## Pre-season run size forecasts for Fraser River sockeye in 2000

A. Cass<br>Fisheries and Oceans Canada<br>Pacific Biological Station<br>3190 Hammond Bay Road<br>Nanaimo, B.C. V9R 5K6

${ }^{1}$ This series documents the scientific basis for the evaluation of fisheries resources in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

#### Abstract

Adult returns of sockeye to the Fraser River on the 2000 cycle line are the lowest of the four cycle lines averaging 4.5 million sockeye compared to an all-year mean of 9.4 million during 1970-99. The major stocks expected in 2000 based on brood year escapement estimates for 1996 are Chilko, Stellako, Early Stuart, Late Stuart, Birkenhead, and Weaver sockeye. Forecasts are made for each of four migratory timing groups and 19 individual stocks. Forecasting methods are unchanged from previous PSARC reviews and are based on a variety of explanatory variables and forecast models. The 2000 forecast, all stocks combined, at the $50 \%$ probability level (point estimate) is 4.1 million sockeye or near the long-term mean (1970-1996). At the $75 \%$ probability level the forecast is 2.3 million fish. The summer run group accounts for $65 \%$ of the forecast. Within that timing group, Chilko and Stellako sockeye respectively account for $33 \%$ and $16 \%$ of the forecast at the $50 \%$ probability level. A cautionary prognosis for 2000 returns is warranted. Estimates of jack returns in 1999 (2000 age-4 returns) to several of the major stocks on the cycle line were very low compared to brood year escapements and compared to jack returns on the previous year in this cycle. Temperatures in the north Pacific Ocean in the spring of 1998 were above average during the transition from intense El Nino conditions in 1997 to cooler La Nina conditions in the latter half of 1998 . Ocean survival of sockeye that went to sea in 1997 was very low. The carry-over effect of above average temperatures in the spring of 1998 on juvenile sockeye survival for the 1996 brood (2000 age-4 returns) is unknown. Qualitative information reported in this document indicate that run sizes may be less than the $50 \%$ probability level.

## Résumé

Les remontées des saumons rouges adultes dans le fleuve Fraser pendant le cycle de 2000 sont les plus faibles des quatre années du cycle, s'établissant en moyenne à 4,5 millions de saumons rouges comparativement à une moyenne combinée de 9,4 millions durant 1970-1999. D'après les estimations de l'échappée de la progéniture de 1996, les principaux stocks prévus en 2000 sont constitués de Chilko, Stellako, Late Stuart, Early Stuart, Birkenhead et de Weaver. Des prévisions sont faites pour chacun des groupes pendant quatre moments de migration et pour 19 stocks individuels. Les méthodes pour établir les prévisions sont les mêmes que dans les examens antérieurs du Comité d'examen de l'évaluation des stocks du Pacifique et sont basées sur une diversité de variables explicatives et de modèles de prévision. Les prévisions de 2000, tous stocks confondus, à un niveau de probabilité de $50 \%$ (estimation ponctuelle) sont de 4,1 millions de saumons rouges ou près de la moyenne à long terme (1970-1996). Au niveau de probabilité de $75 \%$, les prévisions sont de 2,3 millions de poissons. La remontée estivale compte pour $65 \%$ des prévisions. Dans ce groupe, les saumons rouges de la Chilko et de la Stellako représentent respectivement 33 et $16 \%$ des prévisions au niveau de probabilité de $50 \%$. Un pronostic prudent pour les retours de 2000 est justifié. Les estimations des retours des jeunes mâles matures en 1999 (retours des saumons de 4 ans en 2000) vers plusieurs des principaux stocks du cycle étaient très faibles comparativement à l'échappée de la progéniture et aux retours des saumons mâles matures l'année précédente du cycle. Les températures dans l'océan Pacifique nord au printemps de 1998 étaient supérieures à la moyenne pendant la transition des conditions intenses dues à El Nino en 1997 aux conditions plus fraîches de La Nina dans la dernière moitié de 1998. Très peu de saumons rouges qui sont allés à la mer en 1997 ont survécu dans l'océan. L'effet de report des températures supérieures à la moyenne au printemps de 1998 sur la survie des saumons rouges juvéniles de la ponte de 1996 (retours des saumons de 4 ans en 2000) n'est pas connu. D'après l'information qualitative contenue dans ce document, l'effectif de la remontée peut être inférieur au niveau de probabilité de $50 \%$.

### 1.0 Introduction

Adult returns of sockeye to the Fraser River on the 2000 cycle line are the lowest of the four cycle lines averaging 4.5 million sockeye compared to an all-year mean of 9.4 million during 1970-99. The major stocks expected in 2000 based on brood year escapement estimates for 1996 are Chilko ( 974,000 spawners), Stellako (333, 000 spawners), Early Stuart (88,000 spawners), Late Stuart ( 63,000 spawners), Birkenhead ( 56,000 ), and Weaver sockeye ( 54,000 spawners).

Forecasts are made for each of four migratory timing groups and 19 individual sockeye stocks. The spawning escapement for these stocks accounted for $96 \%$ of the estimated total Fraser River escapement in 1996. Forecasts are not provided for a number of small stocks for which data quality is poor. These include Tesako, Momich/Cayenne, Nahatlatch, Harrison and Widgeon Slough sockeye.

Forecasts of adult returns are made using a variety of explanatory variables. For most stocks, forecasts are based on regression models that use spawning escapement to predict adult abundance of age- 4 and age- 5 sockeye. Additional explanatory variables are available for some stocks and include fry, smolt and sibling adult run size estimates. An environmental index has explained some variation in ocean survival of Chilko sockeye (Cass et al. 1995). I also evaluated methods that incorporate attributes of escapement-based and juvenile-based models by pooling results from individual forecast models where time series of different life stages are available.

Sibling models were not considered suitable candidate models for forecasting 2000 returns. Sibling models that use age- 3 jacks to forecast age- 4 returns have recently performed poorly compared to other models. The proportion of age- 3 jack returns have undergone dramatic long-term declines that can not be explained by changes in abundance or growth rates (Cass 1998). The use of sibling models to forecast 2000 returns is particularly suspect because of the discrepancy between in-season Mission acoustic estimates and preliminary estimates based on escapement plus catch up-river of Mission in 1999. Fraser River discharge during the adult spawning migration reach record levels in 1999. The effect of this on jack mortality is unknown but potentially has resulted in a negatively biased estimate of jack returns. Without reliable estimates of age- 3 jacks, sibling models are not useful for predicting 2000 age- 4 sockeye returns.

### 2.0 Methods

Data sources and methods have been extensively reviewed by PSARC (Cass 1999; Cass 1998; Cass 1997; Cass and Blackbourn 1996; Cass et al. 1995; Welch et al. 1994). The data used to forecast Chilko sockeye are listed in Appendix Table 1. Methods used to forecast 2000 returns are unchanged from Cass (1999). Estimates of returns in 1997-99 are very preliminary. Adult sockeye were exposed to high river discharge levels in both 1997 and 1999 during in-river migration. Large, positive differences in returns estimated at Mission in the lower river and the estimates from spawning grounds plus up-river catch occurred in those years. Large positive differences also occurred in 1998, particularly in the Early Stuart run, when temperature was abnormally high. We may never know how much of the difference was due to adverse conditions or to estimation error. For present purposes, the returns in 1997-99 assume the "missing" fish existed and, therefore, the return data include the "missing" fraction of fish.

Except for sub-stocks of early Stuart sockeye, escapements are estimates of "effective females". Effective females are estimates of the number of spawning females contributing to the spawning population each year weighted by egg deposition. The stock-specific catch component of run size (run size $=$ catch + escapement) is estimated by the Pacific Salmon Commission (PSC). A sub-stock of Early Stuart sockeye was analysed separately that excludes the highly cyclic Driftwood River population. The abundance of sockeye that spawn in the Driftwood system is negligible on the 2000 cycle line. Data for the non-Driftwood component were estimated by apportioning the total Early Stuart catch estimates according to the corresponding escapement for the non-Driftwood and Driftwood systems. The data used to forecast the nonDriftwood component Early Stuart sockeye consists of total adult escapements (1959-96) and adult returns (1963-99).

### 2.1 Forecast models

Forecast models used in the present analysis are as follows:

1) Ricker function with log-normal errors and uncorrected for bias (fit to the mode not the mean returns):

$$
\begin{equation*}
R_{i t}=\alpha S_{t-1} e^{-\beta S_{t-1}} * e^{\sigma \varepsilon_{t}} \tag{1}
\end{equation*}
$$

estimated using the linear regression :

$$
\ln \left(R_{i t} / S_{t-1}\right)=\ln (\alpha)-\beta S_{t-1}+\sigma \varepsilon_{t} .
$$

Here the returns $\left(\mathrm{R}_{\mathrm{i}, \mathrm{t}}\right)$ at age i in generation t is related to the spawning escapement in generation $\mathrm{t}-1$. Parameters $\alpha$ and $\beta$ are the density independent and dependent parameters, $\sigma$ is the standard deviation of the residuals and $\varepsilon_{t}$ is a standard normal deviate for generation $t$.
2) Non-linear (power) model :
$R_{i t}=\beta_{0} S_{t-1}^{\beta_{1}} * e^{\sigma \varepsilon}$
estimated by:
$\ln \left(R_{i t}\right)=\beta_{0}+\beta_{1} \ln \left(S_{t-1}\right)+\sigma \varepsilon_{t}$.
3) Geometric mean (GM) return-per-spawner model:
$R_{i t}=S_{t}\left[\frac{G M\left(R_{i 1} \ldots R_{i t-1}\right)}{G M\left(S_{1} \ldots S_{t-1}\right)}\right]$

## 4) Juvenile model:

For Chilko, Quesnel, Shuswap, Nadina, Gates and Weaver sockeye a non-linear power model of the form:
$\ln \left(R_{i t}=\beta_{0}+\beta_{1} \ln \left(N_{t}\right)+\sigma \varepsilon_{t}\right.$,
was fit to adult returns at age i and juvenile data $N$ at generation t . In addition, the forecast performance of escapement (log transformed) when added as a second explanatory variable in a multiple regression was also assessed. For Chilko sockeye additional environmental variables were added to represent precipitation rates and ocean salinity in the smolt year that were shown to explain part of the variation in age-4 Chilko returns in previous forecasts (Cass, 1998). The precipitation data is the average total monthly precipitation in two months (September and October) of the ocean-entry year from two stations: Langara Island, in north-western British Columbia, and Annette Island in southern southeast Alaska. Langara Island precipitation data is published in monthly climate summaries published by the Atmospheric Environment Service of Environment Canada. Precipitation data from Annette are obtained from "Annual Summaries of Climatological Data for the State of Alaska" published by the U.S. National Environmental Satellite, Data and Information Service and obtained from the National Climatic Data Center (NCDC), Asheville, North Carolina. The salinity data are the mean May-June estimates measured at Entrance Island in the ocean-entry year.

## 5) Sibling model:

Sibling regressions for forecasting age-5 returns from sibling age-4 returns are of the forms:
$\ln \left(R_{i+1, t+1}\right)=\beta_{0}+\beta_{1} \ln \left(R_{i t}\right)+\sigma \varepsilon_{t}$.

For reasons discussed, sibling models that use age- 3 jacks to forecast 2000 age- 4 returns are not considered reliable. For stocks with sufficient data, age- 4 females standard length was added as a second explanatory variable to eq. 6 for forecasting age- 5 sockeye.

A method that combines forecasts from models with independent biological explanatory variables (i.e. escapement and fry), hereafter termed the pooled model, was also considered in this analysis. Methods for combining forecasts are based on weighting schemes that weight using some measure of forecast error (McLeod et al. 1987; Noakes et al. 1990). I assume that
forecasts from models that use different life stages are independent. Weights were assigned using the inverse of the forecast prediction variance (Fried and Yuen 1987):
$\ln (F)=\sum_{m=1}^{n}\left[\ln \left(F_{m}\right) / V_{m}\right] / \sum_{m=1}^{n} 1 / V_{m}$,
where F is the weighted mean forecast for n separate forecasts, $\mathrm{F}_{\mathrm{m}}$ is the model-specific forecast and $\mathrm{V}_{\mathrm{m}}$ is the model-specific variance ( $\log _{e}$ of the forecast). For independent explanatory variables the pooled variance $V_{p}$ is valid where:
$V_{p}=1 / \sum_{m=1}^{n} 1 / V_{m}$.

### 3.0 Model Performance

Model performance was evaluated in a retrospective analysis by comparing run size forecasts to estimated (observed) run sizes for years that estimates are available. Starting with the most recent year that estimated returns are available (1999), a retrospective forecast for that year was made from the time series of explanatory variables by leaving out the most recent return data. In this way, retrospective forecasts for each year are based only on the time series available prior to the year being forecast. Retrospective comparisons were made for brood years 1980-95. The retrospective comparison for age-4 Chilko sockeye by model, including the historical performance of the age-4 versus age-3 (jack) sibling model is shown in Figure 1. Note that the scale in Figure 1 is in the log domain so that the true uncertainty, to a large extent, is masked. Model results depicted in Figure 1 show that the $90 \%$ confidence intervals of the forecasts in many years do not overlap the 1:1 line. In other words, the models are poor representations of the natural processes that control survival particularly in years of no overlap of the confidence intervals with the $1: 1$ line.

Forecast errors were quantified using the root mean square error (RMSE) criteria. The model with the lowest RMSE was judged to be the 'best' forecast. If the RMSE criteria failed to differentiate among competing models then the model with the smallest variance was selected. For each stock, the variance of the prediction was computed using standard methods (Snedecor and Cochran 1967; eq. 6.12.1). The combined variances for age-4 plus age-5 sockeye by stock were computed as the sum of the weighted variances (weighted by the age-specific forecasts).

A retrospective analysis was not possible for the Upper Adams stock. Only one forecast model was considered for sockeye returning to the Upper Adams spawning area. Estimates of spawners to the Upper Adams were 25,000 in 1996. This exceeds recent historical estimates by eight fold as a result of stock recovery on this cycle. Because the escapement in 1996 are well beyond levels record for this stock, a simple recruit-per-spawner model was applied that used the mean recruits-per-spawner for all Fraser stocks to forecast a point estimate of returns to the Upper Adams in 2000.

### 4.0 Forecasts and uncertainty

Annual differences between estimated returns and forecast returns (point estimate) during 1990-99 were large (Fig. 2). The mean absolute deviation was $\pm 58 \%$ for all timing groups combined. The error for individual timing groups was of similar magnitude: $\pm 49 \%$ for Early Stuart, $\pm 48 \%$ for Early Summers, $\pm 72 \%$ for Summer and $\pm 60 \%$ for late runs. Forecast errors in 1999 were particularly large and difficult to evaluate because of the "missing" fish issue (Table 1). When missing fish are included in the comparison for 1999 , the forecast was $85 \%$ more than the estimated run for Early Stuart, 36\% more for Early Summer, 197\% more for Summers, 134\% more for Lates and $134 \%$ for all stocks combined. The deviation for 6 of the 18 stock comparisons were outside the $90 \%$ confidence intervals for the "best" forecast model in 1999. When missing fish are excluded from the analysis the forecast error is larger for each timing group and the estimated return in 1999 was outside the $90 \%$ confidence intervals in 13 of the 18 stock comparisons.

Forecasts for 2000 are provided as probability distributions by stock and run-timing group (Table 2). The probability distributions of the 2000 forecasts are large compared to the observed historical returns (Fig. 3) and again attests to large statistical uncertainty in the forecast. The 2000 forecast, all stocks combined, at the $50 \%$ probability level (point estimate) is 4.1 million sockeye or slightly less than the long-term mean (1970-1996). At the $75 \%$ probability level the forecast is 2.3 million fish. The abundance of highly cyclic stocks (Early Stuart, Late Stuart, Quesnel and Shuswap) that return on the 2000 cycle line are low compared to the dominant and sub-dominant years and together account for $23 \%$ of the forecast. The summer run group accounts for $65 \%$ of the forecast. Within that timing group, Chilko and Stellako sockeye respectively account for $33 \%$ and $16 \%$ of the forecast at the $50 \%$ probability level.

A cautionary prognosis for 2000 returns is warranted. Jack returns in 1999 (2000 age-4 returns) to several of the major stocks on the cycle line were estimates to be very low relative to brood year escapements. Sibling forecast models that incorporate jacks perform poorly because the proportion of sockeye that return as jacks has declined independent of age-4 returns from the brood. Nevertheless, the jack returns in 1999 were estimated to be low even when the decline in jack return rates is considered. The quality of the 1999 jack data, however, is suspect and may be biased low due to disproportionate mortality from high discharge rates. If in-river jack mortality was high then the presumption of low survival of the age-4 return in 2000 based on jacks is not justified.

Temperatures in the North Pacific Ocean in the spring of 1998 were above average during the transition from intense El Nino conditions in 1997 to cooler La Nina conditions in the latter half of 1998. Ocean survival of sockeye that went to sea in 1997 was very low. The carryover effect of above average temperatures in the spring of 1998 on juvenile sockeye survival for the 1996 brood ( 2000 age-4 returns) is unknown. Survival of south coast stocks of pink and coho in ocean-entry-year 1998 for which ocean survival rates are estimated were very low. Age4 sockeye returns in 2000 also entered the ocean in 1998. There is no evidence for correlated ocean survival trends among Fraser sockeye and other south coast salmon species. However, the trend in salmon production seen so far from ocean-entry-year 1998 in south coast regions is consistent with the hypothesis of generally unfavourable ocean conditions in 1998. Offshore indices of ocean productivity measured by nitrate concentrations were also low in 1998 (personal communication, Frank Witney, Institute of Ocean Sciences, Sidney, BC). The latter can only be
viewed as qualitative since the nitrate data is not of sufficient quality to link directly to time series of sockeye survival data.

For Chilko sockeye, the low survival in return years 1995 and 1999 is associated with intense El Nino events but overall there is no longer-term trend in survival patterns (Fig. 4). In isolation from other information, these low survival years do not necessarily imply continued low survival of returns in 2000. It is difficult to quantify the effects of low sibling jack returns, low survival trends for other south coast salmon species, and low nitrate levels. They do, however, argue for precautionary management in 2000. If these indexes signal low sockeye survival then returns will likely be lower than the $50 \%$ probability level (Table 2).

## 5.0

 ConclusionForecasts are associated with high uncertainty as shown in Table 2 and Figures 13. Although forecasts are presented as probability distributions, they are based on models that assume average survival conditions. Improvements to pre-season abundance forecasts are unlikely without a better understanding of environmental factors affecting survival. The large differences between forecasts and observed returns in 1995 and 1999 coincide with intense El Ninos in sea entry years 1993 and 1997. At least during the recent period of intense El Nino events, the discrepancies between forecasts and run size is related to poor Fraser sockeye ocean survival (Fig 4). The influence of the very intense 1997-98 El Nino on returns of age-4 sockeye in 2000 is unknown. Age- 5 fish that went to sea in 1997 and return in 2000 are likely to be lower than expected based on ocean survival estimates. The high ocean temperature associated with the most recent El Nino dissipated in the spring of 1998. The effects on ocean survival of age-4 sockeye returning in 2000 is unknown but qualitative information reported in this document indicates that run sizes may be less than the $50 \%$ probability level.

${ }^{a}$ probability that the actual run size will exceed the specified forecast
${ }^{\mathrm{b}}$ the Upper Adams forecast is based on recruits-per-spawner data for all stocks combined.

Figure 1. Comparison of estimated (observed) returns and retrospective run size forecasts (millions ( $\log _{e}$ scale)) of age-4 Chilko sockeye by model. Data points are median (50\%) forecasts and are denoted by return year. Diagonal lines are 1:1 lines not regression lines. Error bars are $90 \%$ confidence intervals.

Figure 2. Proportional deviation of forecasts from observed run size by run-timing group for Fraser River sockeye (1990-99).

Returns

Figure 3. Histogram of historical run size (left axis) and probability distribution of the 2000 forecast (right axis) for major stocks of Fraser River sockeye on the 2000 cycle line.

Figure 4. Recruits-per-spawner (upper) and smolt survival trends for Chilko sockeye (1949-95 brood years).

Appendix Table 1. Chilko sockeye data used to forecast 2000 returns.

| Brood | Escapement |  |  | Proportion spawn | Smolts | returns at age ${ }^{\text {a }}$ |  |  |  |  |  |
