#### Abstract

In 2000, the scallop fishery was in the final year of a three-year (1998-2000) Management Plan. Nominal landings, estimated at $2,647 \mathrm{t}$, were down $12 \%$ from the previous year making it the fourth consecutive year of decline. The number of active vessels prosecuting scallops is down slightly (72 vs. 79 in 1999). As in 1999, effort diversion primarily into crab and shrimp, together with declining availability of scallop, has resulted in catches typically short of pre-emptive catch limits. The nominal catch now is only about one-quarter of the 11,266 t peak in 1996. Overall, excluding Labrador, only $23 \%$ of the available TAC ( $2,647 \mathrm{t}$ out of $11,430 \mathrm{t}$ ) was taken.

#### Abstract

Résumé

La pêche des pétoncles en 2000 en était à sa dernière année d'un plan de gestion triennal (1998-2000). Pour une quatrième année onsécutive, les débarquements nominaux étaient en baisse; estimés à 2647 t , ils ont reculé de 12 $\%$ par rapport à l'année précédente. Le nombre de pétoncliers actifs a diminué légèrement ( 72 contre 79 en 1999). En date de 1999, la réorientation de l'effort, principalement vers le crabe et la crevette, conjuguée à la moins grande disponibilité de pétoncles, s'est traduite par des captures généralement inférieures aux limites de captures anticipées. Les captures nominales ne correspondent désormais qu'au quart environ des captures sans précédent de 11266 t en 1996. Dans l'ensemble, en excluant le Labrador, seulement 23 \% du TAC disponible (2 647 t sur 11430 ) ont été capturés.

## Introduction

Two species of scallop are found in commercial densities in Newfoundland and Labrador: the sea scallop, Placopecten magellanicus and the Iceland scallop, Chlamys islandica.

The sea scallop, the larger of the two, is restricted to the northwest Atlantic. It ranges from the shallow waters along the north shore of the Gulf of St. Lawrence to deeper waters as far south as Cape Hatteras, U.S.A. It's distribution is thought to be temperature limited. Both Canadian and U.S. fishermen have long exploited the species. In Newfoundland, it is fished both recreationally and commercially, especially along the west and south coasts. Offshore, the species is restricted to St. Pierre Bank (NAFO Subdiv. 3Ps), usually in depths less than 30 fms . A pulse fishery occurs here as and when significant recruitment occurs. The fishery is prosecuted intermittently by Maritimes'- based offshore vessels. An enterprise allocation (EA) has been in place since 1989. Currently, it is under a pre-emptive TAC of 415 t . Advice for and management of the offshore fishery is through the Offshore Scallop Advisory Committee (OSAC). Conservation practices for the sea scallop include catch limits, seasons and size regulation, the latter through a minimum meat count, which seeks to discourage growth over-fishing.

The Iceland scallop is widely distributed within the sub-arctic. In Newfoundland, populations are normally found in waters from 30-100 fms, usually on hard bottom with variable substrate composition, consisting largely of sand, gravel, shell fragments, and stones. Being a filter feeder, it is most abundant in areas with strong currents such as in the Strait of Belle Isle, Gulf of St. Lawrence. Commercial aggregations also occur over St. Pierre Bank ( NAFO Subdiv.3Ps), Grand Bank (Div. 3LN), and off the Labrador(Div.2HJ) (Fig. 1). In Canada, Iceland scallops are prosecuted in Newfoundland and Labrador and in Quebec.
Elsewhere, they are harvested in Greenland, Iceland, Norway and Russia. The directed fishery for the species in Newfoundland began in the Strait of Belle Isle in 1969, but later expanded onto St. Pierre Bank (1989) and the Grand Bank (1993). On St. Pierre Bank, the Iceland scallop is sometimes intermixed with sea scallop. Aggregations within each area are now regulated by catch levels and by seasons. Cumulative removals from Newfoundland and Labrador have declined significantly and are now only about one-quarter of what it was just four years ago. In part this is due to the greater relative availability of other species, notably crab and shrimp, but also due to declines in scallop abundance throughout the areas once supporting lucrative fisheries.

The Iceland scallop resource in $4 R$ is updated from a research survey in 2000. For other aggregations, only fishery performance is summarized.

In 2000, the scallop fishery was in the final year of a three-year (1998-2000) Management Plan. Nominal landings, estimated at 2,647t, were down $12 \%$ from the previous year making it the fourth consecutive year of decline (Table 1, Fig. 2). The number of active vessels prosecuting scallops is down slightly ( 72 vs .79 in 1999, Table 2). As in 1999, effort diversion primarily into crab and shrimp, together with declining availability of scallop, has resulted in catches typically short of preemptive catch limits. The nominal catch now is only about one-quarter of the 11,266 t peak in 1996. Overall, excluding Labrador, only $23 \%$ of the available TAC $(2,647 \mathrm{t}$ out of $11,430 \mathrm{t})$ were taken (Table 3 ).

## NAFO Div. 3LNO - Grand Bank

## Fishery

In 2000, eight vessels participated in the Iceland scallop fishery over the Grand Bank, up from six the previous year but well below the 21 vessels recorded in 1998 (Table 4). Only 4.9\% (335t out of 6,800 t) of the available TAC for Divisions 3LNO were taken (Table 3).

Although total removals better than doubled in 2000 (335t vs. 138t in 1999), it still is well short of the $9,454 \mathrm{t}$ recorded in 1996. As in previous years, the majority of the catch, 295 t , came from aggregations around the Lilly Canyon and Carson Canyon ( NAFO Div. 3N, Tables 4 and 5). Catch rates here slipped 8\% from that estimated in 1999 ( $68 \mathrm{~kg} / \mathrm{tow}$ vs. $74 \mathrm{~kg} / \mathrm{tow}$ ), but down 31 \% from 98 kg/tow in 1995, when deposits here were first commercialized (Table 6). Individual meat-weight distributions show a tendency toward slightly smaller meats (Fig. 3) compared to 1999. Also, estimates of meat counts (no. of meats/unit weight) were up slightly to 42/lb from 39/lb in 1999 (Table 7).

None of the aggregations within 3Nf, 3LN and Eastern 3L was fished in 2000. Aggregations close to shore on Cape Ballard Bank yielded 35 t out of a 500 t TAC. Only 5 t were taken from the remainder of 3LNO outside of the "boxed" areas, also under a pre-emptive catch limit $(2,500 \mathrm{t})$.

Research - No new information

# NAFO Subdiv. 3Ps - St. Pierre Bank 

## Iceland scallop

## Fishery

## Canadian Zone

Iceland scallop aggregations here were first exploited in 1989. Landings peaked in 1997 (5,245 t) but have since declined. In 2000, only $32 \%$ of the overall pre-emptive TAC ( 1,134 t out of $3,500 \mathrm{t}$, Table 3) was taken, similar to the catch in 1999 (1,188 t). Most ( 676 t out of $1,134 \mathrm{t}$ or $60 \%$ ) of the catch was drawn from offshore aggregations. As in 1999, very few vessels returned to scallop fishing. The number of vessels participating remained unchanged (35 vs. 34).

Exploitation of Iceland scallop aggregations off St. Mary's the Capes (Perch Rocks) commenced in the early 1990's. A dramatic increase in effort (695 fishing days) was evident in 1997. Since then both catch and effort have declined. In 2000, only 259 days were expended and only $65 \%$ of the pre-emptive TAC (458t out of 700 t ) was taken. The majority of the catch ( 373 t or $81 \%$ ) came from small vessels (< 45 ft . L.O.A.). Proximity to shore remains the most compelling consideration to preferentially harvesting these beds to those located offshore, even if catch rates have fallen to their lowest level ( $34 \mathrm{~kg} / \mathrm{tow}$ ) since 1997(52kg/tow) (Table 8). On the average, individual meat weight was higher in 2000 than in the previous year resulting in significantly lower counts (35/lb vs. 42/lb, Table 9, Fig. 4).

Residual areas outside of discrete TAC "boxes" (Management Areas 10 and 11), but also under pre-emptive catch limits ( 1,000 t per area in 2000), yielded a further 657 t or $33 \%$ of the TAC. Both Eastern St. Pierre Bank ( 0 t ) and Western St. Pierre Bank (19 t) contributed little to the overall removals from this area in 2000. Some sea scallop caught both offshore and in Placentia Bay may be included in the landings, as there was no attempt made dockside to distinguish them.

## Trans-boundary Zone

Neither Canada nor France has fished these aggregations for Iceland scallop since 1998. When last this area was surveyed (1998), it was estimated that more than half (55\%) of scallops sampled were dead. A severe epidemic of predatory starfish has contributed to significant scallop mortality.

Research - No new information.

## Sea scallop

Fishery
After a two-year hiatus, the Maritimes' based offshore sea scallop fleet returned to St. Pierre Bank. Approximately 34 t were taken. Catch rate was higher than in 1997 when last the offshore vessels fished the Bank (30.8kg/hr vs. 20.7 $\mathrm{kg} / \mathrm{hr}$ ). In the absence of new biological information, a pre-emptive TAC of 415 t has been in place for the sea scallop since 1996. Newfoundland-based vessels fishing for the Iceland scallop sometimes catch and retain sea scallop. Regulations currently permit a 10\% tolerance. As scallops are shucked at sea and only "meats" landed, species discrimination for monitoring purposes is fraught with difficulty.

Research - No new information.

## NAFO Subdiv. 4R - Strait of Belle Isle

## Fishery

With the exception of a 4-year hiatus (1975-78), the fishery here has persisted since 1969 (or 31 years) (Table 10, Fig. 5). It is the anchor scallop fishery in Newfoundland and Labrador. Scallop beds here are considered to be a single stock for assessment purposes. The fishery is regulated by TAC (weekly and annual), and by area. In 2000, the TAC (1,100 t vs. a recommended level of 930 t ) was in the final year of a 3-yr (1998-2000) Management Plan. Even though the prescribed catch limit is for the entire area, the fleet typically converges on highdensity scallop aggregations (beds). Vessels here make daily excursions and land a fresh product. In 2000, nearly all (99.7\%) scallops were shucked at sea. The number of active licenses has ranged from a high of 107 (1985) to a low of 11 (1980). Only 32 vessels participated in the fishery in 2000. This is the lowest number of vessels that remained active in this area in nearly a decade (Table 10).

Number of scallop-days-at-sea in 2000 increased 24\% from 1999 (1458 days vs. 1177 days) while the catch/day decreased $17 \%$ to $736 \mathrm{~kg} /$ day from 889 $\mathrm{kg} / \mathrm{day}$. Whereas it took a given enterprise 2-3 days to reach it's weekly catch limit of 800 lb . of meats in 1999, fishers frequently required 5-6 days in 2000 and there were weeks when they could not even reach that limit.

Aggregations to the south have been particularly hard hit throughout the 1990's with removals sometimes, as in 1998, exceeding 90\% of the total (Fig. 6). An attempt was made in 1999 to re-distribute some of this effort to the north. With management of the resource increasingly co-opted to stake holders, it was agreed in 1999 to partition the removals equally between north and south of $51^{\circ} 25^{\prime} \mathrm{N}$. Unfortunately, this did not occur in 1999. The proposed strategy was re-visited in 2000, resulting in the TAC (1,100 t) being partitioned 40:60 (or 440:660 t) in part to
redress the delayed implementation. In 2000, it is estimated that 663 t were taken from the north vs. 410 t to the south as prescribed (Table 11).

Non-standardized CPUE (kg/tow) computed from fishing logs is down $11 \%$ from 1999 ( $26.6 \mathrm{~kg} /$ tow vs. $29.9 \mathrm{~kg} / \mathrm{tow}$ ), making it the second consecutive year of declines greater than 10\% (Table 12). Effort (\%), removals (\%), for the whole area, by zone (north and south of $51^{\circ} 25^{\prime}$ ), CPUEs by week, year and vessel-size class are summarized in Tables 13-15.

Also, in consultation with stake-holders, a corridor 5 mi . wide across the Strait of Belle Isle has been established where scalloping will be prohibited (Fig. 7). The closure became effective in 2000. Encompassing approximately $106.5 \mathrm{n} . \mathrm{mi}^{.}{ }^{2}$ out of 1635.5 n . mi. ${ }^{2}$ (or $6.5 \%$ ) of Fishing Area 14A, the "refugium" is intended to provide an opportunity to examine if settlement and recruitment would be facilitated in the absence of fishing. This indeterminate closure will assist Science in evaluating the extent to which a "pulse" fishing strategy might be incorporated into a management plan for Iceland scallop to achieve long-term sustainability.

Yet another failed attempt, the third in as many years, was made jointly by Science, Department of Fisheries and Aquaculture and the Fish, Food and Allied Workers Union (FFAW) to deploy spat collectors to determine reproductive success of Iceland scallop in 4R.

## Research

A 10-day research survey (August 22-31, 2000) was conducted in 4R (Strait of Belle Isle), last assessed in 1997, to update resource status. All fishing sets were completed with an 8 -ft. New Bedford scallop rake equipped with 3 " rings and interconnected with three and four links on the top and bottom respectively. Mean catch per tow and depths fished are reported in Table 16.

## Size Composition

Notwithstanding repeated claims to the contrary, the continued absence of pre-recruits has long been a recurrent concern in this fishery. Research and at-sea observer coverage in 2000 again indicated that size of scallop here has remained unchanged for five consecutive years (Tables 17 and 18, Fig. 8). The research survey in 2000 estimated that pre-recruits contributed to less than $0.5 \%$ of the total numbers caught and $0.10 \%$ by weight (Table 19). Scallop aggregations here now consist predominantly of large (old) scallops with little potential for further growth.

Size-distribution of cluckers, on the other hand, indicates a relatively higher percentage of small scallops (Fig. 9). As hypothesized previously (Naidu et al. 1998, 2000), this might be indicative of selective mortality to young scallops through intense fishing activity.

Scallops here depict a history of encounters with fishing gear as manifested by the frequency of occurrence of supernumerary "shock" or "stress" rings. This feature is most likely attributable to sub-lethal past encounters with fishing gear. Nearly a third (34\%) of all scallops examined from this area in 1999 and 2000 ( $\mathrm{N}=$ 3278) carried the indelible evidence (Table 20). This observation supports the contention that exploitation rates here have generally been high.

## Meat Yields

Overall meat yield (biological) remained unchanged in 2000 (12.2\% vs. $12.4 \%$ in 1999). Meat counts were slightly higher (31 vs. 28/lb.) (Table 21).

Natural Mortality
Natural mortality, computed from percent occurrence of cluckers (persistent paired valves still attached at the hinge line), was estimated as per Dickie (1955), Mercer (1974) and Naidu (1988) at 0.20 . No significant differences were detected from previous years (Table 22). Estimates of natural mortality are also reported for each of the two zones - north and south of $51^{\circ} 25^{\prime} \mathrm{N}$.

## Starfish

Relative to other areas (3LNO), starfish abundance is not considered problematic (Table 23, Naidu et al. 1998). Catastrophic mortalities ( $\mathrm{M}=0.8$ ) have been reported over St. Pierre Bank, where an infestation of starfish decimated populations of Iceland scallops (Mahe and Briand, 1998). There is no evidence in 4R of extreme starfish-mediated mortality to scallops.

## Stock status

Estimates of highly aggregated populations are biased frequently through sampling error attributable in part to the assumption of spatial homogeneity of density over a given area and the assumption of equal catchability of the target species over the entire area surveyed, related to variable bottom type.

Improved characterization of the sea bottom using an acoustic seabed classification system such as RoxAnn permits mapping the distribution of seabed types favorable for the occurrence of sedentary, epibenthic or infaunal communities. Dedicated RoxAnn transects were first run across the Strait of Belle Isle in 1995.Twelve east-to-west lines between parallels $51^{\circ} 01^{\prime} \mathrm{N}$ and $51^{\circ} 55^{\prime} \mathrm{N}$, each spaced five-miles apart and along 255 mi had been completed over an area estimated at $847 \mathrm{n} . \mathrm{mi}^{2}$. Acoustic information assembled opportunistically while steaming from one transect to another or from one fishing station to the next and during fishing tows is continuously incorporated into the seabed classification database. Total area considered favorable for the presence of scallop had then
been estimated at $282 \mathrm{n} . \mathrm{mi}^{2}{ }^{2}$. In 2000, eleven new transects along 221 n .mi were run in between those completed in 1995, further improving our understanding of the distribution of seabed types over the target area. In sum, we have since 1995 completed 23 transects along 446 n .mi.(Fig. 10). Large areas still exist in which acoustic data is low or non-existent. Where acoustic data on bottom types were unavailable, information on fishing effort distribution was used in combination with RoxAnn outputs in the delineation of areas favorable for the presence of scallop. Censusing and interpreting the distribution of bottom types within the Strait of Belle Isle is fraught with difficulty. The sea bottom here is highly variable and heterogeneous with respect to substrate composition. This renders unambiguous characterization of even small areas problematical, especially that gear efficiency may be expected to vary. In fact, only five (out of 63) of the 0.5 mi tow tracks in 2000 were completed in unambiguously uniform bottom. This is problematical for abundance estimation using the swept area methodology given that gear efficiency varies both within and between tows.

The composite acoustical data and distribution of fishing effort was used to better infer distribution of scallop beds in the area and to optimize survey design. This approach allowed for a more efficient stratification scheme than a simple random survey based on some artificial stratifying variable such as depth. Configuration of scallop beds in the area was modified in 2000 and the number of scallop beds reduced from six (1997) to three (Fig. 11).

While the entire area ( 612 n.mi. ${ }^{2}$ ) within the three defined beds was surveyed in 2000, the abundance estimate within each area was reduced by the ratio of "good" to "bad" bottom. We attempted to do this by inspecting sea-bottom characteristics along each of the 63 sets completed in the area. RoxAnn outputs along each half-mile tow were examined to determine proportions of "good" to "bad" bottom. The total area surveyed was then adjusted to reflect the cumulative ratio of "good" to "bad" bottom. This was done separately for each of the three beds and total fishable biomass estimated.

Overall, it was estimated that only $50 \%$ of the area ( 300 n.mi. ${ }^{2}$ out of 612.2 n.mi. ${ }^{2}$ ) surveyed was considered suitable for the presence of scallop. Based on an efficiency-corrected (20\%) swept area methodology, it is estimated that the biomass now is between 7000t- 10,600t, round with a mean of $8,800 \mathrm{t}$ (Table 24), down from the mean estimated in 1997 ( $9,300 \mathrm{t}$ ). The recommended catch based on $10 \%$ of the mean would be $700 \mathrm{t}-1,060 \mathrm{t}$ with a mean at 880 t .

## Labrador

## Fishery

As per recent years, inshore aggregations here were again harvested with nominal catches estimated at 105 t , down from 644 t in 1999 (Table 1).

## Research

There has been no directed research into scallop aggregations in Labrador.
