# Assessment of Cod in Division 4X in 1999 

by

D. S. Clark and S. D. Paul<br>Department of Fisheries and Oceans<br>Biological Station<br>St. Andrews, New Brunswick<br>E5B 2L9

> ${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.
${ }^{1}$ La présente série documente les bases scientifiques des évaluations des ressources halieutiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au secrétariat.

#### Abstract

Landings of cod from Division 4X have fluctuated since 1948 between 35,500t and a low of $8,200 t$ in 1998. The quota for $1999(7,000 \mathrm{t})$ was prorated to $7,910 \mathrm{t}$ for a 15 -month fishing year ending March 31, 2000. Landings to October 1 were 5,500t. In both 1998 and the first half of 1999 landings were spread amongst ages 3-7, with the 1996 year-class contributing more than expected. The summer RV survey catch per tow was down sharply from 1998, and was among the lowest in the time series. The indices at all ages except 7 were below average. The ITQ survey was down substantially from 1998 in weight and also down in numbers, aside from large numbers at ages 0 and 1.

Based on analyses which suggested either natural mortality (M) or survey catchability (q) may have increased in recent years, a variety of ADAPT formulations were explored. No formulation seemed to adequately capture the variability in data from recent years. Two formulations which best represented the trends in recent years were examined in greater detail; both indicate that the spawning stock biomass is currently at a low level. The $\mathrm{F}_{0.1}$ yields projected for the fishing year commencing April 1, 2000 are in the range of 4,000 t to 6,000 t.

## RÉSUMÉ

Les débarquements de morue en provenance de la division 4X fluctuent depuis 1948 entre 35500 t à et 8200 t en 1998. Le quota de $1999(7000 \mathrm{t})$ a été corrigé au prorata à 7910 t pour une année de pêche de 15 mois se terminant le 31 mars 2000. Les débarquements au $1^{\text {er }}$ octobre s'élevaient à 5500 t . Les débarquements de 1998 et ceux de la première demie de 1999 étaient composés de poissons âgés de 3 à 7 ans, l'apport de la classe d'âge de 1996 étant plus élevé que prévu. Les captures par trait de chalut du relevé de recherche d'été ont été nettement inférieures à celles de 1998 et comptaient parmi les plus faibles de la série chronologique. À l'exception de l'âge 7, les indices pour tous les âges étaient inférieurs à la moyenne. Les résultats du relevé par QIT étaient passablement inférieurs à ceux de 1998, tant en poids qu'en nombre, mais les individus d'âges 0 et 1 étaient très nombreux.

Diverses formulations ADAPT ont été étudiées à partir des analyses qui portaient à croire à une augmentation au cours des dernières années de la mortalité naturelle (M) ou de la vulnérabilité à la capture (q) au moment du relevé. Aucune formulation ne permettait d'expliquer convenablement la variabilité des données des dernières années. Les deux formulations qui représentaient le mieux les tendances au cours de ces années ont été examinées de façon plus approfondie : les deux indiquaient une biomasse de géniteurs actuellement faible. Les rendements prévus au niveau $\mathrm{F}_{0.1}$ pour l'année de pêche débutant le $1^{\mathrm{er}}$ avril, 2000 se situent dans la gamme des 4000 t à 6000 t .

## BRIEF HISTORY OF FISHERY AND ASSESSMENT

Prior to 1963, the cod fishery in Division 4X (including the Canadian portion of Division 5Y; Fig. 1) was primarily an inshore fishery. The majority of fishing was done by Canadians, handlining and long-lining from small vessels. Between 1957 and 1962, 82-87\% of landings were 'inshore', with the remainder split between Canadian and U.S. vessels fishing Browns and LaHave banks (Halliday, 1971). Landings showed a slow decline between 1948 and 1958 from 20,000t to $12,000 t$ (Fig. 2). This decline was attributed primarily to decreases in effort (as fishing was directed more for haddock) but also to declining abundance (Beverton and Hodder, 1962). Foreign and Canadian otter trawlers (OT) began fishing for cod on Browns and LaHave banks in 1962. Due to the increased exploitation on the offshore banks, almost exclusively by OT, landings increased rapidly after 1962, to a maximum of about 35,500t in 1968.

In 1970, landings dropped by 10,000 t. This reduction came almost entirely from Canadian and foreign OT landings, while landings by longline (LL) and handline (HL) were largely unaffected. There was no quota for cod in 4X at this time; however, due to the mixed species nature of the groundfish fishery in this area, management measures implemented to regulate fishing on one species inevitably influenced others. The large reduction in cod landings in 1970 has been linked to reductions in fishing effort due to the establishment of quotas for haddock and the closure of Brown's Bank to fishing for March and April, both of which occurred in 1970.

The 4X area was recognized as including a number of separate cod spawning stocks whose distributional boundaries were unclear, thus, it was felt to be inappropriate to assess it as a unit stock. Assessments were conducted for the offshore (primarily Browns and LaHave banks) which was thought to be a discrete stock, and total allowable catch (TAC) was first established for this area in 1975. These TAC's, however, are thought to have had limited impact on landings due to misreporting to the inshore area, where no TAC was in place (Gagne et al., 1983).

Landings throughout much of the 1970's remained in the region of 20,000t-24,000t, increasing to $31,000 t$ by 1980 . As a result of this rapid increase in landings to near historically high levels, a TAC was imposed for 4X cod for the first time in 1982. The TAC was set at 30,000t (a level selected to prevent landings from exceeding the maximum landings observed in the early 1980's), and held at this level for 4 years. It had little influence on the landings as a whole, which declined from 32,000t to 21,000t between 1982 and 1985. Aside from the <65ft draggers, no quota group met its allocation from 1983 to 1985 (Campana and Simon, 1986).

The treatment of cod in 4 X and 5 Yb as a single stock for assessment purposes commenced in 1985. This step was taken partly in response to changes in fishing practices, and partly because mixing between inshore and offshore stocks appeared to be more extensive than had previously been thought. It was not considered possible to separate landings reliably between inshore and offshore areas. This was not a requirement for logbook records, and the increasing range of much of the fleet made the apportioning of landings to inshore or offshore on the basis of tonnage class unreliable. Furthermore, the results from tagging of cod on Browns Bank in spring suggested there may be mixing between inshore and offshore stocks, as well as among inshore spawning groups. It was felt that an assessment which grouped all of 4 X would be acceptable due to the mixing occurring among spawning groups, and the mixed nature of the fishery (Campana and Simon, 1986).

With the imposition of more stringent quotas for 4X cod in 1986, there were suggestions that unreported landings and misreporting by species had become serious problems, particularly in 1987 and 1988 (Campana and Simon, 1987; Campana and Hamel, 1990). Reported landings since 1989 are considered more accurate due to increased enforcement, and the institution of mandatory weigh-outs in 1990 (Campana and Hamel, 1992; Gavaris, 1993).

Reported landings remained around 20,000t from 1985-1989, then increased to 28,000t in 1991, and subsequently fell to a low of 9,000 t in 1995. The recent reductions in landings are a reflection of the TAC, which declined from 26,000t in 1992 to 9,000 t in 1995. The 1999 quota was 7,000t, however, was prorated to 7,900t to include a 15-month fishing year ending March 31, 2000. Landings to October 1 were 5,500t (70\%).

## SPAWNING AREAS FOR COD IN NAFO DIVISION 4X

Spawning is distributed broadly through the area, both geographically and seasonally. Spawning occurs in the fall (October-December) along the coast of Nova Scotia. This spawning has been described most thoroughly for Halifax Harbour and around Sambro Head to St. Margarets Bay (McKenzie, 1940). Fish aggregating in the deeper water around Sambro Head were the target of a seasonal gill net fishery, which landed roughly 1,000 t of cod annually. This fishery began to decline in the early 1980's, and has now all but disappeared. Fish in spawning state have been caught in this area in recent years, and juvenile cod ( $3-5 \mathrm{~cm}$ ) were captured with a beach seine in Halifax Harbour in May, 1999. Fishermen also continue to catch ripe fish in the Shelburne area in the fall.

Spawning occurs in the spring, primarily on Brown's Bank, but also in other areas. Ripe fish were caught in spring RV surveys conducted in the early 1980's in the Bay of Fundy and around Browns Bank. Fishermen have identified the waters off Digby Neck and Grand Manan as areas where they encounter spawning fish in the spring.

Egg and larval studies support these observations, showing eggs and larvae distributed along the coast of Nova Scotia and into the Bay of Fundy in fall, and on Brown's Bank and in the Bay of Fundy in spring (Neilson and Perley, 1996). The presence of both spring and fall spawners results in a bimodal length frequency for cod at age 1 in the RV and ITQ surveys.

The degree to which fish that spawn in different areas in 4X mix during the year is not clear. Fish tagged in inshore areas show little dispersal from the tagging area, and those tagged in the Bay of Fundy tend to be returned from inside the bay. Fish tagged on Browns Bank in spring, however, disperse widely through the 4X area, with some also recaptured in 5Z. Similarly, some fish tagged on Georges Bank are recaptured in 4X. The proportion of fish tagged on Georges Bank which move into 4 X has generally been considered small, however, recent analyses bring this into question (Hunt et al., 1999). Further work on stock structure in this region is required to resolve this issue.

## DESCRIPTION OF FISHERY

The fishery in 4X takes place year round. Landings generally peak in June and July, however in recent years landings have been distributed more evenly throughout the year (Table 1). The hook and line fishery accounts for roughly half of the landings, with about $10 \%$ more coming from the gill net fishery. The ITQ dragger fleet accounts for the bulk of the remainder, with the EA and TVRP vessels accounting for less than $10 \%$ of the landings (Table 2).

The proportion of landings from the winter-spring fishery, prosecuted predominantly by the otter trawl fleet, declined in the mid-1990's, but increased again in 1998. The increase in 1998 was due to fishing directed primarily for haddock along the Shelf edge around Brown's Bank. Late starts in the fixed gear fishery since 1996 had reduced landings early in the year. In 1997 and 1998 TC $1 \& 2$ hook and line vessels did not catch as high a proportion of their quota in June and July. In some areas this has been a result of poor catch rates; the quota could not be caught in the usual time span. In some areas in 1998 fishermen held off fishing until fall hoping for better inshore fishing due to the low catches experienced by those who started in early summer. In 1999 fishing was reported to have been improved in inshore areas, although it remained poor in some parts of the Bay of Fundy in the summer, and also off Halifax in the fall.

The distribution of landings (Table 3) has also shifted to the west in recent years, with landings from 4Xmno declining to a greater degree than in other areas. In 1997, the proportion of landings coming from the Bay of Fundy was the highest ever, at $48 \%$. There has been little change in the proportion of the hook and line fishery in the Bay of Fundy. The gillnet fishery, however, has switched from a predominantly Scotian Shelf fishery to a fishery split almost equally between the Scotian Shelf and Bay of Fundy (Fig. 3a). Similarly, the otter trawl fishery until recently was concentrated on the Shelf in the spring and winter, moving into the Bay of Fundy in the summer. This fishery was conducted primarily in the Bay of Fundy throughout the year from 1993-1997, resulting in an unusually high proportion of landings coming from the Bay (Fig. 3b). In 1998 and 1999 the winter fishery was again focused primarily on the Shelf, and the proportion of landings coming from the Bay has declined.

Fishermen from around 4X reported mixed success in the cod fishery in 1998. Representatives from both the otter trawl and longline fleets reported that fishing was generally poor for cod east of Browns Bank. In coastal areas throughout 4X fishing was poor in 1998, with some quota groups landing only a small percentage of their quota. Fixed gear groups fishing further offshore and in deeper water, however, reported good fishing. In 1999, most fixed gear groups reported improved fishing. The inshore fishery was better than in the past 3 or 4 years, although it continued to be poor in some areas (Table 4 ).

Effort by the otter trawl and the tonnage class (TC) 2 and 3 longline and gillnet fleets has declined since the early 1990's, although effort directed for cod increased slightly in 1996 and 1997(Clark et al. 1998). Otter trawl effort did not increase in 1998 (Fig. 4a). Effort remains substantially lower than seen in the early 1990's, however fishing mortality was considered to be unsustainable at that time. It is of some concern that fishing effort is currently higher than in 1994, since fishing mortality has been estimated as well above $\mathrm{F}_{0.1}$ for cod and pollock in that year. Effort has also declined substantially in recent years for large gillnet vessels (Fig. 4b).

Effort in days fished is available since 1996 for all vessels (Table 5a). In 1999, a further decline in effort is expected based on an extrapolation from the effort expended in landing the first $41 \%$ of the cod quota. The number of vessels actively engaged in the fishery has dropped since 1996 for all gear types (Table 5b). Effort for all fixed gear vessels declined in 1998, but particularly for handliners.

Catch rates for mobile gear have declined annually since 1996 (Table 5c). Fishermen have indicated this is not indicative of abundance, since they have been avoiding cod as the cod quota has dropped and the haddock quota increased. They maintain that cod is primarily taken as bycatch when fishing for other species. The proportion of cod caught by OT in cod directed trips has dropped from 59\% of landings in 1996 to 36\% of landings in 1999.

Catch rates have increased to the highest level seen in the 4 years examined for all fixed gear types in 1999 (Table 5c). The increase is particularly marked for gillneters, whose catch per day has doubled since 1998. This is in keeping with the observations by fixed gear fishermen of improved success in the fishery in 1999.

## CATCH AND WEIGHT AT AGE

## Commercial Samples

The 1998 catch at age was based on 54 samples that included otoliths, and 93 additional length frequency samples, an increase in numbers from 1997. However, the necessity for combining some cells in the standard age-length key has continued due to a lack of data (Tables 6 a,b). In the first half of 1999, 18 samples which include otoliths, and an additional 37 length frequency samples are available (Tables $6 \mathrm{c}, \mathrm{d}$ ). The involvement of a number of industry groups has increased the amount of commercial sampling. Only selected samples have yet been aged for 1999.

Samples were aggregated by area, quarter and gear type (Clark and Brown, 1996). Aggregation by area was done to account for growth differences between the Bay of Fundy (4Xqrs5Yb) and southwest Scotian Shelf (4Xmnop). Landings reported from 4Xu (unspecified area) were apportioned to Bay of Fundy and Scotian Shelf for each statistical district according to known area landings by gear type and tonnage class for that statistical district and quarter. Landings reported from 5Y from 1983 to 1986 for each statistical district were divided between Scotian Shelf and Bay of Fundy according to the same protocol. Misreporting to 5Y from 4X was identified as a problem in these years in past 4X cod assessments (Campana and Simon, 1987, 1988).

Commercial samples are separated into the Bay of Fundy and the Scotian Shelf, however, variability in growth rates and length composition are still found among fishing grounds within each area. Cod in 4 Xm in summer are generally smaller and slower growing than in other areas on the Scotian Shelf, and length frequency samples from 4Xo tend to include a greater range of lengths. A number of factors are, therefore, considered when aggregating data for the catch at age.

Due to the variability in fisheries within the region, sampling must be proportional to landings from different fishing grounds in order to ensure that the reconstruction of landings is an accurate reflection of the removals. Observer samples in particular tend to be focused on specific fishing grounds and may not be representative of the wider fishery. Where sampling is not proportional to landings, a finer scale of aggregation is at times required.

For the otter trawl fishery in 1998 there were only 4 samples of the 44 collected by the port sampling program which came from trips where cod was the main species caught. The bulk of cod landings, however, came from cod directed trips. In most cases, the assumption was made that the length frequency for cod in trips where cod was a by-catch was representative of the entire cod fishery; however, samples from monkfish directed trips ( 250 mm mesh) and redfish trips ( 90 mm diamond mesh) were down-weighted in the catch at age, as they were thought to be unrepresentative of the bulk of cod landings. Six samples were taken from the otter trawl catch in the Bay of Fundy for the fourth quarter in 1998. Of these, four were taken from cod caught in 4Xq from 90t of landings and one each from 4Xr and 4Xs which contributed 620 t of landings. The samples caught in 4Xq were all from haddock-directed trips inside of German Bank, and displayed a truncated length range in comparison to those taken from 4Xrs (Fig. 5). In light of this, the catch at age for 4 Xq was derived separate from that for 4 Xrs 5 Y in this quarter.

Sampling from the hook and line fishery came primarily from 4Xp and 4Xn in 1998, although the landings were higher in 4Xo. Those samples taken in 4Xo tended to have a broader length range than samples taken in 4 Xn or 4 Xp . One sample provided by a South Shore fisherman consisting of 79 fish was used to represent the entire handline fishery in the second and third quarters on the Scotian Shelf. A reconstruction of catch at age for the 1,500t of landings by the hook and line sector in 4Xo based on three samples was investigated, although not used. This resulted in a higher estimate of age 6 fish in the landings.

For 1999 there were no longline or handline samples from 4Xo available, although this remains the area from which the bulk of the landings originate. The reconstructed catch is based on samples from 4 Xp and 4 Xn only, and may, therefore, underestimate landings of larger, older fish. Such meagre sampling may have led to inaccuracies in the reconstruction of landings.

These cases outline some challenges experienced while attempting to describe the catch at age. With such variability within areas for which the catch is derived, a greater focus on commercial sampling may be needed to maintain an appropriate level of reliability in the catch reconstruction.

The seasonal length-weight parameters used in deriving catch numbers at age (Tables 6 b,d) were those from Campana and Hamel (1992). These parameters were calculated as seasonal averages over the years for which seasonal survey information was available, and have been used since 1985 when seasonal surveys in 4X were discontinued.

Intra-reader age comparison testing was conducted. The level of agreement between separate readings was $92 \%$. Inter-reader testing using samples from the past decade were conducted in 1998 and also showed very high agreement (Clark and Johnston, 1998).

## Landings

In 1998, landings were distributed among ages 2-6 with hook and line vessels catching a larger proportion of young fish (Table 7a). In 1999 gillnet catches continue to show the 1992 year-class as a high proportion of their catch, while the 1996 year-class is dominant in both hook and line and otter trawl catches (Table 7b). As the 1992 year class moves through the fishery, the range of ages in the landings continues to increase (Table 8). All ages younger than age 7+ in 1998 (Figs. 6 and 7), and all ages in 1999 (Figs. 9 and 10) appear to be well represented when compared to the long-term mean. The 1992 year-class, however, along with older ages, are a much lower proportion of the landings than anticipated in both 1998 and 1999 (Figs. 8 and 11).

Weights at age for commercial landings from the Bay of Fundy remain higher than average in recent years. The values for the Scotian Shelf are lower in 1998 than they have been in recent years (Table 9). This is likely a result of the inclusion of sampling from 4Xm in the summer in 1998 (an area from which there has been no sampling in recent years), where weights at age are generally lower than in other areas in 4X. The values for the first half of 1999 are included for comparison, and indicate that the weights at age for cod on the Scotian Shelf are again higher than average for most ages in 1999.

Commercial catch at age data from 1980 to 1999 were used in this assessment. While previous assessments have included landings data from before 1980 (Campana and Hamel, 1992), inconsistencies in F's among cohorts within a year, variation in the weights at age, and unusual patterns in catch curves led to the exclusion of the catch at age for the period 1948-1970 in the 1993 assessment (Gavaris, 1993). Furthermore, commercial sampling prior to 1980 was very low, particularly west of Browns Bank, and it has been concluded that the catch history for the Bay of Fundy could not be reliably reconstructed from the commercial samples during this period (Clark, 1995). Catch at age has been derived for the Scotian Shelf to 1971, and a VPA for the Scotian Shelf in 4X has been conducted with these data to provide a longer term population and recruitment series (Clark, 1997).

## ABUNDANCE INDICES

Annual stratified random surveys have been conducted in 4X during summer since 1970. As in the 4X cod assessments since 1994, calibration of the VPA for this assessment used survey information collected since 1983, when the RV Alfred Needler became the standard survey vessel. Uncertainties in relative fishing power between different survey vessels could have contributed to the residual patterns observed in past assessments (predominantly positive since 1983 and negative before 1983). Furthermore, excluding data prior to 1983 eliminated the retrospective pattern which plagued previous assessments (Gavaris et al, 1994). Based on these considerations, the present assessment was conducted using survey data from 1983-1999.

The distribution of cod was similar to recent years, with no increase in null sets (Fig. 12), however, there were few good catches in the Bay of Fundy. Catch per tow decreased in the Bay of Fundy to about the lowest level observed in 1999. Catch per tow increased slightly in the Scotian Shelf area in 1999, but remained below average (Fig. 13a). Survey catch in 4 X as a whole is at its lowest level in weight per tow (Fig. 13b).

Survey results have suggested the 1992 year-class is well above average (Table 10a,b). This year class has had the highest index in the series at ages 4,5 and 6 , and the second highest at age 3 . At age 7, however, it is only slightly above average. For all other ages, the 1999 survey was below average. The initial indication given by this survey is that the 1997 year-class is also below average. For the first time in the series, there were no fish caught over age 8 (Table 10b).

The age 2 survey index used in the calibration includes sets at depths <50 fathoms, excluding stratum 490 (St. Mary's Bay). When stratum 490 was removed from the analyses, relative error and bias were reduced in population estimates, and the magnitude of the residuals also decreased (Clark et al., 1995).

The fifth annual 4X ITQ groundfish survey was conducted in July, 1999 using commercial trawlers. The survey employs a fixed station design (although the number of stations has increased over the time series), and involves three vessels using balloon trawls with a $1 / 2 \mathrm{in}$. codend liner and rockhopper ground gear. The 4X area was divided into blocks of $100 \mathrm{~nm}^{2}$ and blocks were selected for sampling prior to sailing. The selection of the exact station location within a block was made by the skipper, allowing them scope to identify a suitable location for trawling (O'Boyle et al., 1995). Once co-ordinates for the sampling location were determined, the location was fixed for subsequent years, eliminating the flexibility which was present in initial selection. Two of the three vessels switched from a 300 to 280 balloon trawl between the first and second year to match what was in use on the vessel fishing in the Bay of Fundy, however the skippers felt this was a minor change and should not affect the catch for these vessels. The potential for differences in fishing power among vessels could complicate some analyses, however, comparisons can be made among years for the 124 stations which were sampled in each year ( 170 stations for 1996-99; Tables 11a-c).

There is an increase in the number of stations where no cod were caught to 41 in 1999 from 34 in 1998 (Fig. 14). Catches were down primarily in deep stations along the shelf edge. Catches at the majority of stations were below average for the time series (Fig. 15).

The total weight of cod caught in the ITQ survey declined in all areas in 1999 (Table 11a, Fig 13b). Numbers caught increased on the shelf and inshore in 1999, primarily due to catches of small fish (including one tow of over 8000 cod less than 13 cm ). The decline in catch weights for this survey since 1996 is apparent and of similar magnitude for the subset of stations occupied in all years ( 124 stations), or the larger set ( 170 stations) occupied only since 1996 (Table 11b). As the number of stations included in the analysis is increased in a given year from the original subset of stations, the catch per tow declines. Stations added after the first year tend to be ones where cod abundance is relatively low.

The length frequency of the ITQ survey catch for 1999 on the Scotian Shelf (including only those sets made within Needler strata 470 - 481) peaks at 22 and 31 cm , reflecting numbers at ages 1 and 2 (Fig 16a). This is quite different from what is seen in the RV survey which peaks at 7 and 49 cm .(Fig. 17).

The 1999 ITQ survey length frequency for the Bay of Fundy (Fig. 16b; including only those sets made within Needler strata 484-495) are generally below average, except for peaks at 25 and 58 cm . The RV survey numbers were quite low at all lengths.

In the Inshore area (Fig. 16c), numbers remained below average in the ITQ survey for most lengths above 31 cm . A single large tow of 7-13 cm fish, and a number of sets around Cape Sable Island with fish in the $19-25 \mathrm{~cm}$ range were responsible for the high numbers at lengths reflecting ages 0 and 1 .

The relatively high numbers of small fish caught in the ITQ survey may reflect the differences in gear used in the two surveys. The ITQ survey, unlike the RV, uses rock-hopper ground gear. This gear is more effective at catching small cod, since there is no avenue for escape below the foot gear.

Age disaggregated survey indices were calculated for the ITQ survey (Table 11c) using agelength keys from the RV survey. The ALK from the Bay of Fundy was used for the inshore area, since commercial samples taken from the German Bank area, where most of the inshore stations are located, show growth rates similar to the Bay of Fundy cod. These indices track the strong 1992 year-class, with numbers for each age peaking on this year-class. Similar consistency is displayed for the 1991 and 1995 year-classes, which appear weak at all ages. Catches at age 1 were quite variable, and do not appear to be a good predictor of year-class strength at present.

## ESTIMATION OF STOCK PARAMETERS

The adaptive framework (Gavaris 1988) was used to calibrate the sequential population analysis with the research survey results using the following data:
$C_{a, t}=$ catch for ages $a=1,2, \ldots, 11$ during the quarter year time periods beginning at $t=1980,1980.25,1980.5,1980.75,1981, \ldots, 1999.25$
$I_{s, a, t}=$ survey abundance index for:
$\mathrm{s}=\mathrm{RV}$ survey ages $a=2$ to 10 , years $t=1983.5$ to 1999.5 (excluding 1988.5, ages 3 and 4 ). ITQ survey ages $\mathrm{a}=2$ to 9 , years $\mathrm{t}=1995.5$ to1999.5

The summer survey results were compared to mid-year population abundance. Data from ages 3 and 4 from the 1988 summer survey were excluded from the analysis because catchability at these ages appeared to be anomalously high. These data were influential and their inclusion affected population estimates. Estimates obtained when these data were excluded were considered more appropriate (Gavaris, 1993, Clark et al., 1995).

Statistical error in the survey data was assumed to be independent and identically distributed after taking logarithms and the error in the catch at age was assumed negligible. Natural mortality, M , was assumed constant and equal to 0.2 and the fishing mortality rate, F , for age 12 in the final quarter of each year was assumed equal to the average for ages 6,7 and 8 in the same year and quarter.

A model formulation using ln mid-year population abundances in $1999(t=1999.5)$ as parameters was employed.
$\phi_{\mathrm{a}, 1999.5}=\ln$ population abundance for ages $a=2,3, \ldots, 11$, ( age 1 abundance assumed equal to the geometric mean recruitment 1993-97), and

$$
\kappa_{\mathrm{a}}=\text { calibration constants for Canadian summer survey for ages } a=2,3, \ldots, 10
$$

ADAPT was used to solve for the parameters by minimizing the objective function

$$
\mathrm{Q}_{\mathrm{a}, \mathrm{t}}(\phi, \kappa)=\sum_{\mathrm{a}, \mathrm{t}}\left(\mathrm{q}_{\mathrm{a}, \mathrm{t}}(\phi, \kappa)\right)^{2}=\sum_{\mathrm{a}, \mathrm{t}}\left(\ln \left(\mathrm{I}_{\mathrm{a}, \mathrm{t}}\right)-\ln \left(\kappa_{\mathrm{a}} \mathrm{~N}_{\mathrm{a}, \mathrm{t}}(\phi)\right)\right)^{2}
$$

where the population abundance $\mathrm{N}_{\mathrm{a}, \mathrm{t}}$, is taken at the corresponding time, t , to the survey. Since the sequential population analysis was conducted using quarter year catch at age data, the abundance at the mid-year time, $t=y+0.5$, is directly available.

For $t=1999.5$, the population abundances are obtained directly from the parameter estimates,

$$
N_{a, 1999.5}=\exp \left[\phi_{a, 1999.5}\right] .
$$

For all other years, $\mathrm{y}=1980$ to 1999.25 , the population abundance was computed using the virtual population analysis algorithm which incorporates the exponential decay model

$$
N_{a, t}=N_{a+\Delta t, y+\Delta t} \exp \left[\left(F_{a, t}+M\right) \Delta t\right]
$$

where the fishing mortality for ages 1 to 10 is obtained by solving the catch equation using a Newton-Raphson algorithm,

$$
N_{a, t}=C_{a, t}\left(F_{a, t}+M\right) \Delta t / F_{a, t} \Delta t\left(1-\exp \left[-\left(F_{a, t}+M\right) \Delta t\right]\right) .
$$

Analytical approximations of variance and bias for population abundance estimates and corresponding projected yield were derived following Gavaris (1993).

A second ADAPT formulation is presented following the same protocols, except that only the RV survey numbers for ages 2-7 were used as indices; the ITQ survey was excluded from this model.

## ASSESSMENT RESULTS

For each cohort, the terminal population abundance estimates from ADAPT were adjusted for bias (Table 12a) and used to construct the history of the stock status (Table 13a). Commercial weights at age $a$ from the first quarter, and the last quarter of the previous year for age $a-l$ were averaged to provide a beginning of year weight at age, and these were used to calculate beginning of year population biomass (Table 14a \& Fig 18a).

Residuals for the RV indices also showed a consistent trend across years (Fig. 19a). Residuals were generally positive for ages 3 and over for years since 1994, and negative for earlier years. Thus, surveys in recent years have been indicating a higher population than is estimated
through the VPA.
The residuals for the ITQ survey are generally small, but show a strong trend at ages 4 and over, with 1995 generally strongly positive, and the last two years negative (Fig. 19a). The indices for this survey show little inter-annual variability at most ages, aside from the strong 1992 yearclass. This year-class appears to be very influential in the regression plots and therefore is largely responsible for establishing the q's for this survey. Indices at ages 8 and 9 do not seem to correlate with population numbers, and are likely not reliable at this early point in the survey's evolution.

Fully recruited fishing mortality (ages 4-7) is estimated at 0.4 for 1998; this is higher than was projected in the last assessment, even though over $10 \%$ of the quota on which the projection was based went uncaught. The total fishing mortality rate for ages 4 and older has fluctuated around 0.5 (Table 15a). F increased rapidly after 1989, peaking over 1.0 in 1992. This formulation suggests F remained near 1 in 1992 and 1993 as well, before declining in 1995. Biomass at ages 4+ is estimated to have remained at about 20,000t since 1996. This is similar to the more pessimistic option presented in the 1998 assessment (Clark \& Johnston, 1998).

The assessment in 1998 included ADAPT formulations which examined the possibility that either survey q's or natural mortality may have changed in recent years. This was partly in response to the mismatch between VPA projection of strong population numbers at ages 6-8, and very low landings at these ages in the fishery, and to high survey Z, or total mortality, estimates (Fig. 20). The survey Z calculated between the 1998 and 1999 surveys is very high. Total mortality estimates have been quite variable in recent years, with a pronounced oscillation, suggestive of high variability in survey catches. Using a two year running average to damp the oscillations gives an increasing trend in Z in recent years (Fig. 20).

A variety of formulations were attempted for this assessment to investigate whether the results from models with changes in $q$ or $M$ might better fit with observations from the fishery. Each of these options estimated population biomass lower than the base model described above, and F higher. These results seemed inconsistent with the declining fishing effort, and with the apparent improvements in the fishery this year.

Formulations which estimated separate q's for recent years in the survey resulted in F's that reached 1.3 in 1994 and had remained in the range of 0.7 to 0.9 since then. The 4+ population biomass was estimated at 11,000 t in 1999, which seemed inconsistent with the apparent improvements in the fishery.

A formulations which fixes M at 0.2 prior to 1992, and estimated M in years since 1992 (M estimated at 0.63 ), produced a pattern in residual plots of generally negative residuals at young ages, and positive at older ages. This also estimated F to have stayed quite high after 1992, despite the large drop in effort noted in the 1998 assessment, and continued to show relatively high mean squared residuals.

A formulation which included indices for ages 2-7 only, from both surveys, resulted in improvements in mean squared residuals, and estimated higher population numbers. This formulation, however, estimated F to be quite high on ages 4 and 5, and then decreasing rapidly at older ages. The dome in the F matrix suggested either that the fishery had changed to such an
extent that older fish were excluded from exploitation, or that the older fish were not actually present, and their presence in the population was an artefact of the model. By removing the survey indices for ages above 7 , where low numbers are indicating low population, this model provided nothing to indicate abundance may be low at these ages. The result is high estimates of population number, coupled with low estimates of F . This seems unrealistic.

One final model formulation was investigated in greater detail. The brevity of the ITQ time series, and the lack of range in year class sizes in the five years available, led to the conclusion that q's are likely poorly estimated, and potentially unstable for this survey. The high residual for the first year of the survey suggest that q may have been lower in that year. Changes in gear in the second year, and the trading of a number of stations among the survey vessels may influence the comparability of the 1995 data with that from years since then. These concerns about the stability of survey q's, and patterns in the residuals led to the consideration of a VPA which excluded the ITQ data.

A formulation including ages 2-7 from the RV survey as indices, was investigated (1 index). This 1 index formulation had a much lower mean squared residual (Table 12b), and less of a trend in the residual plots (Fig. 19b). This model estimates population numbers to be low, but stable (Table 13b), a gradually increasing population biomass (Table 14b and Fig 18b), and lower fishing mortalities in recent years (Table 15b), consistent with trends in fishing effort, and reports of improved fishing success. A retrospective analysis for this model shows a marked pattern for the 1990, 1991 and 1992 year-classes, but no pattern for more recent cohorts (Fig. 21). The 1 index model provides estimates of recruitment which are consistently poor since the 1992 year-class (Fig. 22). Fishing mortality is estimated to have dropped dramatically since 1992, and is now below the F seen in the 1980's, though still above the target of 0.2 (Fig 23). The beginning of year population biomass for ages 3 and older (roughly equivalent to the fishable biomass) has increased gradually since 1994 to a recent high in 1999. This is still lower than any biomass seen before 1993. The numbers of fish aged $7+$ are estimated as roughly $18 \%$ of the $3^{+}$numbers. This seems unrealistically high, given the low proportion of the commercial catch these ages comprise. Exploration of the commercial sampling data suggests that older fish may be underestimated in the present catch at age, but not to an extent that would explain the discrepancy between expected proportional catch and what is observed. This indicates their biomass is likely still overestimated, and that the downward retrospective trend indicated for these year-classes will likely continue.

Partial recruitment (PR), derived from the F matrix, appears more strongly domed in recent years for this formulation (Table 16b) than in the base formulation (Table 16a), which includes more ages in the indices. The low survey catches at older ages, which indicate low current population, are excluded, thus the population estimates are higher for these ages. This indicates that population biomass at older ages is likely over-estimated. Projections, therefore, were based on the domed PR estimated for the past 5 years.

The very low survey catches in 1999, particularly for the Bay of Fundy, are obviously a concern. The decline in catch, along with the increase in survey Z , are clearly at odds with the VPA results which indicate a stable or slowly increasing biomass and declining fishing mortality, and with the observations from the commercial fishery. The lack of fish over age 8 in the survey is also of concern. Surveys regularly captured fish at all ages up to 12 in the past. The very high fishing mortality experienced in the early 1990's may be primarily responsible for the lack of older fish.

These patterns in the surveys, and the continued poor fisheries in some areas indicate that a cautious approach to exploitation of this resource is warranted.

Neither of the formulations presented in detail here seems to adequately capture the variability in recent input data for this stock. In both cases, the partial recruitment appears domed in recent years, although there is little reason to anticipate such a change. The formulation including both surveys shows strong patterns in the residuals, and lacks inter-annual stability, with the estimated beginning of 1999 biomass changing by $40 \%$ with the inclusion of an additional years data. The formulation which includes the only the RV survey estimates a steady increase in biomass since 1996, in stark contrast to the survey results. Using a domed partial recruitment to estimate the potential yield may amend the discrepancy, but the biomass estimate remains clearly high.

Although neither formulation would seem to be completely reliable, the conclusions from both on the current status of the resource are fairly similar. The stock status is clearly near its historic low, and with recruitment consistently poor in recent years, the short-term prospects remain poor. If the initial indications from the ITQ survey of a strong 1998 year-class prove reliable, then some increase in biomass may be forthcoming in 2 or 3 years time.

Cod spawning stock structure in 4X is quite complex. There are a number of spawning components, and there is also mixing with adjacent areas. With the biomass of cod in 4X generally low, there are clearly some areas where abundance is very low, and others which are not as depleted. The geographic shifts in the fishery have reflected this. It is possible, as suggested in the 1998 assessment, that the reason the RV survey has been overestimating stock abundance in the past 3 or 4 years (as indicated by the predominance of positive residuals in the VPA results) may be that abundance was particularly low in the unsurveyed inshore areas. This is reflected in the fishery which was quite poor in this area from 1995 to 1998 . The assumption that abundance trends throughout the management area are reflected by the survey may not have held. The resurgence in the inshore fishery in many areas this year is a positive sign, suggesting the abundance in this area, historically the centre of the fishery, may be increasing from low levels.

A summary of a number of important stock attributes are presented in Table 17. These show that there is currently uncertainty in the stock abundance trends, but that measures of current abundance are uniformly low. Measures of current fishing mortality levels, and trends in exploitation are sharply contradictory. In contrast to the uncertainty in abundance trends, indicators of biological parameters (growth and condition) appear positive, and distribution of the resource is also healthy.

## Future Research

Additional work is required to ensure that the best possible use is made of the ITQ survey. Work is also required to better understand the stock structure for cod in this area, and how it affects the assessment. Also, improved monitoring of the commercial fishery is needed to ensure we can accurately reconstruct landings.

## PROGNOSIS

Yield projections indicated that the point estimates for projected yield were biased upward by about $10 \%$ and had a standard error of about $25 \%$ of the mean. As with population abundance estimates, adjusting for bias was considered more appropriate than using the biased point estimate. The incoming year-classes were assumed to be equal to the geometric mean for the last 5 years (Tables 18a,b). Average partial recruitment values for 1990-95 of 0.0, 0.06, 0.42, and 0.76 respectively for ages 1-4 were used in the projections, while ages $5^{+}$were set as fully recruited.

Assuming that landings in the calendar year reach 6,900t from the 7,900t 15-month quota, the resulting fully recruited fishing mortality will be in the range of .26 to .30 for 1999 , as estimated from the two formulations under consideration. The projected yield for 2000 (April 1, 2000 March 31,2001 ) at $\mathrm{F}_{0.1}$ is in the range of $4,200 \mathrm{t}$ to $5,600 \mathrm{t}$. At this fishing level, the age $4^{+}$biomass is expected to increase by between $2,000 \mathrm{t}$ and $4,000 \mathrm{t}$ during the fishing year (Tables 18a,b). This modest increase is due primarily to growth of younger fish.

Further improvements in recruitment are required before any sustained growth in this fishery can be realized. With the concerns expressed about the uncertainty in current stock biomass, it is important to ensure that the exploitation is kept low. To ensure a higher probability of average or better recruitment it is important to ensure that the spawning biomass is high. Given the poor recruitment of recent year-classes, this will require ensuring that fishing mortality is low.

## ACKNOWLEDGMENTS

We would like to thank those members of the fishing industry who assisted us with sampling of commercial landings and those who took the time to meet with us and discuss the state of the fishery. Thank you to Joe Hunt for reviewing an early version of this document. The efforts of Gilbert Donaldson and Emelia Williams in sampling commercial landings, and the continued careful attention of Laura Brown in the interpretation of ageing material is also appreciated.

Table 4. Summary of fishery reports for cod in Division 4X in 1999.

| Gear Type | Fishery Reports |
| :---: | :---: |
| Handline | Landings off Digby Neck were low overall, but catch per vessel increased. This year was better than the previous two years. |
|  | Poor for Yarmouth. |
| Longline | (As with handline) Improvement in fishing along the Southern Shore to Cape |
|  | Sable over the past 3-4 years. Cod were available in coastal waters for the first time in 4 years. Catches were reported to contain a great range of lengths. |
|  | Around Cape Sable there were high proportions of small fish in coastal areas, but these could be avoided by selecting appropriate fishing grounds. Fish were generally reported as more abundant, and larger in 1999. |
|  | Poor in spring off Saint John. |
| Gill net | Good off SW bank in Jul.-Aug., catch rate at least doubled that of the previous |
|  | year. Yielding mainly cod in 1999, this area has traditionally been fished primarily for pollock. |
|  | Catches were good in deep water in the Gulf of Maine in spring. |
|  | Catches were better than recent years off Grand Manan. |
|  | Landings in the fall fishery in eastern 4X were reported to be very poor. Fishermen abandoned the fishery as it was not worth the effort. Some reports of catching less than one fish per string of net. |
| Otter Trawl | Poor fishing east of Browns Bank. Very good catches on Browns in June when the Bank opened, however, the fish dispersed quickly after that. |
|  | Average fishing for recent years in the Bay of Fundy, with some need to avoid cod to pursue haddock. |

*fishing year beginning April 1, 2000.

Fig. 1. Canadian Statistical unit areas in NAFO Divisions 4X and 5Y, showing "Bay of Fundy", "Inshore" and "Scotian Shelf" regions as used in the analysis of the ITQ survey data.

Fig. 2. Nominal landings of cod in Division 4X including catches by Canada in Division 5Y. For 1999, quota and mid-year landings are shown.

Fig. 3a. Annual landings by gill net vessels in the Bay of Fundy and Scotian Shelf.

Fig. 3b. Annual landings by otter trawl vessels in the Bay of Fundy and Scotian Shelf.

Fig. 4a. Fishing effort expended by the OT TC 1-3 fleet in 4X where main species was cod, hadock, pollock, or white hake; TVRP effort excluded.

Fig. 4b. Fishing effort for gill net (TC 2+) fishing vessels by unit area in 4X.

Fig. 5. A comparison of individual commercial otter trawl samples taken in the Bay of Fundy from unit areas 4Xrs and 4Xq in 1998.

Fig. 6. Division 4X cod catch ( t ) at age for 1998 compared to the 1980-96 mean.

Fig. 7. 4X cod catch at age (in numbers) for 1998 compared to the mean for 1980-96.

Fig. 8. Reported and forecast landings of cod in Division 4X for 1998 proportioned by age.

Fig. 11. Reported and forecast landings at age of cod in Division 4X for 1999 (Jan. - July).

Fig. 12. Summer RV groundfish survey 4 X cod catches (Kg/tow).

Fig. 13a. Summer groundfish survey indices for 4 X cod by region.

Fig. 13b. Mean weight (kg) per tow from the RV and ITQ surveys.

Fig. 14. Summer ITQ groundfish survey 4 X cod catches (Kg/tow).

Fig. 15. A comparison of ITQ survey cod catches at repeated stations for 1999 versus the five year average from 1995 to 1999.

- Stations where 1999 value < average
+ Stations where 1999 value $=$ average
o Stations where 1999 value > average

Length (cm)
Fig. 16a. Scotian Shelf length frequencies and mean length at age from the ITQ surveys conducted in Division 4X; common sets from 1995-1999, n=124.

Fig. 16b. Bay of Fundy length frequencies and mean length at age from the ITQ surveys conducted in Division 4X; common sets from 1995-1999, n=124.

Fig. 16c. Inshore length frequencies and mean length at age from the ITQ surveys conducted in Division 4X; common sets from 1995-1999, n=124.

Fig. 17. Length frequencies from the summer groundfish survey in Division 4X.

Fig. 18a. Beginning of year biomass (3+) for cod in Division 4X using the RV index (1983-1999) and the ITQ index (1995-1999).

Fig. 18b. Beginning of year biomass (3+) for cod in Division 4X using the RV index (1983-1999). ages 2-7.

Fig. 19a. Age by age plots of A) the observed and predicted $\ln$ RV abundance index versus $\ln$ population numbers, and B) residuals plotted against year for cod in Division 4X and the Canadian portion of 5Y. RV index 1983-1999, ITQ index 1995-1999.

Fig. 19a (cont). Age by age plots of A) the observed and predicted $\ln$ ITQ abundance index versus $\ln$ population numbers, and B) residuals plotted against year for cod in Division 4X and the Canadian portion of 5Y. RV index 1983-1999, ITQ index 19951999.

Fig. 19b. Age by age plots of A) the observed and predicted $\ln$ RV abundance index versus $\ln$ population numbers, and B) residuals plotted against year for cod in Division 4X and the Canadian portion of 5Y. RV index 1983-1999, ages 2-7.

Fig. 20. Summer groundfish research survey Z (2 year running average) for ages $4+$.

Fig. 21. Retrospective plot for 4X cod with RV survey index (1983-1999), ages 2-7.

Fig. 22. Recruitment (age 1) for cod in Division 4 X using the RV survey index, ages 2-7.

Fig. 23. Fully recruited fishing mortality (F) for 4X cod using the RV survey index (19831999), ages 2-7.

[^0]:    \# LF substituted due to absence of commercial sampling for this gear/area/quarter combination

    * Landed weight for LL Q1 F (4 t) was added to LL Q2 F.

[^1]:    \# LF substituted due to absence of commercial sampling for this gear/area/quarter combination.

[^2]:    * Landings for J anuary - July 1.
