded due to high

and turbid water conditions. Full time observation was terminated October 30 due to very low numbers, and spot-checked thereafter until November 10.

Daily observation was generally from 0.5 hour before sunrise to 0.5 hour after sunset. Additional observations were conducted approximately every 10 days, starting 2 hours before sunrise or continuing 2 hours after sunset, to assess migration rates at these times. Very few fish were observed actively migrating during darkness or near darkness.

Observations were conducted using video, from a waterproof camera mounted on a pole approximately 1m from the left side of the counting tunnel. The field of view was approximately 1m (measured at the rear panel of the counting tunnel). In order to reduce error in assessment of length using the video, the tunnel width was reduced to 8.5 inches in width (from 16in. in 1996).

Salmon were identified and recorded by species, including discrimination of adult and jacks. For example, chinook less than 60 cm total length were recorded as jacks, using reference markings on the base and back of the tunnel.

Observations were conducted in real time through a 21inch high-resolution colour monitor. A Super VHS VCR simultaneously recorded the migration. During observation, species (with jack and adult separated) and direction of migration were entered into an Access database and linked to time/date and observer.

Observer error was estimated from verification of 90 randomly chosen hours of tape. Verification personnel were two of the observers at the Stamp Falls fishway. Prior to verification, these observers met with hatchery staff experienced in salmon identification and came to agreement on criteria used to identify species as seen on videotape. Linear regressions, forced through the origin, were formulated using the verified counts (assumed to be true counts) by species as the independent variable and the observed counts as the dependent variable. There were no significant differences in relationships between verified and observed counts by time, observer, or water conditions.

The total observed counts at Stamp Falls were corrected using the following relationships between verified (V) and observed (O) counts:

Chinook adults Corrected count = V = O / 1.003 $r^2 = 0.9826$ Chinook jacks Corrected count = V = O / .503 $r^2 = 0.2026$

Escapement missed during periods of high water was estimated through a mark-recapture survey. Snorkel surveys were conducted in Stamp Lagoon a few days after the completion of the dead pitch sampling program. A ratio of tailed (i.e., not sampled) to tail-less (i.e., sampled) chinook was determined from these observations. This ratio was applied to the dead-pitch sample size to estimate the number of fish 'missed' during sampling. The 'missed' fish plus dead-pitch samples plus hatchery swim-in samples were used as the total escapement.

2.4 Sampling at Robertson Creek Hatchery

In 1997, the hatchery intake was left open, allowing 19,415 chinook to enter Robertson Creek Hatchery, including only 2537 females (13% of the total). All fish entering the hatchery were handled, counted, checked for AFC, and recorded by sex. Jacks were separated from larger

chinook based on a length of 50-cm post orbital hypural (POH) length. The age composition

of the total return to the hatchery was based on two independent samples for each sex, CWT fish and random scale samples from unmarked fish. Sample data are summarized in Appendix 2. Age composition for each sex was estimated by pooling the number at age in the estimated CWT and scale samples.

2.5 Sampling on Spawning Grounds

Sampling of carcasses in the Stamp River was conducted by 3 people working 5 days per week, from October 1 through November 5, with the exception of a few days when water levels were hazardous to working on the river. The objectives included sampling as many fish as possible for adipose fin clips (AFC), and biological sampling (including scales, otoliths, POH length, sex, egg retention level) of about 500 chinook per sex. Sampling was conducted using a carcass weir when water levels permitted, and searching for carcasses along river banks/bars during high water. Tails were severed from all fish sampled.

In 1997, 5258 chinook were sampled for AFC, with 112 recoveries. Biological sampling was conducted on 807 males and 630 females.

The total in-river escapement was determined by subtraction of the hatchery count from the corrected fishway count. Sample sizes of adult males and jacks in the river are unlikely to be representative of their population sizes due to the post spawning behaviour of males and the absence of small males in the dead pitch. The in-river sex ratio was therefore estimated as the unweighted average of the hatchery sex ratio and the sex ratio for dead pitch sampling in the river

The in-river population was stratified into males, females, and jacks in the following way:

In-river count = Corrected total fishway count - total hatchery count

Total river males (TRM) = in-river count x unweighted sex ratio

River females = in-river count - TRM

River jacks = $TRM \times (jacks / total males)$ in the hatchery

Adult river males = TRM - river jacks

Age composition by sex was estimated as in the hatchery samples.

2.6 Total Estimated Terminal Run

The terminal run was defined as catch in DFO Statistical Area 23, including catch of Somass River and RCH chinook in native, sport, and commercial fisheries, plus spawning escapement to the Stamp River.

Table 1a. Summary of 1997 terminal run of Somass River chinook.

| Fishery | # Age 2 | # Age 3 | # Age 4 | # Age 5 | # Age 6 | Total |
|---------------------|---------|---------|---------|---------|---------|--------|
| Alberni Canal Sport | 129 | 4,288 | 5,316 | 309 | 37 | 10,081 |
| Somass Native | 19 | 2,044 | 3,662 | 0 | 0 | 5,726 |
| Barkley Sound Sport | 84 | 1,958 | 2,438 | 175 | 21 | 4,676 |
| Hatchery Returns | 106 | 15,665 | 3,631 | 13 | 0 | 19,415 |
| River Spawners | 838 | 5,683 | 7,061 | 42 | 0 | 13,623 |
| Total Terminal Run | 1,175 | 29,640 | 22,085 | 540 | 59 | 53,499 |

Overall, the terminal run was within a few percent of the forecast. However, the age 3

component of the total terminal run was 300% greater than forecast, while the age 4 return was approximately 50% of the forecast. Female escapement into the river totalled approximately 3,300 that produced a deposition in the river of approximately 12 to 13 million eggs, considerably less than the 50 million minimum level. Hatchery requirements were achieved from the 2,537 females that swam into the hatchery. Based on expanded CWT data, the estimated proportion of hatchery fish in the total return was 61% including only 51% of the chinook that spawned in the Stamp River.

Table 1b. Summary of total return from hatchery production only, based on expanded CWT.

| Fishery | # Age 2 | # Age 3 | # Age 4 | # Age 5 | # Age 6 | Total |
|---------------------|---------|---------|---------|---------|---------|--------|
| Alberni Sport | 0 | 1,742 | 1,709 | 0 | 0 | 3,451 |
| Somass Native | 0 | 1,136 | 2,921 | 0 | 0 | 4,057 |
| Barkley Sound Sport | 0 | 1,386 | 2,066 | 0 | 0 | 3,452 |
| Hatchery | 72 | 10,884 | 3,696 | 0 | 0 | 14,653 |
| River Spawners | 551 | 3,319 | 3,036 | 0 | 0 | 6,906 |
| Total Terminal Run | 623 | 18,467 | 13,428 | 0 | 0 | 32,518 |

3. Analytical Framework

3.1 Cohort Analyses

Cohort analysis is conducted using 'estimated' CWT recoveries to determine survival rates and exploitation patterns for Robertson Creek Hatchery chinook. The incorporation of in-river tag recoveries provides estimates of the true total exploitation rates for this stock. The cohort model used is documented in Appendix 2 of Starr and Argue (1991) and as modified by the Chinook Technical Committee (CTC) of the Pacific Salmon Commission (PSC, TCCHINOOK (98)-1). In determining incidental mortality, only the brood year method was used. The cohort model was modified by the CTC to account for the chinook non-retention fisheries implemented in Canada during 1996. Modifications are documented by the CTC in Appendix G of TCCHINOOK (98)-1.

For each brood year, information used from the cohort analyses include:

- annual distribution of catch and total fishing mortalities;
- survival of CWT groups to age 2 recruitment; and
- ocean (catch or total fishing mortality) and total exploitation rates by fishery and age.

3.2 Forecasting Models

Sibling regression models have been developed for total production from selected tag codes by age (including total ocean fishing mortality plus total terminal run for brood years used in the cohort analyses). Total production was calculated by multiplying the brood releases (for the selected tag codes) by the estimated total fishing mortality exploitation rates. Tag codes used are listed in Appendix 4.

Two combinations of terminal run and total production data have been used in the sibling regression models. Note that the first model developed in 1995 (i.e., Model 1 - Prod1), based on

regressing total terminal return at one age class to total terminal return at a subsequent age class is not used since constant ocean fishing mortality rates must be assumed between years.

- Model 2 (Prod2). This regression model uses total terminal return at a younger age class (independent variable) to predict total production (the surviving cohort in the ocean) of a subsequent age or ages from the same brood year. The dependent variable is the total (total ocean fishing mortality plus terminal run) production at a subsequent age or ages.
- Model 3 (Prod3). This regression model uses estimated total production (total fishing mortality plus escapement) of an age class(es) to predict total production of subsequent ages (i.e., the surviving cohort) from the same brood year.

Relationships between all possible age class combinations were examined using these two models. The actual models used for the forecast were based on the highest r² values. In the case where more than one age class is used, such as the total terminal run of age 2+3, the total terminal runs at age 2 and age 3 were summed. Estimates of surviving cohort include natural mortality factors and are estimated as the pre-fishery abundance of the youngest age being predicted. All regressions were forced through the origin.

3.3 Spreadsheet Model

A spreadsheet model was developed to examine response in terminal runs to changes in ocean harvest rates by fishery and age. Based on forecasted ocean abundance and average exploitation patterns through the current year (year i), the model estimates terminal runs expected in year i+1 and year i+2 based on changes to harvest rates in ocean fisheries.

Inputs to the spreadsheet include: estimated hatchery production (expanded CWT all tagcodes) in terminal runs by age and year, observed total terminal runs by age and year, and the forecasted age 3, 4, and 5 cohort abundance. Each regression forecast is expanded for total Somass system production to account for hatchery production not associated with the tag codes selected, as well as production from naturally spawning chinook. Expansion scalars are estimated within brood years and by age. These scalars are the ratio of total terminal run (hatchery plus natural) divided by the terminal run of tagged hatchery releases (expanded CWT). This expansion assumes that natural production from the Stamp River exhibits similar behaviour and encounters similar fishing pressure as the hatchery stock.

Other components of the spreadsheet include average total mortality exploitation rates by age and fishery, maturity rates and natural mortality rates by age; and matrices of 'fishery management scalars' for year i+1 and year i+2. These scalars are used to simulate management actions in the fisheries. Cohorts are harvested in ocean and terminal fisheries and/or allowed to become spawners. The surviving immature cohort is passed on to the next age in year i+2. Age 3 cohorts for year i+2 were estimated from average or recent average age 3 survival values (derived from the cohort analysis) times the smolts released in year i-3. These values were then expanded by average brood year scalars to account for natural production.

3.4 Forecast Error

A retrospective assessment of the forecasting methodology was presented in PSARC S96-01, for years 1988 through 1995. Including the 1996 and 1997 forecasts in this assessment, produces an updated estimate of the prediction error. The assessment uses a "leave-one-out" methodology.

Each regression model is re-calculated while omitting each data point (one year) once. The omitted data point is then used as the observed value and the predicted value compared to the observed. Average absolute deviations are used as the forecast error expected for each model.

4. Results and Forecast for 1998

4.1 Cohort Analyses

Cohort analyses for the 1983 through 1995 brood releases from Robertson Creek Hatchery were completed using the total escapement of coded-wire tags to the hatchery and the natural spawning grounds in the upper Stamp River. Returns from the latter 3 broods are incomplete through 1997 and are estimated using average maturation rates from the completed brood returns. Recoveries from the 1992 brood year are very limited (estimated number of recoveries = 10) and the cohort analysis is not reliable. However, for the nine brood years (1983 through 1991) for which total escapement recoveries are available, the total exploitation rates (expressed as adult equivalents to account for changes in size limits over time) have averaged:

ocean total mortality exploitation rates = 44.6% (CV = 13%) (ocean implies non-terminal fisheries, outside Barkley Sound), and brood total mortality exploitation rates = 65.7% (CV = 6%).

Returns from the 1993 brood year indicate significant reduction in exploitation rates (estimated ocean exploitation rate = 37% and total exploitation rate = 51%) as expected due to the conservation actions taken during 1995 through 1997.

Estimates of marine survival continue to demonstrate highly variable survival and very poor survival for the most recent brood year, 1995 (Table 2).

Annual distribution of the total fishing mortality on the Robertson Creek stock has been up-dated through 1997. Conservation actions taken in recent years are again evident in distribution changes (Table 3).

Table 2. Estimated survival rates (smolts released to Age 2 chinook) of coded-wire tagged (CWT) groups released from Robertson Creek Hatchery by brood years. Survival to Age-2 cohort include all recoveries, estimated incidental fishing mortality, and annual rates of natural mortality for all ages (Ages 2 through 5). Survival rates of Age-2 chinook only include recoveries of Age-2 chinook.

| Brood Year | Estimated % Survival Rate for CWT groups: | | | | | | | | |
|---------------|---|---------------|--|--|--|--|--|--|--|
| | Age-2 cohort | Age-2 chinook | | | | | | | |
| 1983 | 0.103 | 0.012 | | | | | | | |
| 1984 | 4.513 | 0.138 | | | | | | | |
| 1985 | 4.358 | 0.147 | | | | | | | |
| 1986 | 12.144 | 0.418 | | | | | | | |
| 1987 | 10.353 | 0.492 | | | | | | | |
| 1988 | 13.156 | 0.606 | | | | | | | |
| 1989 | 9.240 | 0.413 | | | | | | | |
| 1990 | 5.569 | 0.201 | | | | | | | |
| 1991 | 0.994 | 0.048 | | | | | | | |
| 1992 | 0.016 | 0.0002 | | | | | | | |
| 1993 | 2.50* | 0.071 | | | | | | | |
| 1994 | 4.51* | 0.147 | | | | | | | |
| 1995 | | 0.003 | | | | | | | |

Notes: * these broods have incomplete recoveries but are estimated based on observations to-date and assuming average maturation rates from completed brood years.

4.2 Production-based Forecast Models

Table 4 summarizes the results of Prod2 (terminal run vs. total production) and Prod3 regression models. The upper portion of these tables identify each sibling model, the x-value used in the 1998 forecast, the predicted value and its upper and lower 90% confidence bounds, the coefficient of the regression (intercept is zero), the r-squared value, and sigma (residual standard deviation of the regression). Asterisks identify regressions used in the 1998 forecast. Results of the retrospective assessment of each forecasting equation are also presented in the lower portion of tables. For each brood year, the observed and predicted values are presented. The mean absolute deviation (estimated prediction error) varied between 42% and 86% of the known data value for the Prod2, and 25% to 50% for the Prod3 model.

distributions based on cohort analysis through 1997 and using the brood year method to estimate incidental fishing mortality. Some fisheries with very few recoveries have been combined, e.g. Southern nets and other sport include southern BC and Washington recoveries. Table 3. Distribution of total fishing mortality for Robertson Creek Hatchery chinook stock;

4.3 Spreadsheet Model

The terminal run forecast can vary depending on the model used, the scalars used to expand the hatchery production to total Somass production, and management actions in ocean fisheries. Forecasts of total terminal run to Barkley Sound are presented for both Prod2 and Prod3 models in Table 5. Forecasts for the 1998 terminal run range from 53,400 to 64,100 (average is 58,800), based on that 1998 expected ocean exploitation rates from planned fisheries in Alaska and British Columbia¹ and final estimates of the stock composition in fisheries (Chinook Technical Committee model, calibration 9812)

When the age-specific forecasts are combined to predict the total terminal run to Barkley Sound, the forecasting error is, on average, less than for the individual regression models. Figure 1 compares the annual deviations from observed total terminal runs for the Prod2 and Prod3 models. Over the period 1988 to 1997, the models average 1 to 2% error in the forecast. However, when the forecast error is expressed as the average absolute deviation from annual forecasts, the average error increases to 25% for Prod2 and 20% for Prod3. On an annual basis, the forecasted terminal runs can be expected to vary by ± 20 to 25% of the forecast value.

Table 5. Summary of forecasted terminal run size (numbers of chinook) assuming ocean exploitation rates similar to those in 1997.

| Terminal Run size | Prod2 Model | Prod3 Model | Average |
|-------------------|--------------------|-----------------|----------------|
| by ages: | Terminal vs. Total | Total vs. Total | Forecast value |
| Age 3 | 4457 | 5117 | 4787 |
| Age 4 | 46288 | 38036 | 42162 |
| Age 5 | 13378 | 10288 | 11833 |
| Total | 64123 | 53441 | 58782 |
| Number of females | 33489 | 27092 | 30290 |
| % Females | 52% | 51% | 51.5% |

4.4 Escapement Goal

The escapement goal for 1998 is consistent with the minimum target accepted by PSARC in 1994 (PSARC Advisory Doc. S94-1). Given the expected terminal run size (above, average forecast value assumed) and the allocated terminal catches in sport and Native fisheries (21,900 catch referenced in footnote 1); the minimum escapement goal is achievable. The minimum egg requirement for hatchery and natural spawners in the Stamp River is 31,900 spawning chinook in 1998 (Table 6).

4.5 Recommended Forecast

The recommended forecast for the total terminal run of Robertson Creek Hatchery and Stamp River chinook (age 3,4, and 5) to Barkley Sound in 1998, is 58,800±20% based on averaging the

¹ Documented in June 29, 1998 memo from E. Lochbaum to P. Sprout, internal departmental memo.

Prod2 and Prod3 forecasts. The age structure of the return is projected to be: 8% Age 3, 72% Age 4, and 20% Age 5; with an expected sex ratio of 51.5% females. The number of chinook required to meet the minimum spawning escapement goal is 31,900. This goal is achievable if ocean-fishing mortality is equal to or less than those assumed (footnote 1) and terminal catches do not exceed those allocated.

Table 6. Derivation of the number of spawners needed to meet the minimum egg requirements in the 1998 chinook return.

| ESTIMATION PROCEDURE | NUMERICAL VALUES |
|--|------------------|
| Minimum egg target for natural spawners | 50 Million eggs |
| Egg requirement for Robertson Creek Hatchery | 9.3 Million eggs |
| % Females expected in terminal run | 51.5% |
| Average Fecundity expected | 4500 eggs/female |
| | |
| # of females for Hatchery | 2,061 |
| Min. # of females for Natural spawners | 11,080 |
| Pre-spawning mortality allowance | 20% |
| Total # females required (including mortality allowance) | 16,426 |
| Total number of chinook @ 51% female ratio | 31,895 |

4.6 Other West Coast Vancouver Island chinook systems

The detailed assessments and forecasts of the RCH/Stamp chinook are undertaken annually for management of that major stock plus as an indicator of the expected returns to the naturally spawning chinook populations along the west coast of Vancouver Island. Terminal run size and spawning escapements to the RCH/Stamp indicator stock have been similar over the past three years and are projected to be similar and relatively weak again in 1998. However, returns to some of the natural systems were better in 1997 than indicated by this stock (see Appendix Table 3). This is particularly true for returns to populations along the northern half of the Island (Areas 25 to 27); seven populations in these Areas are, in aggregate, used in the Pacific Salmon Commission (PSC) to indicate trends in escapement to naturally spawning chinook along the WCVI.

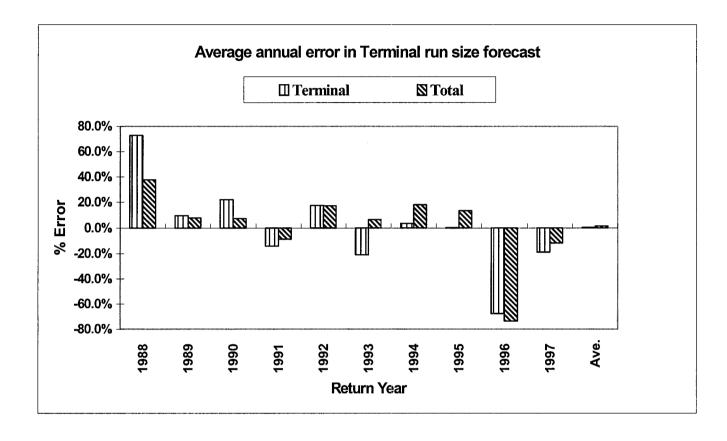

While this is positive indication that the conservation actions taken by Canada to protect these populations has been successful, there are two concerns which suggest caution when planning 1998 chinook fisheries. First, the apparent recovery in the northern populations is not evident in the more southern naturally spawning populations (e.g., the Area 24 populations and Nahmint River). Secondly, the age structure of the 1997 returns was strongly age-4 chinook. Returns of Age-3 chinook to the natural systems did not appear as strong as the return to the RCH/Stamp indicator stock. Consequently, returns in 1998 may be reduced if survival of the 1994 brood year declined again. The only indication of brood survival for these northern populations is the return to Conuma Hatchery. Age-3 returns in 1997 to Conuma were only about 25% of the Age-4 returns observed in the sport fishery and in the escapement.

While the condition of most naturally-spawning chinook populations along the WCVI have improved during recent years, the above concerns and the relatively weak return forecasted for the RCH/Stamp stock indicate a continued need for conservative 1998 management plans in fisheries impacting these stocks.
