<sup>1</sup> This series documents the scientific basis for the evaluation of fisheries resources in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

<sup>1</sup> La présente série documente les bases scientifiques des évaluations des ressources halieutiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

### Abstract

Commercial landings and catch rates, and research vessel survey abundance indices are at or near record lows for the 4VWX/5Zc white hake stock unit. For assessment purposes the stock unit has been partitioned into separate 4V, 4W, and 4X/5 components to reflect discontinuities in white hake distribution. The downward trends in abundance indices and catch rates for 4X/5 suggest that this portion of the stock may be at risk of collapse. Abundance indices of the 4W and 4V components of the stock have remained near record lows since 1995 and 1987 respectively, showing only weak signs of recovery. Current management measures will need to reduce removals significantly to sustain 4VWX/5 white hake.

### Résumé

Les débarquements et les taux de capture de la pêche commerciale de même que les indices d'abondance des relevés par navire de recherche de l'unité du stock de merluche blanche de 4VWX/5Zc ont atteint ou presque atteint les niveaux records les plus faibles. Aux fins de l'évaluation, l'unité du stock a été divisée en éléments distincts pour 4V, 4W et 4X/5 afin de refléter les discontinuités de la répartition de la merluche blanche. Cette tendance à la baisse des indices d'abondance et des taux de capture en 4X/5 porte à croire à un risque d'effondrement pour cette partie du stock. Les indices d'abondance pour les éléments 4W et 4V sont demeurés à des niveaux faibles presque records depuis, respectivement, 1995 et 1987 et les signes de rétablissement sont limités. Des mesures de gestion devront être prises afin de réduire les prélèvements de façon appréciable et ainsi assurer le maintien de la merluche blanche en 4VWX/5.

## Introduction

White hake (*Urophycis tenuis*) on the Scotian Shelf and in the Bay of Fundy was added to the stock assessment agenda of the Department of Fisheries and Oceans (DFO) in 1995, and first assessed in 1996 (Fowler et al., 1996). Previously this species was managed only in the Gulf of St. Lawrence, the fishery for which was closed in 1995. Quota reductions for fisheries on more traditionally sought species (e.g. cod, haddock, pollock) have resulted in the re-direction of fishing effort on species such as white hake that were historically of insufficient commercial value to deliberately target.

## Stock Structure and Management Units

The stock structure of white hake is not well understood, but does not appear to coincide with the boundaries of the current management regions. Based on a review of existing information pertaining to white hake stock distributions and spawning activity (Fowler et al., 1996), which demonstrated consistent discontinuities in distribution over time (Figure 1), and differences in patterns of abundance over time evidenced by summer research vessel (RV) surveys, we now assess 4V, 4W and 4X/5 as separate components of a stock complex. The present management units for white hake (*Urophycis tenuis*) are North Atlantic Fisheries Organization (NAFO) Divisions 4T, 4VWX+5Zc (Figure 2), and the United States part of 5Z plus 5Y and 6. It is likely that white hake in 4X/5 are contiguous with the US Gulf of Maine - Georges Bank stock unit, and that the 4V fish are contiguous with the 4T Gulf of St. Lawrence stock unit.

## Fisheries Management Activities

Before 1996 there were no restrictions on fishing effort for white hake in 4VWX and 5Zc. Based on the 1995 Stock Status Report for white hake , which stated that catches should be restricted to the average landings of 2,500t observed during the 1970s, a Total Allowable Catch (TAC) was implemented for the first time in 1996. The fixed gear under 65' fleet sector was allocated 3420t, with 2,000t for 4X , 920t for 5Zc, and 500t for 4VW. For 5Zc, the fixed gear quota in 1996 was set at double the 1994/95 landings. The rationale for the increase was that the cod and haddock TACs on Georges Bank were higher in 1996 relative to 1995. Other fleet sectors have been restricted with by-catch regulations: 20% limit for the ITQ fleet under 65', 10% limit for trawlers over 65'. In 1997 the fixed gear under 65' TAC was reduced to 3100t, with 2400t allocated to 4X/5Zc and 700t to 4VW. There have been no separate allocations for 5Zc since 1996. The 1998 TAC is 3500t. The fixed gear (less than 65') quota is allocated proportionally to each association based on number of vessels per group. Quota trades between groups are permitted.

## The Fishery

Landings from 1966 to 1998 are shown by NAFO Divisions in Table 1. Most of the landings during the past three decades have come from 4X. Total landings have declined since 1995. Landings were already in decline throughout the 1990's in 4VW. Landings from 5Zc began to fall in 1994. Area closures in 4VW prompted a general shift in fishing effort to the 4X/5 region in 1995, primarily to the southwestern (more offshore) unit areas 4Xq, 4Xp and 4Xn (Table 2). Landings of white hake from 4X/5Y rose considerably in 1995 as a result, but then dropped in 1996 to the lowest level seen since 1983, and have since continued to fall. Landings in 4VWX/5 to date (1423t to Oct 7, 1998) suggest that 1998 may prove the lowest in three decades.

The seasonal characteristics of the Canadian fishery on white hake (Table 3) are difficult to interpret, being confounded by management measures applied to major stocks (cod, haddock, pollock) that can result in sudden redirections of effort onto or off of white hake. In 1995, for instance, the suggestion of a seasonal pattern of spring/early summer and fall peaks, often indicative of migratory movements of a population, actually reflects fishery responses to the end of March closure of Browns Bank and fall exhaustion of 4X cod/haddock/pollock TACs.

The 1993 to 1998 Canadian landings by unit area and gear type (Table 4) depict a transition in the fishery from initial domination by longliners with gillnets and otter trawlers secondary, to relative parity between longline and gillnet sectors by 1997. Concern has been expressed that the fishing mortality associated with the increased proportion of the landings being taken by the gillnet fleet may be greater than would be suggested by landings alone, due to a perceived practice of leaving active nets untended in order to return to port to offload. This matter should be investigated to ensure compliance with the 40 net per boat limitation, and otherwise dissuade any tendency to leave nets untended, should the allegations prove founded.

The proportion of the Canadian landings for which the logs indicate that white hake was directed for, is shown from 1966 to 1998 in Table 5. Until 1988 a large proportion of the landings were unspecified with respect to the species being targeted, nor has the processing of commercial landings since then been able to distinguish between white and red hake. Given the small size of red hake, which average 30-35cm (Scott and Scott, 1988), it appears unlikely that they could represent any appreciable component of the catch in Scotian Shelf or Bay of Fundy waters, as the fishery rarely catches hake under 40cm. Some doubt exists regarding the accuracy of the reported landings in some years, especially when fishing was restricted by pollock quota. It has been suggested that some portion of the white hake landings might actually be misreported pollock ('black hake'), which would inflate both the total landings and the apparent proportions of directed catch of white hake in the relevant years.

The landed values and rough estimates of the price per kg during the past several years are shown in Table 6. The calculations suggest that the unit price for white hake

increased from \$0.37/kg in 1988 to \$1.05/kg in 1995. The price has remained at about \$1.00/kg since 1995. The landed value has been between 2 and 4 million dollars annually.

### Length Composition of Landings

Sampling of the Canadian commercial landings for white hake length composition had been inconsistent over time, area and gear sector until the mid-90's (Table 7). The 1993 to 1998 samples allow some comparison between gear types and areas (Figures 3a-c). No clear trends with time are evident in the gillnet and otter trawl samples. We only have gillnet samples from 4X/5, and they exhibit a much narrower length range than other gears, with a mean of 69-70cm across all years. Samples from 4X/5 depict larger fish than 4V in both longline (59-67cm vs 51-58cm) and trawl (61-71cm vs 41-55cm) fisheries. Longliners in 4X/5 caught relatively more large fish in 1997-98 than in previous years, while those in 4V caught fewer large fish than in previous years. The increase in mean length of the size composition in 4X/5 may reflect a westerly shift in fishing effort in response to declines in more nearshore catches , as white hake tend to be larger to the west or offshore (Table 8).

### Commercial Catch Rates

A dataset of 1990-98 catch per set for 144 identified vessels that directed for white hake for at least 5 successive years during 1989-98 (Table 9) was created to examine effort and catch per unit effort trends with time. This subset of the catch/effort database represents 17-54% of total landings by year since 1992, with coverage since 1995 at 41% or more. The commercial catch rates of these index fishers, illustrated in Figure 4, have declined since 1996 for all major fleets (longline, gillnet, otter trawl). The decline has been very extreme for longliners and gillnetters, and 1998 presents the lowest catch rates in the series (1990-98) for all fleets.

Analysis of variance using a generalized linear model (S-Plus), of just the 4X/5 catch rates (Table 10), was conducted to obtain standardized catch rates and fishing effort for the 1990-98 period. There were insufficient landings from 4VW to include in the analysis. The formulations are the same as achieved using STANDAR, but with the added flexibility of incorporating interaction effects into the model, and permitting iterative reduction in variance to determine order of entry of main effects. The resulting model demonstrates the critical role of gear sector, location and month of fishing on catch rates, as well as the significance of interactions between year and all other main effects. No attempt has been made to extend the analysis beyond two-way interactions, and a prediction for catch rates by year was generated from this model. The standardized catch rates suggest a cyclic pattern of peaks (1991,1996) and troughs (1994) that may reflect the passage of dominant cohorts, but the long-term trend (peak to peak) is downward.

## Research Vessel Survey Abundance Trends

Summer research vessel (RV) survey biomass and catch rate estimates have been computed separately for 4V (strata 440-452), 4W (strata 453-466), and 4X (strata 470-495). The survey strata and their corresponding NAFO division associations are shown in Figure 5. An intercalibration study (Fanning, 1985) to compare catchability of the three different vessels used over the time series (1970-1998) suggests that no adjustment is required to standardize white hake catches across survey periods (catchability coefficient = 1.0). And based on catch distributions from recent 4X summer ITQ (Individual Transferable Quota) surveys (Figure 6), we feel confident that summer RV sampling of white hake (Figure 7) has not been confounded by the inability of research vessels to sample inshore areas. Very little white hake is caught outside the distributional limits of the summer RV survey.

Prior to at least 1981, no attempt was made to distinguish red hake (*Urophycis chuss*) from white hake on surveys. Since at least 1983 the policy was changed, such that the two species were intended to be identified, but some doubt exists as to the accuracy of the methods used to identify the two species. Based on one leg of the 1996 summer RV survey for which a proven technique (gill raker counts) was consistently used to separate the species, it is apparent that red hake can account for up to half the catch in numbers of the two species. As red hake rarely exceed 35cm, the risk of misidentification is limited to the pre-recruitment component of the white hake catch, but this confounds interpretations of potential recruitment for white hake. A study of identification error probabilities using the different methods should be conducted to quantify possible adjustments for this problem.

Summer RV biomass estimates for 4X (Table 11a and Figures 8-10) have dropped sharply since 1996, with the 1998 estimate of 7824t the lowest since 1971. The size composition (Figure 11) has shifted towards smaller fish since 1995, but with no evidence of a recruitment pulse since 1996. Biomass estimates from the Georges Bank RV survey in March (Table 9 and Figure 10) dropped since 1991 to a record low in 1996, and remain low. Summer RV estimates for 4W (Table 11b and Figure 8) declined from 1986 to a record low in 1995, and have since risen slightly but consistently each year thereafter (2655t in 1998), mostly due to growth rather than recruitment (Figure 12). They are still the lowest of the three components (4X, 4W, 4V) in the summer RV surveys. Summer RV estimates for 4V (Table 11c and Figure 8) dropped sharply from 1985 to 1987, and have since remained low but relatively stable (3096t in 1998). An increase in 1997, mostly attributable to fish of recruited size (Figure 12), was not maintained in 1998, possibly reflecting transiency of 4V white hake. The spring RV survey of 4VsW (Table 12 and Figure 13) indicates extreme decline in biomass since 1987 to a record low in 1993, and began to rise back in 1996. Catches in the 4VsW Sentinel survey (Figure 14) dropped from 1996 to 1997. Catches in the 4Vn Sentinel survey (Figure 15) dropped from 1994 through 1996, but rose in 1997. US spring and fall surveys from 1970 to 1997-8 (Figure 16) track reasonably well within themselves, but vary considerably from the Canadian summer RV survey, especially prior to 1982. Mean weights per tow for both US spring

and US fall surveys since 1983 are generally lower than previous years, and have been at or near record lows since 1994. Early (1978-84) Canadian spring and fall surveys (Table 13, Figures 10 and 13) also diverge from the Canadian summer survey, and although suggestive of some degree of correspondence with the US surveys, were not conducted for enough years to substantiate a relationship. Mean individual weights of white hake in summer RV surveys (Figure 17) in general have declined since 1984.

The declines in 4V may in part be due to colder water temperatures causing either expiration or relocation of white hake. Summer temperature profiles for 1970-92 on the Scotian Shelf (Simon and Comeau, 1994) demonstrate a long-term cold-water phase throughout the 1980s and into the 1990s. In 4Vn and 4Vs bottom temperatures fell below 2.5°C, less than the 3°C loosely regarded as the lower temperature threshold for white hake, and far below the 4°C threshold for large catches of this species from RV surveys. In 4W the temperature didn't fall below 5°C, suggesting that declines were attributable to fishing. This may account for the slight but consistent recovery trend in 4W abundance estimates.

The standardized commercial and RV survey catch rates for 4X+5 and 4X respectively, track one another quite well in most years (Figure 18), giving some confidence that we are not seeing extreme anomalies. Survey catch rates for fish over 45cm, a compromise length to reflect fishable biomass without including misidentified red hake, show less correspondence with the commercial catch rate (mostly due to the 1996 datum).

### **Estimates of Fishing Mortality**

Removals at length (Table 14 and Figure 19) for combined longline/gillnet/otter trawl fisheries from 1993 to 1997 (minimum 97% of landings in any year) were estimated by applying RV survey length-weight relationships to the commercial length frequencies, and bumping up the result in proportion to the landings. A von Bertalanffy growth equation for the US Gulf of Maine - Georges Bank white hake stock unit (Sosebee, 1998) was then used to assign ages to the removals at length, and mortality rates, just for the 4X/5 stock component, estimated using the linearized catch curve based on age composition. This method is described in section 4.4.5 of Sparre et al (1989). The same method was applied to the RV survey catch at age without weighting by landings. As well the traditional method of pooling ages according to

$$Z = \text{natural log}[\text{number age 3-6} / \text{number age 4-7}]$$

, was applied to the unweighted RV catch at age for comparison.

Using either of the Jones or Sparre methods, the mortality rates for the 4X white hake derived from RV survey catch at length data depict an increase in fishing mortality from 1980-81 through 1993, followed by a decline through 1995, an increase in 1996, and

decline through 1997 or 1998 (Figure 20). From 1992 through 1996 the catch curve mortalities depict exploitation rates in excess of 50%. The mortality rates derived from commercial catch at length data for the 1993-1997 period in 4X/5 reflect the same pattern as the RV mortality rates, but are less indicative of a continuing decline after 1996. The overall patterns of mortality, regardless of data source or computational method, correspond with each other, and appear to broadly follow the pattern of landings as well.

### Acknowledgements

I would like to thank Kees Zwanenburg for drawing attention to the pervasive decline in individual weights of most species in the ECNASAP survey database. Paul Fanning resolved some last-minute confusion about catch curve mortality estimates. Peter Comeau remembered the hake identification problem on the summer RV survey. Gerry Black (ACON) was always there. And Steve Campana fielded yet another addition to an overloaded working group.
