#### Abstract

The status of the $2 \mathrm{~J}+3 \mathrm{KL}$ cod stock is updated based on an additional year of research bottom-trawl surveys, sentinel surveys, a prerecruit survey, acoustic surveys in specific areas, returns from tagging studies, a questionnaire completed by fishing communities, and catches and catch rates from the index fishery. Considerable uncertainty exists about the structure of this stock and consequently in this assessment the stock status was assessed under two hypotheses: a) the cod currently inshore belong to an inshore subpopulation that is functionally separate from the offshore; and b) inshore and offshore fish together constitute a single functional population. Under the hypothesis of a separate inshore population, it is not clear whether the spawning stock has been sustained by recent levels of recruitment at the current levels of natural and fishing mortality. Catch rates from the sentinel survey, commercial logbooks and autumn research bottom-trawl surveys in the inshore show a decreasing trend in exploitable biomass since 1998. However, estimates of exploitable stock size based on tagging studies have been relatively constant. Under the single functional population hypothesis, there is no doubt that the $2 \mathrm{~J}+3 \mathrm{KL}$ cod spawner biomass remains at an extremely low level compared to historical size, and there is no evidence of a recovery. Any fishery on the remnant in the inshore will delay recovery of the stock. Predation by harp seals is estimated to be $37,000 \mathrm{t}$ and may be preventing the recovery of the cod stock.

## Résumé

L'état du stock de morue dans les divisions $2 \mathrm{~J}+3 \mathrm{KL}$ est mis à jour à la suite d'une année supplémentaire de relevés au chalut de fond, de relevés par pêche sentinelle, de relevés des pré-recrues, de relevés acoustiques dans certaines zones, de données issues d'étiquettes retournées, des réponses à un questionnaire rempli par les pêcheurs, ainsi que des prises et des taux de prises de la pêche indicatrice. De nombreuses incertitudes subsistent quant à la structure de ce stock et par conséquent, l'a présente évaluation de l'état du stock se fonde sur deux hypothèses : a) la morue actuellement en zone côtière appartient à une souspopulation côtière qui est fonctionnellement distincte de la population des eaux hauturières et b) les poissons des eaux hauturières et les poissons des eaux côtières constituent une seule sous-population. Quand on se base sur l'hypothèse d'une population côtière distincte, on ne sait pas très bien si le stock reproducteur a été maintenu aux niveaux actuels de mortalité naturelle et de mortalité due à la pêche grâce aux récents niveaux de recrutement. Les taux de prise issus du relevé par pêche sentinelle, des registres des bateaux de pêche commerciale et des relevés au chalut de fond faits en automne dans les eaux côtières indiquent une tendance à la baisse de la biomasse exploitable depuis 1998. Cependant, les estimations de la taille du stock exploitable fondées sur les études d'étiquetage ont été relativement constantes. Si l'on adopte l'hypothèse de la sous-population unique, il ne fait aucun doute que la biomasse de géniteurs dans les divisions $2 \mathrm{~J}+3 \mathrm{KL}$ demeure à un niveau extrêmement faible par rapport à sa taille historique et qu'il n'y a aucun signe de rétablissement du stock. Toute pêche sur le reste de la zone côtière retardera le rétablissement du stock. La prédation par les phoques du Groenland est évaluée à 37000 t et empêche peut-être ce stock de se rétablir.

## 1 Introduction

Historically, many of the cod in NAFO Divisions $2 \mathrm{~J}+3 \mathrm{KL}$ (the "northern cod") migrated between overwintering areas in deep water near the shelf break and feeding areas in shallow waters both on the plateau of Grand Bank and along the coasts of Labrador and eastern Newfoundland (Fig. 1a). Some cod remained inshore throughout the winter in deep water both within the bays and off the headlands. For several centuries various nations pursued the cod while they were in the shallow areas, first with hook and line and later with nets which evolved by the late 1800s into the highly effective Newfoundland cod trap. The deep waters, both inshore and offshore, remained refugia until the 1950s, when longliners designed to exploit populations of cod in deep coastal waters were introduced to eastern Newfoundland and distant water fleets from Europe started to employ bottomtrawlers to fish the deeper water of the outer banks, first mainly in summer/autumn but later in the winter and early spring when the cod were highly aggregated. Landings increased dramatically in the 1960s as large numbers of bottom-trawlers targeted the overwintering aggregations on the edge of the Labrador Shelf and the Northeast Newfoundland Shelf. At the same time, the numbers of large cod in deep nearshore waters are thought to have declined quickly as the longliner fleet switched to synthetic gillnets. Additional details on the history of the northern cod fishery, including changes in technology and temporal variability in the spatial distribution of fishing effort, may be found in Templeman (1966), Lear and Parsons (1993), Hutchings and Myers (1995) and Neis et al. (1999).

The number and individual size of the fish declined through the 1960s and 1970s and the stock reached a very low biomass by the mid-1970s (Baird et al. 1991). Following Canada's extension of jurisdiction to 200 miles in 1977, the stock began to recover as a consequence of smaller catches, entry of the strong 1973-1975 year-classes and an increase in the growth rate of individual fish. Fishing effort by an expanding Canadian trawler fleet increased dramatically following extension of jurisdiction and this fleet took a large portion of the total allowable catch, which almost doubled between 1978 and 1984. It became clear in retrospect that the stock size was overestimated during this period. Fishing mortality was about twice as high as the $\mathrm{F}_{0.1}$ target level. In addition, the 1976-1977 yearclasses were weak and individual growth rate declined. The 1978-1982 year-classes were moderate to strong but the 1983-1985 year-classes were weak. The spawner biomass did not increase after about 1982 and the $3+$ population size peaked in 1984-1985.

Reasons for the overestimation of stock size include changes in the method by which the sequential population analysis (SPA) was calibrated and the "retrospective" problem, a phenomenon whereby adding additional data on each year-class results in downward revisions of population size. In addition, the 1986 survey was positively biased. It was recognized in 1988 that the 1986 value had contributed to severe overestimation of stock size (Baird et al. 1991; Lear and Parsons 1993; Bishop and Shelton 1997). The catch predicted for an $\mathrm{F}_{0.1}$ fishing mortality in 1989 was much lower than the TAC's and catches of preceding years, and the fixed fishing mortality approach was suspended in favour of an approach that reduced quotas more gradually in hopes of avoiding undue hardship to the
fishing industry. Fishing mortality was allowed to escalate. Simulations indicate that the change in the approach to setting the quota turned what might have been a severe stock decline under a fixed fishing mortality rate into a collapse (Shelton 1998).

By the early 1990s much hope was placed on the 1986 and 1987 year-classes, which appeared to be strong in the research vessel surveys and initially contributed strongly to commercial catches. However, in concert with older year-classes, these two year-classes appeared to decline very rapidly. Fishing mortality was very high but reported landings including documented discards were insufficient to account for the abrupt decline observed in the research vessel indices in 1990-1991. The stock was closed to Canadian fishing in July 1992. The research vessel index showed a further large decline in autumn 1992. It was thought that there might have been a substantial increase in natural mortality, especially during the first half of 1991 (Lear and Parsons 1993; Atkinson and Bennett 1994). Research vessel indices continued to decline in the absence of a Canadian fishery and reached a very low level by 1994.

Controversy continues regarding the time course and causation of the collapse. Some analyses found no support for a sudden increase in natural mortality in 1990-1991 (Myers and Cadigan 1995) and attributed the decline to fishing mortality alone (Hutchings and Myers 1994; Hutchings 1996; Myers et al. 1996a,b; Myers et al. 1997a,b). However, in the late 1980s and early 1990s the stock underwent several changes that may not have been related to fishing. For example, the distribution during the autumn was increasingly concentrated toward the outer edge of the banks (Lilly 1994; Taggart et al. 1994), the distribution during the winter was increasingly toward the south and to deeper water (Baird et al. 1992b; Kulka et al. 1995), the inshore fishery started late (Davis 1992) and fish experienced a pronounced decline in growth, condition and age at maturity, especially in the north (Taggart et al. 1994). In addition, declines in abundance and changes in distribution were experienced by many other groundfish, both commercial and noncommercial (Atkinson 1994; Gomes et al. 1995). Changes in the lightly exploited American plaice in Divisions 2J and 3K (Bowering et al. 1997) parallel many of the changes in cod. Capelin, the dominant pelagic species in the area and the major prey of cod, almost disappeared from Division 2J, increased in abundance in areas where they were previously uncommon (Flemish Cap and eastern Scotian Shelf), became inaccessible to acoustic surveys conducted at traditional times, arrived late in the inshore for spawning, and experienced low growth rates (Lilly 1994; Frank et al. 1996; Nakashima 1996; Carscadden et al. 1997; Carscadden and Nakashima 1997). Arctic cod, a cold water species, appeared to increase in abundance and expand its distribution (Lilly et al. 1994; Lilly and Simpson 2000). Changes were observed in salmon (Narayanan et al. 1995) and several other pelagic species, especially migrants from the south (Montevecchi and Myers 1996). These changes in cod and many other species may have been related to the prolonged period of low water temperatures starting in the early 1980s and to a particularly cold period in the early 1990s (Narayanan et al. 1995; Drinkwater 1996; Colbourne et al. 1997), but causal links between changes in water temperature and changes in fish biology remain to be established in many cases, especially for the cod (e.g. Lilly 1994). Although much of the published literature concludes that fishing was the major and even the sole cause of the collapse of the $2 \mathrm{~J}+3 \mathrm{KL}$ cod during the late 1980 s and early 1990 s, the possible
impacts of factors such as water temperature, the abundance and availability of prey (especially capelin) and predation by seals require additional study.

A thorough review of all analyses relating to the decline of cod in $2 \mathrm{~J}+3 \mathrm{KL}$ from the mid1980s to the early 1990s is beyond the scope of this paper. However, one specific aspect may be mentioned as illustrative of the degree of uncertainty. Various analyses have been presented in support of the hypothesis that the cod shifted southward (Kulka et al. 1995; Wroblewski et al. 1995b), possibly in response to a decline in water temperature (deYoung and Rose 1993; Rose et al. 1994; Atkinson et al. 1997; Rose et al. 2000) or a southward shift in the distribution of capelin (Rose et al. 2000), and that this shift increased the vulnerability of the cod to both Canadian and non-Canadian fleets (Rose et al. 1994; Atkinson, et al. 1997; Rose and Kulka 1999). Other analyses find no support for the southward shift hypothesis (Hutchings and Myers 1994; Hutchings 1996; Myers et al. 1996a). There can be little progress in determining what caused the deaths of the fish until there is better understanding of where and when the deaths occurred.

Uncertainty about the time course of the decline lies at the heart of the inability to reconcile catch data and the autumn research vessel index within a sequential population analysis (SPA). One may class the various possibilities for the discrepancy into three groups. First, the stock decline may have been more gradual than indicated by the surveys. Under this scenario, the survey index had positive year effects for several years in the late 1980s and early 1990s. These effects may have been associated with the increased degree of aggregation toward the shelf edge at the time of the surveys. Hutchings (1996), for example, has conducted a modelling exercise that he suggests demonstrates how aggregations could cause overestimation in a random stratified survey. If, however, the autumn survey index accurately reflected the changes in cod abundance, then the decline occurred rapidly and a large number of fish remain unaccounted for in the catches. This leads to the second and third sets of hypotheses. The second is that catches in the late 1980s and early 1990s were grossly underestimated. This could include under-reporting of landings and the dumping of fish (including discarding of small fish) in Canadian fisheries (Hutchings 1996; Myers et al. 1997a; Hutchings and Ferguson 2000) and underestimation of the catch by distant water fleets on the Nose of the Bank. The third group of hypotheses involves an increase in natural mortality, caused for example by seal predation or a decrease in condition.

Shelton and Lilly (2000) conducted diagnostic studies to determine the magnitude of the departure from standard SPA assumptions required to allow the SPA to fit the data. They found that the departures were too large to be explained with independent data currently available. They concluded that unreported deaths caused by the offshore fishery may be most plausible as the main contributing factor to lack of model fit but that factors such as increased natural mortality, and possibly changes in survey catchability, also played a role.

The inshore region has gained a greatly increased degree of prominence in the assessment of $2 \mathrm{~J}+3 \mathrm{KL}$ cod since the mid-1990s. By the autumn of 1994 there appeared to be very few cod left within the boundaries of the $2 \mathrm{~J}+3 \mathrm{KL}$ stock complex. In spring 1995, a research vessel unexpectedly found a dense aggregation of cod in Smith Sound, Trinity Bay, and
during summer/autumn of 1995 participants in the new sentinel survey program experienced good catch rates of commercial size cod over much of the area from central 3 K to southern 3L. These reports of cod in the inshore called into question the adequacy of the offshore survey as an index of total stock abundance. Information on the general biology (e.g. distribution, spawning, feeding, growth, condition) of cod in the inshore may be found in Lilly et al. (1998a) and Lilly et al. (1999), and in the many sources cited therein. Our knowledge of the biology of cod in the inshore has increased rapidly through interviews with fishermen (e.g. Neis et al. 1999; Jarvis and Stead 2001) and an intensification of study, including a tagging program, sentinel surveys, a logbook program for commercial vessels under 35 feet in length, acoustic surveys in specific areas, and an extension of the autumn survey into new strata in the inshore.

Attention should be drawn to one specific portion of the inshore. Gilbert Bay in southern Labrador has been shown to have a small resident population of cod (Green and Wroblewski 2000) that are genetically distinct from other cod in the 2J3KL area (Ruzzante et al. 2000). Gilbert Bay has been identified as an Area of Interest, which is a step along the way to becoming a Marine Protected Area. Because of its small size, limited distribution and genetic distinctiveness, the Gilbert Bay population was not included in the present assessment of $2 \mathrm{~J}+3 \mathrm{KL}$ cod.

A narrative of the assessment process for $2 \mathrm{~J}+3 \mathrm{KL}$ cod from extension of Canadian jurisdiction in 1977 to the moratorium in 1992 has been compiled by Bishop and Shelton (1997). Their report provides details of the annual assessments, including the data and methods used to determine stock status and the results of the assessments. The latter include TAC projections in terms of the standard requested reference points. The origin and evolution of the important databases such as catch at age, catch rate indices, and research survey data are discussed. Topics related to the assessments, such as the various committees and commissions that were struck to provide advice on scientific aspects of the assessments, and important issues such as the "retrospective problem", are also given attention. Documentation supporting assessments since 1992 may be found in Bishop et al. (1993; 1994; 1995a,b), Shelton et al. (1996), Murphy et al. (1997) and Lilly et al. (1998b; 1999, 2000b). Reports of the Canadian assessment meetings during 1993-1996, 1999 and 2001 may be found in Sinclair (1993), Shelton and Atkinson (1994), Shelton (1996), Evans (1996), Rivard (1999) and Morgan (2001). NAFO deliberations are documented in NAFO Scientific Council Reports.

The 2001 assessment updated the status of the $2 \mathrm{~J}+3 \mathrm{KL}$ cod stock to the end of 2000 based on an additional year of research bottom-trawl surveys, sentinel surveys, a prerecruit survey, acoustic surveys in specific areas, returns from tagging studies, a questionnaire completed by fishing communities, and catches and catch rates from the index fishery. A summary of the assessment is provided in the Stock Status Report (DFO 2001). Technical details are provided in the present document and in several additional documents referenced in the text.

## 2 The fishery

### 2.1 Fishery quota and management plan for 2000

In May 2000, the Fisheries Resource Conservation Council recommended that only sentinel fisheries be prosecuted in 2J, that only sentinel and index fisheries be prosecuted in 3 KL , and that the total catch for coastal 2 J 3 KL not exceed $7,000 \mathrm{t}$ (FRCC 2000). The Minister of Fisheries and Oceans announced on June 14 that an index fishery will be conducted in the inshore portion of 2 J 3 KL and that sentinel surveys will continue. A TAC of 7,000 $t$ was established for the 2000-2001 fishery, with $6,600 t$ for the index fishery, 300 t for the sentinel survey and 100 t for by-catch. A recreational / food fishery was also announced.

### 2.1.1 Index fishery

Management measures for the index fishery were similar to the 1999 commercial fishery. The fishery was conducted on an IQ basis, with each licenced fisher permitted to harvest $8,400 \mathrm{lbs}$ round weight ( $7,000 \mathrm{lbs}$ head-on gutted weight). Fishers were restricted to fishing only in the NAFO Division of their homeport, with the additional limitation that fishers in Division 3L were restricted to fishing to the north or south of Grates Point (between Trinity Bay and Conception Bay), again based on the location of their homeport. (There were some special provisions for fishers living close to the dividing line.) Smith Sound in Trinity Bay was limited to fishers with homeports in the Sound. All fishing was restricted to within the 12 nm limit. Fishers were permitted to direct for cod with one gear type combination; either longlines and handlines or gillnets and handlines, but not both combinations during the same week. Fishers were permitted to use a maximum of six 50fathom gillnets ( $51 / 2-6 \frac{1}{2}$ inch mesh) or longlines with a maximum of 2,000 hooks. A small number of fishers were permitted to use cod traps to obtain fish for growout. All landings were subject to an industry-funded 100\% Dockside Monitoring Program.

Two fishing seasons were announced: June 26 - July 29 and September 11 - October 28. The second period was subsequently extended to November 18 and then again to November 30.

### 2.1.2 Sentinel surveys

Sentinel surveys were conducted for the sixth year. Protocols are described in Maddock Parsons et al. (2001).

### 2.1.3 Recreational / food fishery

A recreational / food fishery was held during three weekends: August 25-27, September 24 and September 23-24. (The initial announcement specified only the first two weekends. The third was added because of poor weather.) Fishing was by hook-and-line (hand-held or angling). Jiggers were not permitted. The individual catch limit was 10 groundfish per day.

The estimated level of participation was 56,000 person-days. The estimated total catch was 302,000 fish weighing 499 t (Fisheries Management Branch, DFO, Newfoundland Region, unpublished data). In comparison, 57,000 person-days caught 98,000 fish weighing 220 t during the 8-day 1999 fishery and 57,000 person-days caught 340,000 fish weighing 696 t during the 3-day 1998 fishery.

### 2.2 Catch and catch at age

### 2.2.1 Nominal catch

Landings from this stock increased during the late 1950s and early 1960s and peaked at just over $800,000 \mathrm{t}$ in 1968 (Table 1; Fig. 2). Landings then declined rapidly to a minimum of $139,000 \mathrm{t}$ in 1978, increased to a plateau of approximately $250,000 \mathrm{t}$ in the mid- to late 1980s and then declined very quickly in the early 1990s. The portion of the landings coming from each of the Divisions changed over time. During the 1960s, when the fishery was primarily by non-Canadian fleets (Fig. 3), landings were taken mainly from Divisions 2J and 3L (Fig. 4). Division 3K became prominent in the mid-1970s. Landings from Division 2J were relatively small in the mid-1980s. Division 3L dominated from the mid1980s until the moratorium in 1992.

The fixed gear landings (Table 2; Fig. 5) increased from just $41,000 \mathrm{t}$ in 1975 to a peak of $113,000 \mathrm{t}$ in 1982, declined to $74,000 \mathrm{t}$ in 1986, and increased again to a peak of $117,000 \mathrm{t}$ in 1990, just 2 years before declaration of the moratorium. There was a substantial decline to $61,000 \mathrm{t}$ in 1991. The commercial fishery was closed in July 1992 and only 12,000 t were landed that year. Some of the increase in the late 1980s was due to a resurgence of gillnet landings in southern Division 2J and trap landings in Division 3L, but much was due to an expansion of the gillnet fishery to the Virgin Rocks and other offshore areas in Division 3L (see Table 3 of Shelton et al. 1996).

Landings have been small since 1992. In 1993 a recreational fishery together with bycatches accounted for $11,000 \mathrm{t}$. In 1994 a limited ( 10 d ) food fishery during August and September, together with by-catch, accounted for about $1,300 \mathrm{t}$. In 1995 there was no recreational or food fishery but a sentinel survey was introduced to provide catch-effort information from fixed gear fished in a manner similar to a commercial fishery. Reported landings were only 330 t . In 1996 the sentinel survey continued and a food fishery was allowed on two consecutive 3-day weekends. These two fisheries together with by-catch landed approximately $1,700 \mathrm{t}$. In 1997 there was no food fishery. Sentinel surveys accounted for about $70 \%$ of the total landings of 500 t .

In 1998 there was a quota of $4,000 \mathrm{t}$, divided among by-catch ( 275 t ), sentinel surveys ( 375 t ), and an index fishery, which was itself divided into an inshore component ( 3000 t ) and an offshore component ( 350 t ). [The concept of an index fishery was introduced by the Fisheries Resource Conservation Council (FRCC 1998). An index fishery is not a commercial fishery, but rather a small directed fishery conducted by commercial fishermen "to provide additional information to supplement sentinel programs and to add confidence
... in cod population estimates". It was stated that the program should be designed such that "this program supplements (and not duplicates) the sentinel survey data". The magnitude of an index fishery, if the only objective were to provide information for scientific analysis of the size of the resource, has not been debated. The magnitude of an index fishery (in the context of $2 \mathrm{~J}+3 \mathrm{KL}$ cod) as defined by the FRCC may be inferred from their use of the term "index" for TAC's of $4,000 \mathrm{t}$ (FRCC 1998) and 7,000 t(FRCC 2000) and the term "commercial" for a TAC of between 6,000 and $9,000 \mathrm{t}$ (FRCC 1999).] The reported landings in 1998 were 398 t from by-catch, 388 t from sentinel surveys, $3,019 \mathrm{t}$ from the inshore index fishery, and essentially zero from the offshore index fishery. In addition, there was a 3-day food fishery that is estimated to have taken 696 t .

In 1999 there was a quota of $9,000 \mathrm{t}$ in the inshore portion of 2 J 3 KL . The quota available for a commercial fishery was set at $8,600 \mathrm{t}$ after allowances of 300 t for the sentinel survey and 100 t for by-catch. Reported landings were about $8,050 \mathrm{t}$ from the commercial fishery and 200 t from the sentinel survey. An additional 220 t were estimated to have been taken by the food/recreational fishery.

In 2000 / 2001 a quota of $7,000 \mathrm{t}$ was established for an index fishery and sentinel surveys in the inshore for vessels under 65 feet (see Section 2.1). Reported landings were approximately $4,700 \mathrm{t}$ from the index fishery and 200 t from the sentinel surveys, which together with the estimate of 500 t for the food / recreational fishery totalled approximately 5,400 t.

The index fishery in 2000 was conducted on the basis of individual quotas. Participants were licenced to fish only in the Division of their home port, with an additional restriction within 3L to either north or south of Grates Point, so landings within each Division (or area within 3 L ) reflected both the relative availability of fish and the number of licences in the area. The percentage of the landings by Division increased from $2 \mathrm{~J}(<1 \%$ by weight) to $3 \mathrm{~K}(27 \%)$ to $3 \mathrm{~L}(73 \%)$. The percentage taken in 3 K was considerably reduced from the $43 \%$ in 1999.

The landings in 2000 from all sources (commercial fishery including by-catch, sentinel survey and food / recreational fishery) are presented by gear, unit area and month in Table 3. Gillnets contributed $76 \%$ by weight, linetrawls $4 \%$ and handlines $18 \%$. There was also a small catch from traps and a very small by-catch in the yellowtail fishery by large otter trawlers on Grand Bank (3L). Most (75\%) of the catch came from the area between central Notre Dame Bay and Grates Point; 22\% in 3Ki (Twillingate - Fogo), $27 \%$ in 3La (Bonavista Bay) and $26 \%$ in 3Lb (Trinity Bay). As in 1999, the months of highest catch were July ( $28 \%$ ) and September (38\%).

It is known that in recent years there have been removals in excess of sentinel surveys and legal fisheries. The magnitude of these removals cannot be estimated but is thought to be substantial.

### 2.2.2 By-catch and discards

The Canadian observer program, jointly funded by DFO and industry, provides varying levels of coverage of fishing activity by the various fleet sectors off Newfoundland. The primary purpose of the program is enforcement and control, but useful data for science are also generated. These data include length frequencies, otolith samples, and estimates of catch, effort, by-catch and discarding. Data for 2000 were evaluated to gauge the possible impact of by-catch and discards on the recovery of the northern cod stock. The percentage of the sets covered were about $1 \%$ for vessels less than $35 \mathrm{ft}, 8 \%$ for vessels $35-65 \mathrm{ft}, 18 \%$ for vessels $65-100 \mathrm{ft}$, and $73 \%$ for vessels greater than 100 ft (including $100 \%$ coverage on vessels directing on yellowtail). In the 2 J 3 KL area there were 1,633 sets observed. Of these sets, 3 were directed at black back flounder, 10 at capelin, 102 at cod, 9 at crab, 213 at Greenland halibut, 4 at herring, 32 at lumpfish, 951 at shrimp and 309 at yellowtail. The weight of cod kept or discarded in the non-cod directed observed sets totalled 28 t . No attempt is made in the current assessment to estimate the by-catch and discards in the unobserved sets for the non-cod directed fisheries using the rates in the observed sets. The amount of cod discarded in the cod directed sets totalled only 156 kg for an observed kept catch of $11,725 \mathrm{~kg}$, giving a discard rate of 0.0133 . Taking into account the total recorded landings of $5,365 \mathrm{t}$ for 2000/2001, the amount of cod discarded in the cod-directed fishing in the past season is thus estimated to be 71 t . An implicit assumption made in this calculation is that observed and unobserved sets have equal discard rates.

Although bias is a major issue, analysis should be carried out on the observer data to attempt to estimate overall by-catch and discard rates for each fishery, which can then be extrapolated, using an appropriate model, to estimate total by-catch and discards. Clearly this should be carried out on a directed species/gear basis and it may be useful to consider temporal and spatial effects in the data, and to account for discarding by length. To do the appropriate analysis, two data files will have to be interrogated together - the observer data and the commercial catch-effort database. This will be set as a priority for the next assessment.

### 2.2.3 Sampling of catch in 2000

The sentinel survey was sampled intensively. Most gear / unit area cells in the index fishery were well sampled during July and September, but there were some shortfalls, the most noticeable being the absence of sampling at any time in 3Lj (eastern Avalon Peninsula). There was no sampling of the food/recreational fishery.

The number of fish measured in 2000 is given by gear, unit area and month in Table 4. The number of fish aged is given by gear, unit area and quarter in Table 5.

### 2.2.4 Catch numbers and weights at age

The age composition and mean length-at-age of the landings were initially calculated by gear, unit area and quarter as described in Gavaris and Gavaris (1983). The following relationship was applied in deriving average weight-at-age:

$$
\log (\text { weight })=3.0879 * \log (\text { length })-5.2106
$$

In terms of numbers of fish, the landings in 2000 were dominated by gillnet ( $65 \%$ ), followed by handline ( $24 \%$ ), linetrawl (7\%), trap (4\%) and otter trawl ( $<1 \%$ ) (Table 6). The dominance of gillnet was less than in 1999, when that gear accounted for $81 \%$ of the landings.

The total catch-at-age in 2000 comprised a range of ages, with ages 3 to 10 each contributing at least $5 \%$ by number and ages 5 and 6 most prominent (Table 6; Fig 6). Only $2 \%$ (by number) of the total catch in 2000 was older than age 10 (the 1990 year-class). The total catch at age in 2000 strongly reflects the selectivity of the gillnets, which tend to select ages 6 and 7 but caught roughly equal numbers of ages 5 to 8 in 2000. Hook and line gears caught cod of a wide range in age, with ages 3-5 most prominent in linetrawls and ages $4-5$ most prominent in handlines. The trap catch was dominated by age 4 and the otter trawl by-catch by ages 3-4. The small size of cod in the otter trawl by-catch presumably results from the use of restrictor grates in the yellowtail fishery.

The numbers at age for fish in the reported landings from 1962 to 2000 are presented in Table 7. The 1989 year-class was the most important contributor to the catch in 19931994. The 1990 year-class was the most important contributor in 1995-1997 and was still an important contributor in 2000. The 1992 year-class was the most important contributor in 1998-1999, but was less prominent in 2000.

The mean weights-at-age calculated from mean lengths-at-age in the landings have varied over time (Table 8; Fig. 7). There was an increase in the late 1970s and early 1980s, followed by a decline through the 1980s to low levels in the early 1990s. There has been substantial improvement in the latter half of the 1990s, and for some age-groups (e.g. ages 4-7) the weights-at-age calculated for 2000 were at or near the highest levels in the timeseries. Interpretation of changes in the weights-at-age is difficult because of changes in the relative contributions of the various gear components and changes in the location and timing of catches from each gear component. For example, much of the landings prior to the moratorium came from otter trawling offshore early in the year, whereas since the moratorium most of the catch has come from fixed gear inshore in the second half of the year. The high proportion of landings coming from gillnets in 2000 will tend to increase the calculated mean weight-at-age of those age-classes entering the selection range of the gear. This may apply in particular to ages 5 and 6 in 2000 . There may also be an underestimate of weight-at-age for those age-classes leaving the selection range of gillnets.

There are clearly problems with the 1993 weights-at-age that remain to be resolved.

The biomass at age for fish in the reported landings from 1962 to 2000 is presented in Table 9.

### 2.2.5 Weights-at-age at the beginning of the year

Weights-at-age at mid-year and the beginning of the year were required for explorations of whole stock analyses employing sequential population analysis (SPA). Although these SPA explorations were not at this time considered helpful in assessing present status of the stock and are not reported, it is thought that the weights-at-age employed in these explorations should be documented as a record of what had been used and to assist additional explorations.

A satisfactory time-series of stock weights-at-age is not available. Estimates have in the past been obtained by adjusting to the beginning of the year those mean weights-at-age calculated from sampling during the commercial fishery (see, for example, Rivard 1982, p. 14). A problem with such data is that the commercial fishery may be conducted with a variety of gears, each with its peculiar selection pattern, and the temporal pattern of fishing may not centre on the time when the fish attains the mid-point of its annual length increment. In addition, both the relative contribution of each gear to the total catch and the temporal and spatial pattern of fishing may vary among years. Prior to preparation of the 1998 assessment of $2 \mathrm{~J}+3 \mathrm{KL}$ cod it was thought that weights-at-age derived from sampling during research bottom-trawl surveys might provide a more representative measure of weight-at-age at the beginning of the year. Based on a comparison of data from research surveys and the commercial fishery in Subdivision 3Ps (Lilly 1998b), it was decided that data from the research vessel survey were too variable at older ages and that it would be prudent to continue to use estimates from commercial fishery data until more representative data were available. The use of survey data for the $2 \mathrm{~J}+3 \mathrm{KL}$ stock in recent years is further constrained by poor or nil representation for some of the older age groups caught in the inshore fisheries from the mid-1990s to the present. This is most apparent in Divisions 2J and 3K. Even with the above concerns, it may be desirable to use information from the bottom-trawl surveys to provide estimates for the younger ages, since commercial gears tend to select the larger individuals at these ages, but to date the modeling of seasonal growth required to adjust the autumn survey data to mid-year and January 1 estimates has not been attempted. It was decided that the commercial weights-at-age would continue to be used to estimate January 1 weights-at-age.

As noted by Lilly (1998a), there are several aspects of the commercial weight-at-age data (Table 8; Fig. 7) that require particular attention. (1) Constant values have been assumed in some of the early years. Weights at ages 2-20 are constant from 1962 to 1971 and weights at ages 19 and 20 are constant from 1972 to 1977 . The value for age 20 jumps from 7.19 kg in the first period to 17.46 in the second. (2) Some values seem unusually high or low compared with adjacent values. The most notable instances are values for ages 8 and 9 in 1993, which seem much too high, and the value for age 12 in 1995, which is too low. It is assumed that these outliers arise from sampling error, often associated with small sample sizes, although there may be other reasons not yet discovered.

There are some missing values for age 2 and ages $10-20$, especially since 1991 . Values for age 2 are required for reconstruction of the population biomass and have been set at 0.26 kg , which is the average of non-missing values in the period 1974-1997. Values are required for some of the other missing ages as well, and for consistency have been supplied for all instances of missing values in the matrix. Where possible a missing value was assumed to equal the average of the values in the nearest two non-missing years preceding and two non-missing years following. Where values were not available for following years, values were assumed to be equal to the average of the nearest three preceding nonmissing years. The exception to this was age 20 in 1990-1997, which was set equal to the value of the nearest four preceding years because the value for 1988 seemed low compared to the others. The high values at ages 8 and 9 in 1993 and the low value for age 12 in 1995 were replaced with values calculated with the above protocol. The resulting matrix is presented in Table 10.

Weights-at-age at the beginning of the year were calculated from the commercial weights-at-age using formulae in Rivard (1982, p. 14). For ages 3-20, weight-at-age at the beginning of year $\mathrm{t}\left(\hat{W}_{i, t}\right)$ was approximated by

$$
\hat{W}_{i, t}=e^{\left(\ln W_{i-0.5, t-0.5}+\ln W_{i+0.5, t+0.5}\right) / 2}
$$

For age 2, the $\hat{W}_{2, t}$ were approximated by the relationship

$$
\hat{W}_{2, t}=e^{\left(2 \ln W_{i+0.5, t+0.5}-\ln \hat{W}_{i+1, t+1}\right)}
$$

The resultant matrix is presented in Table 11.

## 3 Industry perspective

A perspective on several aspects of the 2000 sentinel survey and commercial index fishery is available from the responses to a questionnaire sent by the Fish, Food and Allied Workers Union (FFAW) to the Fish Harvester Committees representing the 55 sites where a sentinel survey was conducted by the FFAW in 2000 (Jarvis and Stead 2001).

In response to whether commercial catch rates in 2000 were low, average or high compared with historical results, $67 \%$ said low, $23 \%$ said average and $10 \%$ said high. All responses but one from southern Labrador to White Bay were "low". "Low" responses also came from some areas on the Baie Verte Peninsula, two areas in eastern Notre Dame Bay, and several areas in the region from inner Trinity Bay to the southern Avalon Peninsula. "High" responses came from two sites in inner Bonavista Bay, two on the western side of Trinity Bay and one on the southern Avalon Peninsula.

In response to whether commercial catch rates were lower, the same or higher than during the 1999 commercial fishery, $67 \%$ said lower, $27 \%$ said they were the same, and $6 \%$ said higher. The "lower" responses came from most sites from southern Labrador to eastern 3K and all sites from inner Trinity Bay to the southeastern Avalon Peninsula.

In response to whether "signs" of small (up to 18 inches) fish were worse, the same or better than in $1999,7 \%$ said worse, $25 \%$ said the same and $68 \%$ said better. In response to whether the overall condition of cod caught during 2000 was poor, average or good, $2 \%$ said poor, $25 \%$ said average and $73 \%$ said good. In $1999,90 \%$ had said good.

The Fish Harvester Committees felt that warm water, inclement weather and restrictions imposed by the 2000 Conservation Harvesting Plan negatively affected catch rates in the index fishery.

## 4 Resource Status

### 4.1 Stock structure

Numerous studies have indicated the likelihood of substock structure within the northern cod complex (see Lear 1986 for an overview). For example, there was a north-south cline in size-at-age and spawning time, there was a change in vertebral counts at approximately the north slope of Grand Bank, and cod tagged at specific locations in the offshore in winter tended to migrate to specific but broad areas of the inshore for feeding and then returned to approximately the area of tagging in subsequent winters. It was also known that cod overwintered in various locations inshore and that some spawning occurred inshore.

The stock collapsed during the late 1980s and early 1990s, and by 1994 there seemed to be very few cod anywhere in the stock area. Beginning in 1995 the perception of stock size and distribution changed when a large aggregation of cod was located in Smith Sound (Trinity Bay). The sentinel surveys, which started that year, achieved good catch rates in much of the area from White Bay in central 3 K southward to the boundary with 3Ps.

Recent interest has focussed on whether those cod currently inshore are distinct from cod currently offshore. As summarized in the assessment documents for 1999 and 2000 (Lilly et al. 1999, 2000b), several sources of information are consistent with the hypothesis that there are distinct inshore or bay stocks along the east coast of Newfoundland. The information includes the presence of cod inshore in the winter, the historic existence of spring fisheries in the inner reaches of Bonavista and Trinity bays before cod arrived at the headlands from the offshore, the occurrence of spawning within the bays, and the paucity of returns offshore from cod tagged inshore in the winter.

Tagging studies, conducted during the post-moratorium period while the overall stock size has been extremely low (Brattey et al. 2001), indicate that the inshore of 3 KL is currently inhabited by at least two groups of cod: (1) a northern resident coastal group that inhabits an area from western Trinity Bay northward to western Notre Dame Bay and (2) a migrant
group from inshore and offshore areas of 3Ps that moves into southern 3L and less commonly into northern 3 L and 3 K during late spring and summer and returns to 3Ps during the autumn. Only a small number of tagged cod from 3Ps were caught north of Trinity Bay. The tagging also indicates considerable movement of cod among Trinity, Bonavista and Notre Dame Bays. It is not known if there is currently movement between the inshore and the offshore in 2J3KL. No tags have been applied to cod in the offshore in recent years because no aggregations sufficiently large to warrant tagging have been located. In addition, there have been no reported offshore recaptures of cod tagged inshore, although it must be noted that there is no directed offshore cod fishery and the by-catch of cod from fisheries directed at other species is thought to be small relative to the coddirected inshore catch.

There are two conflicting interpretations of genetic studies. One is that cod in the inshore and offshore are genetically distinct from one another; the other is that there is no differentiation among groups of $2 \mathrm{~J}+3 \mathrm{KL}$ cod. These differences originate in part in methodology. The results of studies employing microsatellite loci are interpreted to support the existence of considerable sub-stock structure between the inshore and the offshore and within both the inshore and the offshore (Bentzen et al. 1996; Ruzzante et al. 1996, 1997, 1998, 1999, 2000; Taggart et al. 1998; Beacham et al. 1999, 2000). In contrast, the results of studies with mitochondrial DNA provide no evidence of substock structure within 2J3KL (Pepin and Carr 1993; Carr et al. 1995). The conflicting interpretations of stock structure are not just a consequence of the use of different methodologies. Carr and Crutcher (1998) state that "re-evaluation of (the) microsatellite data supports the conclusion of extremely limited genetic differentiation among populations in the Northwest Atlantic". Those who support the interpretation of considerable substock structure contend that the mitochondrial DNA approach lacks the ability to detect the structure that is there.

Neither interpretation of the genetic data would preclude the possibility that functional subpopulations exist without significant genetic differentiation or the possibility that inshore populations could colonize the offshore areas.

In light of the uncertainty about stock structure, in this assessment the stock status is assessed under two hypotheses regarding stock structure: a) the inshore constitutes a separate inshore subpopulation that is functionally separate from the offshore; and b) inshore and offshore fish together constitute a single functional population.

### 4.2 Population indices

### 4.2.1 Bottom-trawl surveys

### 4.2.1.1 Survey design

Research vessel surveys have been conducted by Canada during the autumn in Divisions 2J, 3K and 3L since 1977, 1978 and 1981 respectively. No survey was conducted in Division 3L in 1984, but the results of a summer (August-September) survey in 1984 have been used for some analyses. The 1995 autumn survey continued into late January 1996.

Spring surveys have been conducted by Canada in Division 3L during the years 1971-1982 and 1985-present.

The autumn surveys in Divisions 2J and 3K were conducted by RV Gadus Atlantica until 1994. In 1995-2000 they were conducted mainly by RV Teleost, although RV Wilfred Templeman surveyed part of Division 3K. Surveys in Division 3L were conducted by RV A.T. Cameron (1971-1982) and RV Wilfred Templeman or its sister ship RV Alfred Needler (1985-2000 for spring and 1983-2000 for autumn). In recent years, RV Teleost occupied some of the 3L stations, particularly those in deep water.

In the autumn 1995 survey both ships used for the first time the Campelen 1800 shrimp trawl with rockhopper footgear, replacing the Engel 145 Hi-rise trawl that had been used since the start of the surveys in 2 J and 3 K and since the change to the RV Wilfred Templeman in Division 3L. In addition, the Campelen trawl was towed at 3.0 knots for 15 min instead of 3.5 knots for 30 min . The selectivities of the two nets were found through comparative fishing experiments in 1995 and 1996 to be markedly different, with the Campelen being far more effective at catching small cod (Warren 1997; Warren et al. 1997). There were limited data for the comparison of larger cod. Conversion of Engel catches to Campelen equivalent catches is reported by Stansbury (1996, 1997).

The survey stratification scheme, illustrated in Fig. 8-10, is based on depth intervals intersected by lines of latitude and longitude (Doubleday 1981; Bishop 1994). The strata used in 1996 were similar to those in previous years except that the survey was extended to 1500 m and 25 new strata were added to the inshore in Divisions 3 K and 3L to obtain an estimate of the cod landward of the standard survey area. The survey in 1997 was similar to that in 1996, except that some of the new inshore strata were modified and one stratum was added. The survey in 1998 was as in 1997. The survey in 1999 was as in 1997 and 1998 except that the new inshore strata were not fished. The survey in 2000 was again similar to the previous 5 years in the offshore, and the inshore strata in 3 K and 3 L were fished once again. A few strata in both 3 K and 3 L were either not fished or received only 1 set in 2000 because of vessel problems.

Prior to 1988, set allocation was proportional to stratum area, with the provision that each stratum be allocated at least 2 sets. In 1989 and 1990 an "adaptive design" was introduced in an attempt to minimize variance. It was found that this method introduced a bias and the additional sets fished during the second phase of these surveys have been excluded from analyses. In 1991-1994, additional sets were allocated in advance to certain strata based on past observed stratum variance (Gagnon 1991). In 1995-2000, set allocation was based once again on stratum area alone (with the provision that there be at least 2 sets in each stratum).

### 4.2.1.2 Autumn bottom-trawl surveys

### 4.2.1.2.1 Autumn abundance and biomass

Abundance and biomass have been estimated by areal expansion of the stratified arithmetic mean catch per tow (Smith and Somerton 1981). To account for incomplete coverage of some strata in some years, estimates of biomass and abundance for non-sampled strata were obtained using a multiplicative model.

Estimates of abundance and biomass for the autumn surveys in 1978-1994 (Divisions 2J and 3K) and 1981-1994 (Division 3L) may be found in Tables 12-19 of Shelton et al. (1996). The data from 1983 to 1994 have been converted to Campelen equivalents and are presented in this paper along with the actual Campelen data from 1995-2000. Data for Division 2J are in Tables 12-15 and data for Division 3K are in Tables 16-19. Note that data for 1993-2000 are presented separately from earlier years for Divisions 2J and 3K because of the change in stratification scheme introduced in 1993 (Bishop 1994). Estimates for surveys in Division 3L in 1983-1987 are in Tables 16-18 of Lilly et al. (1999). Estimates for strata $<=200$ fathoms in Division 3L in 1988-2000 are in Tables 2021 of the present paper. Estimates for strata $>200$ fathoms in Division 3L in 1990-2000 are in Table 22.

Because there have been changes over time in the depths fished, annual variability in the abundance and biomass of cod has been monitored for those strata that have been fished most consistently since the start of the surveys. These "index" strata are those in the depth range 100-500 m in Divisions 2J and 3K and 55-366 m (30-200 fathoms) in Division 3L. The inshore strata fished in 1996-1998 and 2000 are not included in the index. Because an index has also been calculated for the inshore strata, the former "index" will now be referred to in this paper as the "offshore index".

Changes in abundance and biomass in the offshore index strata are shown by Division for the years 1983-2000 in Fig. 11. The patterns in abundance and biomass differ in detail, reflecting changes in the relative abundance of small and large fish. Of note are the positive anomaly in 2 J and 3 K in 1986, the very large increase in 3 K in 1989 and the rapid decline during the early 1990s. Abundance and biomass have remained at extremely low levels in all Divisions since 1993.

Abundance and biomass estimates for the new inshore strata in 1996-1998 and 2000 (Table 23) are less than estimated for the offshore but are relatively high given the much smaller area of the inshore strata. The total abundance and biomass of all strata fished in 19831998 are provided by Division and year in Table 24.

The abundance and biomass for offshore index strata, deep offshore strata and inshore strata are provided in Table 25 by Division and year for the 6 years since introduction of the Campelen trawl. Abundance in offshore index strata declined from 1995 to 1997 and increased from 1998 to 2000, with the largest increase in 1998-1999. Biomass in offshore index strata increased from 1995 to 1997, remained unchanged in 1998, nearly doubled in

1999 and increased a little in 2000. The biomass in offshore index strata in 2000 was about $30,000 \mathrm{t}$, which is about $2.5 \%$ of the average biomass of $1,200,000 \mathrm{t}$ (in Campelen equivalents) in the period 1983-1988 (excluding the high value in 1986).

### 4.2.1.2.2 Autumn mean catch at age per tow

Offshore index strata
The divisional mean number caught at age per tow in offshore index strata during autumn surveys from 1979 (1981 in Division 3L) to 1994, and the mean number per tow for Divisions 2J, 3K and 3L combined, may be found in Tables 3-6 of Bishop et al. (1995b). The data from 1983 to 1994 have been converted to Campelen equivalents and are presented along with the actual Campelen data from 1995-2000 in Table 26 for Divisions $2 \mathrm{~J}, 3 \mathrm{~K}$ and 3L separately and for all three Divisions combined. Mean catch per tow has continued to be very low for each age in each Division during the past few years when compared with many years in the 1980s and early 1990s. An increase in the abundance index from 1998 to 1999 occurred in 3 K and 3L but not in 2J. The index was up in all Divisions in 2000 compared with 1999, but was still far below levels seen prior to 1993.

The overall 2 J 3 KL catch at age 1 in 2000 was similar to that in 1995 , indicating that the 1999 year-class may be comparable to the 1994 year-class, which has been recognized as the strongest in the offshore since the early 1990s. The 1994 year-class was well represented in 2 J and 3 K , but not in 3L, whereas the 1999 year-class was weaker in 2 J , of comparable strength in 3 K , and stronger in 3 L .

The weakness of recent year-classes is emphasized when mean catch at age per tow is plotted for the 1976-1999 year-classes at ages 1-3 (Fig. 12). For age 1, year-class strength declined from 1994 to 1996 and has since increased. The 1994 and 1999 year-classes at age 1 were relatively large compared with actual catches of earlier year-classes, but look very weak compared to previous year classes following conversion to Campelen equivalent numbers. At age 3 all year-classes from 1992 to 1997 look weak even when compared with unconverted catches of some of the year-classes from the early and late 1980s.

An index of spawner biomass in divisions 2J3KL combined in 1983-2000 was calculated from the mean catch per tow at age, the proportion mature at age (Section 4.3.2), and the commercial Jan. 1 weights-at-age (Section 2.2.5). (The latter two were moved back one age and one year to correspond to the timing of the autumn survey.) The index declined quickly after 1989 to reach a minimum in 1995 (Fig. 13). There was a slight increase during the late 1990s and no trend during the past few years. The index in 2000 stood at about $1.6 \%$ of the average index in the period 1983-1988 (excluding the high value in 1986).

Inshore strata
Inshore strata in 3K and 3L were fished in 1996-1998 and 2000. The mean catch at age per tow was calculated for 3 K and 3L separately (Table 27) and for 3KL combined (Table 28). Each 3 KL catch at age index is the mean of the divisional means, weighted by the divisional survey areas (where the area of inshore strata is $3,235 \mathrm{sqn}$ miles in 3 K and $3,107 \mathrm{sq} \mathrm{n}$ miles in 3 L ).

The inshore catch at age data are displayed in three ways in Fig. 14; as an index of abundance for ages 1-4 and 5+, as an index of biomass for ages 1-4 and 5+, and as an index of spawner biomass. The biomass index is the abundance index with commercial Jan. 1 weights-at-age applied, and the spawner biomass index is the biomass index with the proportions mature at age applied. The Jan. 1 weights-at-age and proportions mature at age were moved back one age and one year to correspond to the timing of the autumn survey. It was stated in the Stock Status Report (DFO 2001) that "the inshore biomass of fish age 1-4 has been increasing since 1997 but the biomass of older fish has been decreasing since 1996." As illustrated in Fig. 14, the above statement is appropriate for abundance, not biomass. Inshore biomass of fish age 1-4 declined from 1996 to 1998 and increased in 2000. The same pattern was seen in older fish, except that the decline from 1996 to 1998 was proportionally greater and the increase in 2000 was proportionally less.

### 4.2.1.2.3 Autumn distribution (all ages combined)

The distribution of cod at the time of the autumn surveys has been illustrated in numbers per standard tow (Shelton et al. 1996; Murphy et al. 1997) and in weight (kg) per standard tow (Lilly 1994, 1995). The catch from each tow in the period 1983-1994 has been recalculated to Campelen equivalents, and plots of these recalculated catches for 19851994 are shown together with the actual catches in 1995-1998 in Lilly et al. (1999). The catches in 1987-1988 are presented in Fig. 15 of the present paper as an example of the relatively large catches that were obtained during the 1980s.

For the period 1981-1988 catches were widespread over the survey area. The first indication of the big changes to come occurred in 1988, when almost no fish were caught in the area of Harrison Bank in northwestern Division 2J. Commencing in 1989 the fish in Divisions 2 J and 3 K became increasingly concentrated toward the edge of the bank. By 1991, concentrations on Hamilton Bank and the plateau of Grand Bank disappeared, leaving fish in inner Hawke Saddle and in the saddles between Belle Isle Bank and Funk Island Bank and between Funk Island Bank and Grand Bank. In 1992, only the concentration between Funk Island Bank and Grand Bank remained. This concentration was smaller in 1993 and disappeared in 1994.

Catches in 1995-2000 are presented in Fig. 16 a-c. (Note the change in scale between Fig. 15 and Fig. 16.) During this period catches tended to be very small. On the southern Labrador Shelf and the Northeast Newfoundland Shelf the larger catches were broadly spread, with a tendency toward occurring off the banks. In Division 3L, catches tended to be small in 1995-1998, but somewhat larger and more broadly distributed in 1999 and 2000.

### 4.2.1.2.4 Autumn distribution (juveniles)

Previous work on the distribution of juvenile cod in Divisions 2J3KL has revealed that individuals of ages 0 and 1 were found mainly in shallow waters near the coast off southern Labrador and northeastern Newfoundland and on the northern Grand Bank, that individuals of ages 3 and 4 were mainly in those offshore areas occupied by older cod, and that individuals of age 2 were intermediate in distribution (Lilly 1992; Dalley and Anderson 1997; Anderson and Gregory 2000). Catches from autumn surveys in 1995-1998 revealed a similar pattern, with the notable exception that the 1994 year-class, which was the strongest year-class appearing in the surveys during the early to mid-1990s, was already well onto the shelf by age 1 (Lilly et al. 2000a). More recent year-classes have been extremely weak in Division 2J, but have been somewhat more abundant adjacent to the coast in Divisions 3K and 3L.

The distributions of cod of ages 0 to 5 in autumn 1999 were illustrated in Fig. 16 of Lilly et al. (2000b). The occurrence of cod of ages 0 and 1 off the northern tip of Newfoundland and in southwestern Division 3L has been a consistent feature of such plots. The occurrence of cod of ages 1-3 in the southern Funk Island Deep has been seen consistently since 1995, as has the appearance of cod of ages 2 or 3 to the east of Funk Island Bank. The relatively large catches on the Nose of the Bank were mainly of ages 2 and 3 . Distribution at age in autumn 2000 was not available at the time of the assessment meeting.

### 4.2.1.3 Spring 3L bottom-trawl surveys

### 4.2.1.3.1 Spring 3L abundance and biomass

Abundance and biomass of cod in Division 3L in the spring have been estimated by areal expansion of the stratified arithmetic mean catch per tow. Estimates for the surveys from 1978 to 1995 may be found in Tables 20-21 of Shelton et al. (1996). The data from 1985 to 1995 have been converted to Campelen equivalents and are presented along with the actual Campelen data from 1996-1998 in Lilly et al. (2000b). The data from 1988 to 2000 for the index strata (depths $<=366 \mathrm{~m}$ or 200 fathoms) are provided in Tables 29-30 of the present document. The indices declined very rapidly from 1990 to 1994 and have remained very low in subsequent surveys (Fig. 17). Despite a small increase since the mid1990s, the biomass index for 2000 was only $1.5 \%$ of the average in the period 1986-1989.

Fishing in waters deeper than 200 fathoms started on a regular basis in 1991 (Table 31). In some years, most notably 1992, a substantial biomass was estimated to lie in these deeper strata. There may have been a large biomass in the deeper water in 1991 as well, because several sources of information indicate that cod were unusually deep in the early 1990s and stratum 735 (201-300 f), which was estimated to contain 50,000 t in 1992, was not fished in 1991 because of ice cover. The percentage of the total estimated biomass found in depths greater than 200 f was as high as $92 \%$ in 1994, but was only $2 \%$ in 1999.

The mean number caught at age per tow in index strata during 3 L spring surveys from 1985 to 2000 are presented in Table 32. The values from 1985 to 1995 are Campelen equivalents and those from 1996 onward are based on actual Campelen catches. Mean catch per tow declined precipitously in the early 1990s. There were increases in both 1999 and 2000, but values continue to be well below levels obtained prior to 1993.

Part of the increase in total catch per tow in 1999 and 2000 was due to the strength of the 1998 and 1999 year-classes, both of which were stronger at age 1 than the preceding 3 year-classes. In addition, catch per tow increased from 1999 to 2000 for each of the 1996 to 1998 year-classes, indicating either sampling variability or immigration into the 3L survey area. On the other hand, catch per tow of fish older than age 6 declined from 1999 to 2000 .

### 4.2.1.3.3 Spring distribution

The distribution of cod during spring surveys in Division 3L is shown together with distribution in Divisions 3NO for the years 1984-1995 in Fig. 18. Because the catches became very small by the mid-1990s, the catches for 1992-1999 (Fig. 19) are displayed with a finer scale.

During the second half of the 1980s the spring distribution in Division 3L was similar to that observed during the autumn, in that the highest densities were generally on the plateau of the bank and along the northern and northeastern slopes of the bank. However, there were in some years moderately large catches in the area between the northern slope and the plateau, a situation much less evident in the autumn. The spring of 1990 was unusual, in that few cod were taken on the plateau but very large catches were taken along the full length of the northeastern slope. Much of the northeastern slope could not be surveyed in 1991 because of ice cover, but catches seemed to be smaller. Catches continued to decline until 1995 when very few cod were caught. Catch rates increased with the introduction of the Campelen trawl in 1996, but have remained far below the levels in the 1980s. Starting in 1996 the cod in 3NO appeared to be further onto the bank at the time of the surveys than they were in the early 1990s. In 1999 there was a hint, for the first time in many years, of a continuous distribution of cod from the southwestern part of 3 O across the $3 \mathrm{~L} / 3 \mathrm{NO}$ boundary into the area of the Virgin Rocks. In 2000 cod were caught from the southernmost part of the Northeast Newfoundland Shelf in northern 3L along the northeastern slope of Grand Bank and on the Nose of the Bank (Fig. 20). Small catches were also taken on the plateau of the bank and in the Avalon Channel.

### 4.2.1.4 Southern Northeast Newfoundland Shelf and Nose of Grand Bank

There are indications from several sources of a recent increase in cod density on the southern Northeast Newfoundland Shelf and along the northeastern slope of Grand Bank onto the Nose of Grand Bank. For example, several acoustic studies since May 1999 have reported aggregations of cod in this area (see Section 4.2.2.1). In addition, NAFO
inspection reports of commercial vessels targeting Greenland halibut in deep water on the Nose of Grand Bank during April 2000 record the presence of small catches of cod, the first time this was noted since the early 1990s.

Plots of the distribution of cod during spring and autumn bottom-trawl surveys in southeastern 3K and eastern 3L in 1995-2000 (Fig. $21 \mathrm{a}-\mathrm{c}$ ) reveal spotty catches throughout the period, and an increase starting at least as early as autumn 1999.

### 4.2.2 Acoustic surveys and observations

### 4.2.2.1 Offshore

Acoustic studies were conducted in Hawke Channel in 2J in June 1994-1996 and 19982000. The biomass decreased by half from 1994 to 1995, decreased further in 1996 (Anderson and Rose 2000), and has since remained rather stable at this lower level (G. Rose, Memorial University of Newfoundland, St. John's, pers. comm.).

As discussed in Section 4.2.1.4, there are indications from several sources of a recent increase in cod density on the southern end of the Northeast Newfoundland Shelf, particularly toward the shelf break. During an acoustic study of capelin in May 2000, small cod marks were common throughout the deep water to the north of Grand Bank and marks of larger cod were seen near the bays and in one larger concentration on the shelf break between $49^{\circ} 00^{\prime} \mathrm{N}$ and $49^{\circ} 15^{\prime} \mathrm{N}$ (F. Mowbray, DFO, St. John's, pers. comm.). Cod densities as indicated from acoustic records were greater than those observed in May 1999. A cod-directed acoustic study by G. Rose (Memorial University of Newfoundland, St. John's, pers. comm.) in June 2000 located at least one concentration of cod in this general area, and a study in January 2001located relatively high cod densities in deeper waters seaward of the location where cod were found the previous June.

### 4.2.2.2 Inshore (Smith Sound)

Acoustic studies have been conducted in Smith Sound in western Trinity Bay at various times since spring 1995. The quantity of cod detected in the Sound at any specific time will depend not only on population size but also on where the cod are in their annual cycle of movements. Fish overwinter in deep water in the Sound and some of them spawn there in the spring. Most of them move into shallow water and northward along the coast from late spring to early autumn. They then return to the Sound in late autumn or early winter.

Estimates of the biomass of cod within Smith Sound have varied considerably. Acoustic surveys by Rose (2000) provided biomass estimates of 13,000 t in May 1995, 14,000 t in June 1998, 15,000 t in January 1999 and 1,000 t in June 1999. Two acoustic surveys in January 2000 provided an average biomass of about $22,000 \mathrm{t}$. Other winter/spring biomass estimates for Smith Sound have been as low as 150 t in April 1996 and as high as 21,000 t in April 1997 (Brattey and Porter 1997; Porter et al. 1998; Wheeler 2000). The quantity of cod detected in Smith Sound during autumn surveys was low in 1996 and 1997 but substantially higher in 1999 (Anderson et al. 1998; Wheeler 2000). Much of the variability
among these estimates can be attributed to the seasonal migration described above, but it is also possible that some of the fish move into and out of the Sound on a short-term basis during the winter/spring, and that there is annual variability in the timing and extent of the seasonal migration. Some of the variability is also attributable to differences in acoustic gear and the method of data analysis.

If one focuses on recent acoustic surveys in January, the average index of biomass has increased rapidly from about $15,000 \mathrm{t}$ in 1999 to about $22,000 \mathrm{t}$ in 2000 (Rose 2000) and to about 31,000 t in 2001 (G. Rose, Memorial University of Newfoundland, St. John's, pers. comm.). Sampling by bottom-trawl showed that the 1995, 1996 and 1997 year-classes formed a substantial portion of the fish in Smith Sound over the past few years and that the 1990 and 1992 year-classes continue to be present in relatively large numbers.

It is not clear at the time of writing whether the $110 \%$ increase in the biomass estimates from 1999 to 2001 is due entirely to population growth. There may also have been some immigration or some among-year variability in the proportion of the population available to the surveys.

The presence of older fish in Smith Sound may be an indication of better survival rates in this area than in those areas covered by the research bottom-trawl surveys.

### 4.2.3 Beach seine surveys

A broadscale beach seine survey of demersal 0 -group and 1 -group cod was conducted in divisions 3KL during 1992-1997 (Methven et al. 1998). Results of surveys on a much smaller spatial scale in Newman Sound (Bonavista Bay, 3K) in 1995-1996 and 1998 were consistent with the broadscale survey (Gregory et al. 1999, 2000). The Newman Sound studies continued in 1999 and 2000. A combination of the two series indicated that the 1997-1999 year-classes should rank comparatively high relative to other year-classes in the mid- to late 1990s, especially the 1995 and 1996 year-classes (Gregory et al. 2000). The 2000 year-class was weak at age 0 (R.S. Gregory, DFO, St. John's, NF, pers. comm.). The Newman Sound data were entered into the recruitment model for the first time during the present assessment.

### 4.2.4 Sentinel surveys

Sentinel surveys for cod were conducted by fishing enterprises operating from many communities (Fig. 1d) in Divisions 2J, 3K and 3L at various times during summer and autumn 1995-2000. The primary goal of these surveys was to obtain information on catch rates on traditional inshore fishing grounds during the moratorium. The surveys have been conducted primarily with gillnets. Linetrawls have been used extensively in only a few areas. Handlines and cod traps have been used much less.

The sentinel surveys were also intended to provide samples that would yield information on various aspects of the biology of cod in the inshore, including age compositions, size-atage, condition, maturity and feeding. Various analyses are available for data collected in

1995-1997 (Lilly 1997; Lilly et al. 1998a), but these have not been updated. However, age compositions for the full time period are now available in the form of standardized catch rates at age (see Section 4.2.4.2).

### 4.2.4.1 Sentinel site-by-site descriptions

Maddock Parsons et al. (2000) provided weekly average catch rates by sentinel survey site, gear and year (1995-1999). There is considerable among-site variability in the timing of the fishing and in the seasonal and annual patterns in fishing success.

Maddock Parsons et al. (2001) presented weekly average catch rates and annual relative length frequencies (number of fish at length divided by amount of gear) by NAFO division, gear and year. With few exceptions, average catch rates were lower in 2000 than in 1999 in all gears fished. Catches in 2J have remained very low since 1995 with only the $31 / 4$ inch gillnets showing catches comparable to those in other areas. In 3 K , catches from gillnet, linetrawl and handline declined in 2000. In 3L, linetrawl catches in 2000 were similar to those in 1999 , but catch rates in $51 / 2$ inch gillnets were down. Catch rates in small mesh ( $31 / 4$ inch) gillnets were up in 2000 compared to 1999.

### 4.2.4.2 Sentinel standardized CPUE

An age-disaggregated index of standardized relative abundance for cod in the inshore of 2 J 3 KL was calculated from data gathered from sentinel fishing with gillnets and linetrawls (Stansbury et al. 2000). The catch from 2J3KL was divided into cells defined by gear type (gillnet $51 / 2$ inch, gillnet $31 / 4$ inch and linetrawl), NAFO Division (2J, 3K, 3L), statistical unit area (e.g. $3 \mathrm{Ki}, 3 \mathrm{Lh}$ ), year (1995-2000) and quarter. Age-length keys were generated for each cell using fish sampled from both fixed and experimental survey methods. There were no fixed sites using $31 / 4$ inch gillnets. Length frequencies and age-length keys are combined within cells. Numbers of fish at length were assigned ages using an age-length key. Because there were little or no discards in the sentinel fishery and the fish harvesters measured the length of all of the fish for linetrawl and gillnet sets, obtaining catch numbers-at-age was relatively straight forward (see Stansbury et al. (2000) for details).

The catch per unit effort (CPUE) at age data were standardised to remove site and seasonal effects. For gillnets, only sets fished during July to November with a soak time between 18 and 24 hours were included in the analysis. For linetrawl, sets fished during August to November with a soak time less than or equal to 12 hours were selected. Sets with effort and no catch for some or all ages were considered valid entries in the model. Ages in the model ranged from 3 to 10 for $5 \frac{1}{2}$ inch gillnet, 2 to 10 for $31 / 4$ inch gillnet and 3 to 9 for linetrawl. Fish older than age 10 were not included because of their rarity. Application of the various criteria listed above resulted in the elimination of as much as $40 \%$ of the data.

A generalized linear model (McCullagh and Nelder 1989) was applied to the catch and effort data for each gear and survey method. The response distribution was specified as Poisson and the link function was chosen to be log. That is, the Poisson mean parameter $\mu_{i}$ is related to the linear predictor by

$$
\log \left(\mu_{i}\right)=X_{i}^{\prime} \beta
$$

where $\mathrm{X}_{i}$ is a vector of explanatory factors for catch observation $i$ (i.e. month, site, age and year) and $\beta$ is a vector of coefficients to be estimated from the data.

Thus catch is assumed to have a Poisson probability distribution with the mean $\mu_{i}$ related to the factors month nested within site and age nested within year by

$$
\log \left(\mu_{j k l m}\right)=\log (E)+\beta_{j k}+\beta_{l m}
$$

where $E$ is an offset parameter for fishing effort and $j, k, l, m$ indicate the level for each of the four factors, for example June for the factor month, and where

$$
\text { month }_{i}(j)=\left\{\begin{array}{l}
1 \text { if month }=j \\
0 \text { if month } \neq j
\end{array} .\right.
$$

Site/month combinations where no fish were landed in all years where deleted from the analysis. The model was fit using the SAS procedure GENMOD. Amount of gear is expressed as number of nets for gillnet and number of hooks for line trawl. Estimates for age nested in year were adjusted for month nested in site effects and transformed to a linear scale to give the relative index at age for each year.

Additional information regarding the models (proportion of available data that was actually included, model output and residual plots) are not presented this year, but they are similar to the findings of the 1995-1999 analyses, which are described in detail by Stansbury et al. (2000).

Gillnet catch rates increased from 1995 to 1998 but declined from 1998 to 1999 and decreased further in 2000 (Fig. 22). Linetrawl catch rates showed relatively little change from 1995 to 1996, increased in 1997, and declined again in 1998, 1999 and 2000.

Catch rates at age (Fig. 23) decreased in 2000, especially at ages 5 to 7 . The catch rate at age 4 by $31 / 4$ inch gillnets in the last 3 years has been less than half compared to the level in 1996 and 1997. Inspection of catch rates at age from all 6 years revealed that the 1990 and 1992 year-classes were relatively strong and that all subsequent year-classes are weaker. The pattern in age-aggregated gillnet catch rates is consistent with the 1990 and 1992 yearclasses entering and then passing through the fishery and being replaced by the weaker year-classes. It is also possible that the decline from 1998 to 2000 could be attributed in part to decreased availability of fish to the gear, such as might occur if the fish were distributed over a greater range of depths.

### 4.2.5 Commercial fishery CPUE

Catch rates were calculated from catch and effort data recorded in logbooks maintained by the $<35$ foot sector participants in the index fisheries in 1998 and 2000 and the commercial fishery in 1999. Only catch rates from gillnet fisheries were examined in detail because the
effort with other gears was relatively small and less representative in space. Median gillnet catch rates were calculated by statistical section (Fig. 1c) for each of the three years (Fig. 24). The spatial pattern since fishing re-commenced in 1998 has been similar among years. Catch rates were very low north of White Bay, increasing from White Bay to eastern Notre Dame Bay, generally highest from northern Bonavista Bay to western Trinity Bay, lower from eastern Trinity Bay to the eastern Avalon Peninsula and increasing again on the southern Avalon Peninsula. Over the three-year period (1998-2000) catch rates remained relatively stable in Bonavista and Trinity bays but declined in southern 3K and especially on the eastern and southern Avalon Peninsula.

The catch and effort data were standardized by using a generalized linear model to remove spatial (unit area, Fig. 1b) and seasonal (month) effects to produce annual estimates of average catch rates for 3 K and 3 L combined. The data were aggregated (summed) by week and site within month and unit area for both the catch and the amount of gear used (i.e. number of nets). The model approach used was very similar to that applied to the sentinel data.

Gillnet catch rates declined from 1998 to 1999 to 2000 (Fig. 25). Data were insufficient to fit the same model for linetrawl.

### 4.3 Population Biology

### 4.3.1 Autumn size-at-age and condition

### 4.3.1.1 Size-at-age

The lengths-at-age and weights-at-age of cod sampled during the autumn surveys confirm the general pattern of a decline in the 1980s and early 1990s as observed in commercial weights-at-age (Fig. 7). The research survey data (Tables 33, 34; Figs. 26, 27) illustrate that the changes varied with Division; there was a strong decline in Division 2J, a lesser decline in Division 3K, and little or no decline in Division 3L. These Divisional differences are more apparent in Fig. 28, which focuses on changes in mean lengths and weights of cod of ages 4 and 6 . Superimposed on the long-term decline are periods of relatively quicker or slower growth associated with changes in water temperature (Shelton et al.1999). The trend toward low mean lengths-at-age and weights-at-age in the early 1990s appears to have been reversed during the latter half of the 1990s. However, size-atage declined again at some ages, particularly in 3L, from 1999 to 2000. Sample sizes at ages greater than age 4 have been very small since about 1992-1994 (Lilly 1998a), so the accuracy of these estimates is likely to be poor.

### 4.3.1.2 Condition

Condition can be expressed in various formulations. In this paper it is presented as $\mathrm{W} / \mathrm{L}^{3}$, where W is either the gutted weight of the fish or the liver weight, and L is the length. Arithmetic means by Division, year and age are presented for gutted condition (Table 35; Fig. 29) and liver index (Table 36: Fig. 30).

In Division 2J, both gutted condition and liver index declined in the early 1990s. During the second half of the 1990s gutted condition returned to approximately normal, whereas the liver index improved but did not fully recover. There is evidence of a decline in condition, particularly in the liver index, in 2000.

In Division 3K, gutted condition declined during the early 1990s and improved during the latter half of the 1990s. Liver index changed little during the 1990s. As in Division 2J, there is evidence of a decline in condition, particularly in the liver index, in 2000.

In Division 3L, gutted condition has remained relatively unchanged over time whereas liver index increased considerably in the early 1990 s and has since declined to an intermediate level.

The cause of the decline in condition in 2J and 3 K in 2000 has not yet been sought. Historic trends in condition indices are complex and poorly understood (Lilly 1996, 1997).

### 4.3.2 Maturity at age

The observed proportions mature at age for female cod in divisions 2 J 3 KL combined from 1982 to 2001 based on sampling conducted during autumn bottom-trawl surveys in 1981 to 2000 are shown in Table 37. Also provided are parameters for a probit model fitted with a logit-link function, as well as estimated age at $50 \%$ maturity (A50) and upper and lower $95 \%$ confidence intervals. A time series of estimated proportions mature at age for females is provided in Table 38 and illustrated for ages 4-6 in Fig. 31. The proportion mature at age increased among young females during the early 1990s and has fluctuated since. For example, the proportion of age 6 cod that are mature increased from about $40 \%$ in the 1980s to $70 \%$ or more in recent years.

The model estimates for A50 for females (Fig. 32) were a little above age 6 through most of the 1980s, declined from the late 1980s until the mid-1990s to about age 5, and varied considerably during the past few years.

Age at $50 \%$ maturity has also been calculated for females by year-class (Fig. 33). A decline in $50 \%$ maturity occurred between the year-classes of the mid-1980s and those of the late 1980s. Year-classes born in the 1990s tended to mature about one year earlier than those born prior to the mid-1980s.

Males generally mature about one year younger than females and show a similar trend over time.

### 4.4 Population Analysis

An attempt to combine catch data and various indices in a sequential population analysis for the whole stock was attempted but was unsuccessful because of the change in the proportion of the stock covered by the survey and the change in the survey gear. Therefore,
there is currently no synthesis that can provide an estimate of the size of the $2 \mathrm{~J}+3 \mathrm{KL}$ cod stock as a whole. However, a number of analyses of the available data were carried out under both stock hypotheses to determine stock status.

### 4.4.1 Inshore harvest rates and biomass

Estimates of the biomass of exploitable fish in the inshore were derived from tagging studies in conjunction with reported catches.

### 4.4.1.1 Harvest rates

A new series of tagging studies in inshore areas of 2J3KL and in 3Ps was initiated in 1997. Since then a total of 50,000 fish have been tagged. Of the 2553 fish tagged in 3 K and 3 L in the early part of year $2000,6.3 \%$ have been recovered suggesting a harvest rate for the tagged population of at least this amount (Brattey et al. 2001). In practice however not all fish survive tagging, some tags fall off the fish particularly in the first year, and not all recaptured tagged fish are reported. Accounting for these effects leads to a higher estimate of harvest rate of $11.2 \%$. However, harvest rates clearly vary between fish tagged in different areas; for example, in 1999 harvest rates were particularly high (43\%) on fish tagged in 3K compared to northern 3L (13.2\%) and southern 3L (23.6\%). Results for 2000 give harvest rates of $10.3 \%$ for fish tagged in $3 \mathrm{~K}, 10.7 \%$ in northern 3 L (Trinity and Bonavista Bays), and $22 \%$ in southern 3L.

The above values are estimates of the rate at which tagged fish were harvested but the harvesting may occur in an area different from where the fish were tagged. For example more fish tagged in southern 3L were harvested in 3Ps than in 3L. This makes it difficult to use these rates to convert local catches to estimates of local fishable biomass.

It is possible to estimate local harvest rates (except for southern 3L) using more detailed models. Harvest rates from these models are broadly similar to those given above. Two different models were examined.

### 4.4.1.2 Model 1

A relatively simple model included a treatment of migration but did not incorporate some practical problems such as fish growth and gear selectivity (Pope and Brattey 2001). The exploitable biomass of cod in northern 3L and in 3 K from 1998 to 2000 is estimated to have been of the order of $40,000 \mathrm{t}$. The majority of this estimated biomass (about $30,000 \mathrm{t}$ ) was in Bonavista Bay and Trinity Bay.

### 4.4.1.3 Model 2

A more detailed model considered gear selection, fish growth, and within season harvest but not migration. The model is similar to the one used in the 2000 northern cod assessment (Cadigan and Brattey, 2000); that is, exploitation was estimated separately for
three regions in 3 KL ( 3 K , northern 3L, southern 3L; see Table 39). However, there were two modifications. The first modification involved how the fishery removals of tagged fish were accounted for, and the second modification involved how weekly exploitation rates were estimated.

In Cadigan and Brattey (2000) the size of the tagged population available to the fishery each week ( $M_{t}$ ) was estimated using $M_{t}=\xi_{t} e^{-m\left(t-t_{x}\right)} M$, where $M$ is the number of tagged fish released. In this model $e^{-m\left(t-t_{x}\right)}$ is the fraction of $M$ that survived natural mortality between release week $t_{x}$ and recapture week $t$, and $\xi_{t}$ is the estimated cumulative fraction that survived fishing mortality. $\xi_{t}=\prod_{j=t_{x}}^{t-1}\left(1-\mu_{j}\right)$ was estimated using the tagging model estimates of weekly exploitation rates, $\mu_{t}\left(t=t_{x}, \ldots, t-1\right)$, and these were based only on returns from the same region of release (i.e. 3 K , etc). Cadigan and Brattey (2000) also adjusted $M_{t}$ for tag loss, and the adjustment depended on the number of tags (single or double). The size of the tagged population available to the fishery was estimated for each tagging experiment, for each release length class, and for the four different types of tags that are returned. The different tag types and the specific models that are appropriate for these tag types are described in Cadigan and Brattey (1999, 2000).

The formulation of the model we use for the size of the tagged population each week $(t)$ in the present analysis is

$$
M_{t}=M_{t-1} e^{-m}-R_{t-1} / \lambda
$$

where $R_{t-1}$ is the number of tagged fish captured and reported by the fishery at time $t-1$, and $\lambda$ is the reporting rate. This model can be used recursively to express $M_{t}$ in terms of the number of tagged fish released, $M$, similar to the approach in Cadigan and Brattey (2000). For simple models it is possible to show that exploitation rates estimated using this model are identical to those estimated using the methods in Cadigan and Brattey (2000). This model was run for each tagging experiment, for each release length class, and for the different tag types.

One advantage of the current formulation is computational, because the size of the tagged population available to the fishery is estimated directly from the data, whereas Cadigan and Brattey (2000) estimated $M_{t}$ and $\mu_{t}$ simultaneously. Another advantage is that the new model suggests an easy method to improve the analysis, which is to remove the tagged catch at time $t-1$ from all regions, and not just those fish that were caught in the same area of release. This is a better approach for estimating the size of the tagged population available to the fishery; however, there are still problems with this approach in that the migration of part of the tagged population outside the region of release is still not fully accounted for. Only those fish that are caught outside of the release region are removed from the size of the tagged population. This is an improvement over Cadigan and Brattey (2000) who did not adjust the size of the tagged population for any fishing mortality that occurred outside of the release region; however, further adjustments are still necessary to
produce absolute estimates of exploitation rates and stock size. The current approach still only provides a lower bound on exploitation rates.

The second modification was to use some smoothing when estimating the fully recruited exploitation rates each week and for each gear type. The kernel smoothing method was used to estimate exploitation rates. The smoothing neighbourhood gave $95 \%$ weight to $\pm 2$ weeks. The smoothing was done separately for each gear type.

Another change was that temporal variability in reporting rates was investigated. The results suggested that reporting rates are not significantly different in each region except northern 3L, where reporting rates in 2000 appear low relative to 1999 . The reporting rate estimates are presented in Table 39. Note that the reporting rate estimates for regions outside of 3 KL are required to adjust and remove tag catches outside of 3 KL .

Tag loss was assumed to be the same in all regions. This is reasonable because the mechanisms contributing to tag loss do not seem location dependent. The Kirkwood model for tag loss was used (see Cadigan and Brattey 2000). The estimated tag retention rate is plotted in Fig. 34. The vertical line marks the time it takes for $5 \%$ of tagged fish to loose their tag, which is 18 weeks.

The model was run twice. The first run used annual estimates of reporting rates for all regions. The second run used annual estimates of reporting rates for the northern part of 3L, and constant estimates across years for the other regions. There was little reason to prefer either run so, since the second run was more similar to the formulation used in the last assessment of this stock, it was decided that this would be the analysis to report.

The model output is similar in format to that presented in Cadigan and Brattey (2000). To save space we do not report on all of the model results. The gear selectivity estimates were similar to those in Cadigan and Brattey (2000). Estimates of the fully recruited (over lengths) exploitation rates for each gear type are presented in Fig. 35, 36. The units are in $\%$. The estimates are combined with estimates of the length selectivity for the various gears to estimate weekly exploitation rates at length. The estimates are combined with information on the length composition of the commercial landings to produce estimates of weekly total biomass at length, which can be summed over lengths to produce estimates of weekly biomass and weekly total exploitation rates (catch weight divided by population biomass). The results are shown in Figure 37. The weeks are numbered from the beginning of the year. Note that estimates are shown only for those weeks in which at least 25 tonnes of cod were landed in each region. Total exploitation was taken to be total catch weight for fish of lengths 40 cm and greater, divided by average weekly estimated population biomass for the same range of lengths. The average is based on weeks with at least 50 tonnes of fish landed by the commercial fishery. Year 2000 average weekly biomass in 3 K is 42,000 tonnes and in northern 3L is 35,000 tonnes. The estimates of total exploitation in 2000 were $3.4 \%$ and $8 \%$ for 3 K and northern 3 L .

Note: Subsequent to the stock assessment, it was noted that 535 tags (of a single tag type but accumulated across various areas and years) had not been included in the analysis. When these data were added, the estimate of exploitation rate for 3 K increased to $3.8 \%$ and
the upper limit estimated for exploitable biomass decreased to $37,000 \mathrm{t}$. For northern 3L, the exploitation rate increased to $10 \%$ and the upper limit estimated for exploitable biomass decreased to $27,000 \mathrm{t}$. The effect of these additional tags on the estimates from the simple migration model (Model 1) have not been determined.

### 4.4.1.4 Summary of model estimates of biomass

The results of the two models are broadly similar for northern 3L. The estimate from Model 1 is about $30,000 \mathrm{t}$ and the upper limit estimated from Model 2 is $35,000 \mathrm{t}$. However, there is a considerable difference for 3 K , where the estimate from Model 1 is $10,000 \mathrm{t}$ and the upper limit estimated from Model 2 is $42,000 \mathrm{t}$. The extent to which this difference in estimates for 3 K might be attributable to the absence of tagging in 3 K in 2000 prior to the beginning of the fishery is not known. As noted above, no concentrations of fish suitable for tagging were located in 3 K prior to the fishery.

It was not possible to estimate a biomass for southern 3L fish because tagging results indicated that many of the fish currently caught in the southern 3L area are seasonal migrants from 3Ps.

### 4.4.2 Autumn total mortality (Z)

Total mortality rates at age in each year, $Z_{a, y}$ were estimated from catch rate at age per tow during the autumn research bottom-trawl surveys in 2 J 3 KL (combined) by applying the following equation:

$$
Z_{a, y}=\ln \left(R V_{a, y} / R V_{a+1, y+1}\right)
$$

where ages $(a)=1$ to 14 and years $(y)=1983$ to 1999 .
The estimates for ages 1-14 are illustrated in Fig. 38, and those for ages 4 and 6 are isolated for additional clarity in Fig. 39. In general, the estimates increased up until 1992, coinciding with the beginning of the moratorium. The rates then declined until 1995, and since then have remained at levels similar to those observed in the late-1980s when there was a substantial fishery. The decline in the survey index estimates for cohorts after they reach age 2 is indicative of high levels of mortality, given what is known about the selectivity of the gear and the distribution of young fish. The reason for mortality levels in excess of the commonly assumed natural mortality rate of 0.2 is not understood.

The presence of older fish in the bottom-trawl tows conducted in conjunction with the acoustic studies in Smith Sound and in the catches of the sentinel surveys and the index fishery may indicate that mortality in some areas of the inshore has been less than in the offshore.

### 4.4.3 Recruitment index

The recruitment index introduced in 2000 (Shelton and Stansbury 2000) was updated with data collected in 2000 and the addition of a new index. The following studies were used to derive the index in 2000: experimental squid traps; experimental fixed-station bottomtrawling (FS BT) with a Campelen trawl, both inshore and offshore; beach seining from White Bay to St. Mary's Bay (Fleming survey); pelagic 0-group monitoring with an IYGPT trawl, both inshore and offshore; sentinel survey linetrawl (LT); sentinel survey 5.5 inch gillnet (GN 5.5); sentinel survey 3.25 inch gillnet (GN 3.25); and stratified-random bottom-trawl (SR BT) monitoring with a Campelen trawl, both inshore and offshore. The index added for the first time was derived from the beach seining in Newman Sound, Bonavista Bay (BB) (see Section 4.2.3). For each source of information, catch rates were available for one or more ages of juvenile cod in the age range 0-3 (as appropriate for the gear and area). The years during which each series was operational and the ages of cod caught and considered during this analysis are provided in the following text table.

| Data source | Cod ages | Years |
| :--- | :---: | :---: |
| Squid trap | $0-3$ | $1991-1994$ |
| FS BT inshore | $0-3$ | $1992-1995$ |
| FS BT offshore | $0-3$ | $1992-1995$ |
| Beach seine Fleming | $0-2$ | $1992-1997$ |
| Beach seine BB | $0-1$ | $1995-96,1998-2000$ |
| IYGPT inshore | 0 | $1994-1999$ |
| IYGPT offshore | 0 | $1994-1999$ |
| Sentinel LT | 3 | $1995-2000$ |
| Sentinel GN 5.5 | 3 | $1995-2000$ |
| Sentinel GN 3.25 | $2-3$ | $1996-2000$ |
| SR BT inshore | $1-3$ | $1996-98,2000$ |
| SR BT offshore | $0-3$ | $1995-2000$ |

The total number of surveys considered in the analysis was 12 and the number of survey/age indices was 30 . The squid trap data are from experimental studies during the Northern Cod Science Program (E. Dalley and E. Dawe, DFO, SOE Branch, Newfoundland Region, pers. comm.); the fixed station bottom-trawl data, both inshore and offshore, are from Dalley and Anderson (1997); the broad-scale beach seine data (Fleming survey) are from Methven et al. (1998); the beach seine data from Newman Sound are from Gregory et al. (2001); the IYGPT trawl data are from Dalley et al. (2000); the sentinel data are from Stansbury et al. (2000) and updated in Section 4.2.4.2 of the present paper; and the stratified-random bottom-trawl data, both offshore and inshore, are from Section 4.2.1.2.2 of the present paper.

An iterative reweighting multiplicative model was fitted to the survey at age indices to remove survey and age effects and thereby reveal the signal of year-class strength:

$$
\mathrm{I}_{\mathrm{say}}=\mathrm{q}_{\mathrm{s}, \mathrm{a}} \mathrm{~N}_{\mathrm{o}, \mathrm{y}},
$$

where $I_{\text {say }}$ is the index for survey $s$ at age a in year $y, q$ is the catchability parameter for the survey index at age, and $\mathrm{N}_{0}$ is the year-class effect. The weighting factor is the reciprocal of the variance for each survey age index. To prevent one index from capturing all the weight, indices were ranked by their variances and the top $1 / 3$ of the indices were assigned the variance of lowest index in the top third. All other index weightings were $1 /$ variance $_{\text {sa }}$. The weighting values were also standardized for each iteration to sum to 10 . The values of $1 / 3$ for a cut off and the sum of the weights equal to 10 are arbitrary. The recruitment data from inshore and offshore were treated together because the inshore appears to be an important nursery area for cod spawning in both the inshore and the offshore (Lilly et al. 2000a). These data were combined to produce a single index of relative year-class strength (Fig. 40).

The 1998 to 2000 year-classes are higher than earlier year-classes in the time series. Their present strength is known only imprecisely and their ultimate strength is yet to be determined.

It should be noted that strength of all of these year-classes is much lower than the strength of those that occurred during the 1980s. Moreover, the ability of the index to predict recruitment to the fishable population remains uncertain, particularly because it does not pick up the 1992 year-class, which was relatively strong in sentinel and commercial catches.

### 4.4.4 Spawner biomass levels and recruitment

Under the precautionary approach it is desirable to establish spawner biomass reference levels that trigger specific management actions to ensure sustainability and to conserve the population. One of these levels is a lower limit to spawner biomass ( $\mathrm{B}_{\text {lim }}$ ) below which there is considerable concern about the viability of the stock. Spawner biomass reference levels have yet to be established for $2 \mathrm{~J}+3 \mathrm{KL}$ cod. In this section a preliminary reference level is described under the hypothesis of a single functional population comprising both the inshore and the offshore.

The unaccounted for decline in the 1986 and 1987 year-classes has precluded an acceptable sequential population analysis of northern cod since the 1992 assessment (Baird et al. 1992a; Shelton and Lilly 2000). That assessment carried out the last population projection and $F_{0.1}$ TAC calculation, despite rising concern regarding the residual pattern caused by the disappearance of the 1986 and 1987 year-classes (Bishop and Shelton 1997). The estimates of spawner biomass and recruitment from the 1992 assessment provide useful insights for considering spawner biomass reference levels for $2 \mathrm{~J}+3 \mathrm{KL}$ cod.

Although there was a substantial decline in spawner biomass (males and females aged 7+) in this stock from over 1.5 million tons in 1962 to a level of less than 200,000 $t$ by the time of extension of jurisdiction in 1977 (Fig 41), several strong year-classes arose during the 1980s at spawner biomass levels above 200,000 t. These year classes led to a partial recovery of the spawner biomass. There has been no good recruitment at spawning stock
biomass levels below $200,000 \mathrm{t}$ and only a few reasonably strong year-classes at spawner biomass levels below 400,000 t (Fig. 42). Although it is difficult to define a $\mathrm{B}_{\mathrm{lim}}$ at this stage, it would clearly be desirable to have the spawning stock above $200,000 \mathrm{t}$ in the shortest possible time and ultimately above $400,000 \mathrm{t}$. It is generally accepted that an approach of no directed fishing is consistent with the precautionary approach for a stock that is below $\mathrm{B}_{\mathrm{lim}}$. Any fishery on the remnant in the inshore will delay recovery of the stock.

## 5 Other considerations

### 5.1 Temperature and other physical oceanography

In general, the below normal oceanographic trends in temperature and salinity, established in the late 1980s, reached a peak in 1991 (Colbourne 2000). This cold trend continued into 1993 but started to moderate during 1994 and 1995. During 1996-1999, ocean temperatures continued above normal over most areas.

There is some evidence that, in general, relatively warm temperatures are favourable for stocks toward the northern end of a species' range (e.g. Planque and Frédou 1999). However, there were no new analyses to determine whether the recent increase in temperature has affected recruitment, growth, mortality or distribution of $2 \mathrm{~J}+3 \mathrm{KL}$ cod.

### 5.2 Predators

A wide variety of predators are known to consume cod, mainly during the cod's juvenile stages (Pálsson 1994; Bundy et al. 2000). Cannibalism is well documented for 2J+3KL cod and is thought to be an important source of mortality in other cod stocks (Bogstad et al. 1994). However, the predator that has attracted the most interest and concern in recent years is the harp seal.

### 5.2.1 Quantity of cod consumed by harp seals

The quantity of cod consumed by harp seals during the period 1965-2000 was calculated using estimates of harp seal population numbers, energy requirements of individual seals, the average duration of seal occurrence within 2 J 3 KL , the relative distribution of seals between inshore and offshore, and stomach contents of seals sampled in the inshore and offshore in winter and summer (Stenson and Perry 2001). An average diet was calculated for each of the four combinations of area (inshore and offshore) and season (winter and summer) using all stomach content data collected in 2J3KL during the years 1982 and 1986-1998. Stomachs collected since 1998 have not yet been analyzed. Uncertainty in the estimates of numbers at age, diets, residency time in 2 J 3 KL and the proportion of seals in nearshore areas, were used to evaluate the possible range in consumption estimates. The only factor effecting annual changes in the estimates of prey consumption is the estimate of seal population numbers. Recent estimates of harp seal population size show that the population reached about 5 million in 1996 and has been fairly stable since.

Based on the average diets, it is calculated that harp seals consumed $37,000 \mathrm{t}$ of cod in 2000 (with a $95 \%$ confidence interval of $14,000-62,000 \mathrm{t}$ ). The estimate for 1998 is also about $37,000 \mathrm{t}$. This is less than previous estimates of consumption for that year ( $50,000 \mathrm{t}$ estimated in 1999 and 108,000 t estimated in 1998). Reasons for the change in the estimate from 1998 to 1999 were described in Lilly et al. (1999). The single change that contributed most to the additional decrease in the current analysis was the removal of some offshore samples that were obtained in the vicinity of research vessels conducting surveys for cod. Examination of these samples indicated that these seals might have been feeding on discards from the vessel or cod in the survey net. In addition, the equations used to estimate the lengths of Atlantic cod, squid, American plaice, and other flatfish from hard parts were revised. The new equations were based on additional data and/or equations developed using local data that are more appropriate for the area. The previous estimate incorporated a $10 \%$ 'correction factor' for unidentified prey to account for biases associated with using hard parts to identify prey. Because the degree of potential bias associated with the consumption of soft-bodied prey, the digestion of small otoliths, and belly feeding could not be estimated, this correction factor was removed.

Diet data from the inshore show that the per capita consumption of cod by harp seals has not declined with the collapse of the cod stock. In 1998 there was an increase in per capita consumption in the inshore, especially in the winter. This increase occurred in various areas from White Bay to Trinity Bay.

### 5.2.2 Observations of harp seals consuming cod bellies

In recent winters there have been many reports of harp seals in inshore waters, often very close to land, taking bites from the bellies of large cod, thereby removing the liver and stomach and leaving the rest of the body untouched (Lilly et al. 1999; p. 42). During the winters of 1997-1998 and 1998-1999 there were numerous instances of such observations, particularly in eastern Notre Dame Bay and southwestern Bonavista Bay (Lilly et al. 1999; p. 14-15). Additional observations were reported during the winter of 1999-2000, most notably in southwestern Bonavista Bay in early April 2000. Incidents reported during the winter of 2000-2001 have been less dramatic than those in previous years. Most reports have come from Bonavista Bay and the Smith Sound area of Trinity Bay. There are no estimates of the numbers of cod killed by "belly-feeding", so this form of predation has not been incorporated into the estimates of consumption.

### 5.2.3 Numbers at age eaten by harp seals

The revised estimates of the quantity of cod consumed by harp seals were used to estimate numbers of cod (at age) consumed by the seals in 1986-1998 using methods similar to those described by Stansbury et al. (1998). Stomach contents of seals sampled in 1999 and 2000 are not yet available for analysis.

Length frequencies were derived from the new otolith length - fork length regression found in Stenson and Perry (2001). Data were originally separated into quarterly time periods for each year for inshore and offshore. In the current analysis, the inshore and
offshore were combined because of the paucity of data from the offshore. In addition, the quarters were combined into the first half and the second half of the year because of low sampling intensity in some quarters.

The length frequencies reconstructed from otoliths in the stomach samples were compiled into half-yearly length frequencies for each year (Fig. 43). Although otoliths from the seal stomachs have been aged, the data are not extensive enough to be used to break down the annual length frequencies by half year. For this reason age sampling from the spring 3L research surveys using the Campelen trawl in 1996-1998 were combined to give a key for the first half of the year (Table 40) and sampling from the autumn surveys in 2J, 3K and 3L using the Campelen in 1995-1997 were combined for the second half of the year (Table 41). These keys were applied to the seal length frequencies on a half-yearly basis for each year to give the numbers at age.

Mean weights at length were calculated from the standard weight-length regression and used in conjunction with the length frequencies and the estimates of biomass consumed to calculate numbers of cod consumed. The estimates of mean weights of cod consumed and the number of cod consumed are illustrated by half-year and year in Fig. 44. Proportions at age were calculated by applying the semi-annual age-length keys to the semi-annual length frequencies in each year.

Estimates of the number of cod at age consumed by harp seals during 1986-1998 are provided by half-year and year in Table 42 and illustrated by year in Fig. 45. There is considerable variability in the estimates. For instance, the number of age 0 cod consumed in the second half of the year varies by up to 3 orders of magnitude during the period 19871993. In general, the matrix of consumption at age in the second half would appear to be influenced more strongly by year effects than year-class effects. In addition, the pattern in consumption at age is sometimes very dissimilar between the first and the second halves of the year. For example, in 1998 the consumption of age $1 \operatorname{cod}$ is estimated at 1,116 thousand in the first half and 6 thousand in the second half.

Despite these apparent inconsistencies in the estimates, there are some generalities that can be emphasized. From 1986 to 1996, cod age 0 and 1 were the predominant age groups found in harp seal stomachs. In 1997 and 1998 older fish (ages 3-5) were the dominant age groups and fish as old as age 7 were found more frequently than in previous years. With this shift to older, larger cod in recent years the estimates of total number of fish consumed have decreased while the estimates of total biomass consumed have been relatively constant.

### 5.2.4 Uncertainties regarding the estimation of cod consumption by seals

Information regarding the population size, distribution and feeding behaviour of seals increases each year and leads to changes in estimates of the number, size and age of cod and other species consumed by the seals. Changes in perception can be large, as illustrated by the considerable reduction over the past few years in the estimates of the quantity of cod consumed by seals. Much of the uncertainty associated with the consumption of cod arises
because cod is a minor prey of the harp seal. This increases the possibility of sampling error leading to large among-year differences in the number of seals having cod otoliths in their stomachs and in the size composition of those otoliths that are found. The population of harp seals is large, so slight changes in the proportion of cod in the diet samples can lead to large changes in the quantity of cod which the seals are estimated to consume.

The estimates of cod consumption may be biased upwards because diet reconstruction relies on the presence and identification of hard parts (such as cod otoliths) in the stomachs of those seals that are sampled. Diet contributions from soft bodied animals or fish with small otoliths may be missed or under-represented.

On the other hand, the estimates of cod consumption may be biased downwards because incidences of belly-feeding may be undetected and therefore not incorporated into the diet reconstructions. It is also recognized that the weight of cod killed by belly-feeding is much higher than the weight of cod consumed. The feeding on bellies also causes the size composition of the cod killed to move toward larger sizes compared with a size composition based solely on otoliths. At this time there is little information on the proportion of the seal population engaging in this form of predation, the number of days on which it happens and how many cod each of these seals kills per day.

### 5.2.5 The impact of seals on population dynamics of cod

In the absence of a sequential population analysis for the cod stock (see Section 4.4), the importance of seal predation to cod population dynamics was not explored further.

However, the estimates of removals of cod by harp seals, based on reconstructed diets, are high ( $37,000 \mathrm{t}$ in 2000) and do not incorporate the mortality caused by seals feeding on cod bellies alone. It appears that the number of cod eaten by seals annually has been high since at least 1986. It is assumed that the mortality imposed on the cod stock increased toward the mid-1990s as the removals by seals remained high and the cod population declined.

It is possibile that predation by seals is preventing the recovery of the cod stock. See Shelton and Healey (1999) for a discussion of the possibility that the lack of recovery is due to a decline in per capita reproductive success, perhaps as a result of increased predation on prerecruit fish by seals. It is also important to recognize that some of the cod eaten by seals are mature fish that have survived the juvenile years when natural mortality is high. That is, some of the predation by seals affects the cod spawning population directly.

It is speculated that belly-feeding may be an important source of mortality for local cod aggregations, especially in the area from White Bay to Bonavista Bay. The occurrence of harp seals is reported to be increasing in Trinity Bay, notably in Smith Sound.

The hooded seal is also known to prey on cod, and estimates of their consumption of cod ( $34,000 \mathrm{t}$ in 1996; Hammill and Stenson 2000) should be updated and incorporated into an
analysis of the removals of cod by all predators, including cod itself. The potential impact of this predation on the population dynamics of cod should be explored through modelling.

### 5.3 Prey

Capelin has historically been the dominant pelagic species in the area and the major prey of cod. In the early 1990s capelin almost disappeared from Division 2J, increased in abundance in areas where they were previously uncommon (Flemish Cap and eastern Scotian Shelf), became inaccessible to acoustic surveys conducted at traditional times, arrived late in the inshore for spawning, and experienced low growth rates (Lilly 1994; Frank et al. 1996; Nakashima 1996; Carscadden et al. 1997; Carscadden and Nakashima 1997). In the past 2-3 years there are indications that some aspects of capelin biology, notably their offshore distributions, appear to be changing to more closely resemble patterns observed in the 1980s (Lilly and Simpson 2000; DFO 2000).

The trend in biomass of capelin has been uncertain since the late 1980s (DFO 2000). Recent acoustic studies have detected some aggregations of capelin in the inshore but few offshore compared to the 1980s (O'Driscoll et al. 2000; DFO 2000). (There are no reports to date of the distribution or biomass of capelin in 2000.)

There is concern that there may not be sufficient capelin in the offshore, particularly in the north, to support good condition in cod. Other prey items exist in the offshore, but capelin was historically the most important prey in the diet of $2 \mathrm{~J}+3 \mathrm{KL}$ cod and changes in capelin biomass, as determined from acoustic surveys, explain some of the interannual variability in growth and condition of cod (Krohn et al. 1997). Parallels with other ecosystems also provide cause for concern. Declines in capelin biomass have been associated with reductions in growth rate of cod in waters around Iceland (Steinarsson and Stefánsson 1996) and in the Barents Sea (Mehl and Sunnanå 1991; Jørgensen 1992) and with a reduction in somatic condition and lipid reserves of cod in the Barents sea (Jørgensen 1992; Marshall et al. 1999).

### 5.4 Ecosystem approach

There has been very little progress in the adoption of an ecosystem approach in the context of biological interactions among capelin, cod and seals. It is likely that many of the questions regarding the recovery of northern cod and the sustainability of future fisheries can be answered only by developing a more complex realization of the ecosystem than that used in the 1980s and early 1990s. Vital data for developing an ecosystem approach include abundance of predators and prey and diet composition of predators. The current paucity of data on the abundance of capelin (and other planktivores, such as Arctic cod) and the diets of harp seals (and hooded seals, cod and other important predators) compromises any useful ecosystem modelling related to cod in the foreseeable future.

## 6 Outlook

The text for the outlook for the $2 \mathrm{~J}+3 \mathrm{KL}$ cod stock is taken directly from the Stock Status Report (DFO 2001).

### 6.1 Outlook for the stock under two hypotheses regarding stock structure

The stock is assessed under two hypotheses regarding stock structure: a) the inshore constitutes a separate inshore subpopulation that is functionally separate from the offshore; and b) inshore and offshore fish together constitute a single functional population.

### 6.1.1 Separate inshore subpopulation hypothesis

The acoustic data for Smith Sound show an increase in the biomass index from about $15,000 \mathrm{t}$ in 1999 to about $31,000 \mathrm{t}$ in 2001 while the research bottom-trawl index for inshore strata in 3 K and 3L suggests that the inshore biomass of fish age 1-4 has been increasing since 1997 but the biomass of older fish has been decreasing since 1996. Catch rates from the sentinel survey and from the commercial logbooks show decreasing trends from 1998. The fishing community questionnaire indicates that overall the catch rates in 2000 were low compared with the historical average. In the fall surveys, few fish older than age 5 have been found in inshore 3 K and 3 L and the age composition is consistent with a high overall mortality rate. The age structure (presence of older fish) in Smith Sound and the inshore commercial catch may indicate that the mortality in some areas of the nearshore is lower.

Tagging data indicate that the 1999 fishery resulted in a $43 \%$ harvest rate for fish tagged in 3 K compared to northern 3 L ( $13.2 \%$ ) and southern 3 L ( $23.6 \%$ ). Tag returns indicate harvest rates in 2000 of about $10 \%$ for fish tagged in 3 K and northern 3 L and $22 \%$ for fish tagged in southern 3L. Based on reported catches, the corresponding exploitable biomass estimates from a simple migration model were roughly $40,000 \mathrm{t}$ in 3 K and northern 3 L combined over the period 1998-2000. A more detailed model without migration gives a biomass of no more than $77,000 \mathrm{t}$ in 3 KL in 2000.

The recruitment model, based on both inshore and offshore data, estimates that the 1998 to 2000 year-classes are stronger than earlier year-classes in the 1990s. It is considered that these levels are extremely low compared to recruitment to the whole $2 \mathrm{~J}+3 \mathrm{KL}$ stock in the 1980s. The inshore is thought to be a preferred nursery area for young cod (ages 0 and 1) irrespective of whether they originate from spawning in the inshore or the offshore. Yearclasses after 1996 are slightly stronger and may lead to increases in the abundance of commercial size fish and the spawning biomass in the inshore in the future if mortality rates are low.

The overall decreasing trend in indices of the abundance of commercial size and spawning age fish suggest that, at current levels of mortality, stock size has not been sustained by recent levels of recruitment. The particularly weak 1996 year-class is likely to exacerbate this situation. However, declining levels of biomass are not apparent in tagging results.

There is no information on what levels of biomass could be supported in the inshore, or on what would constitute an undesirably low spawner biomass under a precautionary approach. If the inshore biomass is considered to be above any such low level, then a harvest rate of $10 \%$ could be considered consistent with a precautionary approach under the hypothesis of a functionally separate inshore subpopulation. Indices of exploitable biomass from commercial and sentinel catch rates and the fall bottom-trawl survey in inshore strata appear to be inconsistent with estimates from tagging in their information about trends. Therefore, we cannot say whether recent levels of exploitation have been sustainable. The fact that only about $70 \%$ of the TAC was taken in the 2000 index fishery may be further cause for concern.

### 6.1.2 Single functional population hypothesis

Overall, there is no doubt that the $2 \mathrm{~J}+3 \mathrm{KL}$ cod spawner biomass remains at an extremely low level and there is no evidence of a recovery. The offshore research bottom-trawl survey results show extremely low abundance levels, although the remaining fish are widespread. Mortality rate of fish in the offshore is estimated to be as high as levels in the 1980s when a substantial commercial fishery existed. Slightly elevated abundances of fish have been detected in 1999-2000 in acoustic surveys and bottom trawl surveys on the shelf near the boundary between southern 3 K and northern 3 L . This overlaps the areas in which the Greenland halibut and shrimp directed fisheries are being carried out. Although reported by-catches on observed vessels are low (less than 40 t in 2000), there is concern that by-catch mortality could delay or impede the recovery of the stock.

Although there was a substantial decline in spawner biomass in this stock over the 1960s to a level of less than 200,000 $t$ by the time of extension of jurisdiction in 1977, several strong year-classes arose during the 1980s at a spawner biomass level of about $400,000 \mathrm{t}$. There has been no good recruitment at spawning stock biomass levels below 200,000 t. Although it is difficult to define a $\mathrm{B}_{\text {lim }}$ at this stage, it would clearly be desirable to have the spawning stock above $200,000 \mathrm{t}$. It is generally accepted that an approach of no directed fishing is consistent with the precautionary approach for a stock that is below $\mathrm{B}_{\text {lim }}$. Any fishery on the remnant in the inshore will delay recovery of the stock.

### 6.1.3 Impact of harp seals

The estimates of removals of cod by harp seals, based on reconstructed diets, are high ( $37,000 \mathrm{t}$ in 2000) and do not incorporate the mortality caused by seals feeding on cod bellies alone. It appears that predation by seals has been an important source of mortality of cod since the start of the moratorium. There is also the possibility that predation by seals is preventing the recovery of the cod stock, not simply because considerable numbers of cod are being consumed but also because some of those cod eaten are mature fish.

${ }^{1}$ Provisional catches.
${ }^{2}$ Catch is 4000 (t) less than Canadian statistics as this quantity is considered 3 NO gillnet catch misreported in 3L.
${ }^{3}$ Estimate for recreational fishery has been reported as 3L Handline.
${ }^{4}$ Comprised of sentinel survey catch of 294 t , a food fishery catch of 1155 t and by-catch 142 t . An amount of 103 t must still be allocated by gear type and division from the sentinel catches.

Table 3. Catch (t) in 2000 from all sources (index fishery including by-catch, sentinel survey and food/recreational fishery), by gear, unit area and month.

Table 12. Estimates of cod abundance (thousands) from surveys in Division 2J in 1983-1992, in Campelen equivalent units.

${ }^{1}$ Not all strata in the depth range have been fished. Strata not fished in the $<=500$ meter depth range have been filled using
a multiplicative model using data to 1992. Std are for strata fished in the depth range.

Table 13. Estimates of cod biomass (t) from surveys in Division 2J in 1983-1992, in Campelen equivalent units.

nf Not all strata in the depth range hav been fished. Strata not fished in the greater than $\mathbf{2 0 0}$ fathom depth range
have not been filled using a multiplicative model.

Table 23. Estimates of cod abundance (thousands) and biomass ( t ) from surveys in inshore strata of divisions 3K and 3L in 1996-1998 and 2000. Also shown are totals for offshore strata and for all strata fished.

Table 27. Autumn bottom-trawl mean catch (number) per tow at age in inshore strata in 3 K and 3L in 1996-1998 and 2000. For each year and Division, an age-length key was constructed from sampling conducted both inshore and offshore, and this key was applied to the catch rate at length from the inshore strata in the appropriate year and Division. The lower part of the table indicates with an X those strata that were fished during each year.

Table 28. Autumn bottom-trawl mean catch (number) per tow at age in inshore strata in 3 KL combined in 1996-1998 and 2000. Each 3KL catch at age index is the mean of the divisional means (Table 27), weighted by the divisional survey areas (where the area of inshore strata is 3235 sq n miles in 3 K and 3107 sq n miles in 3 L ). (Note that corrections have been made to the comparable table from last year; Table 22b in Lilly et al. MS 2000.)

${ }^{1}$ Not all strata in the depth range have been fished. Strata not fished in the $<=\mathbf{2 0 0}$ fathom depth range have been filled using
a multiplicative model using data to 1992. Std are for strata fished in the depth range.

Table 30. Estimates of cod biomass (t) from spring surveys in Division 3L in 1988-2000 in depths $<=200$ fathoms. The 1988-1995 data are in Campelen equivalent units and the 1996-2000 data are in actual Campelen units.

Table 36. Mean liver index at age of cod sampled during autumn bottom-trawl surveys in divisions $2 \mathrm{~J}, 3 \mathrm{~K}$ and 3 L in 1978-2000.
Highlighted entries are based on fewer than 5 aged fish. (Instances where fewer than 5 fish were available are not indicated for years prior to 1995.) There were no surveys in Division 3L in 1978-1980 and 1984.

Table 37. Observed proportion mature at age of female cod in divisions 2J3KL (1982-2001). A50=median age at maturity (years); L95\% and $\mathrm{U} 95 \%=$ lower and upper $95 \%$ confidence intervals. Parameter estimates of the logit model are shown: Int=intercept, $\mathrm{SE}=$ standard error, $\mathrm{n}=$ number of fish examined, dot=no fish sampled. Years are spawning years. (Each observations was made during the autumn survey of the previous year.)

Fig. 1a. Map of the stock area, showing physiographic features and NAFO Divisions.

Fig. 1b. Map of the stock area, showing commercial fishery statistical unit areas.

Fig. 1c. Map of the stock area, showing commercial fishery statistical sections.

Fig. 1d. Map of the stock area, showing sentinel survey sites.

Fig. 2. Divisions 2J +3 KL TAC and landings from fixed and mobile gear, 1959-2000.

Fig. 3. Divisions 2J+3KL landings by Canadian and non-Canadian vessels, 1959-2000.

Fig. 4. Division 2J +3 KL landings by Division, 1959-2000.

Fig. 5. Division 2J+3KL fixed gear landings by gear type, 1975-2000.

Fig. 6. The estimated catch at age for all gears combined and for individual gears in 2 J 3 KL in 2000. All sources of catch (commercial, sentinel survey and food / recreational) are combined.

Fig. 7. Mean weights-at-age calculated from mean lengths-at-age in the catch, 19722000.

Fig. 8. Strata used for research bottom-trawl surveys in Division 2J.

Fig. 9. Strata used for research bottom-trawl surveys in Division 3K.

Fig. 10. Strata used for research bottom-trawl surveys in Division 3L.

Fig. 11. Indices of abundance and biomass of cod from autumn bottom-trawl surveys in the offshore index strata of divisions 2J3KL in 1983-2000. The estimates for 1983-1994 are adjusted to Campelen equivalents.

Fig. 12. Mean catch per tow of the 1976-1999 year-classes at ages 1-3 during autumn bottom-trawl surveys in divisions $2 \mathrm{~J}, 3 \mathrm{~K}$ and 3 L combined. Data obtained prior to the introduction of the Campelen trawl in 1995 are shown as actual (unconverted) numbers (from Shelton et al. (MS 1996)) and in numbers converted to Campelen equivalents.

Fig. 13. Index of spawner biomass of cod from autumn bottom-trawl surveys in divisions 2 J 3 KL in 1983-2000. The index is calculated from the mean catch per tow at age (with 1983-1994 adjusted to Campelen equivalents), the proportion mature at age, and the commercial Jan. 1 weights-at-age. (The latter two were moved back one age and one year to correspond to the timing of the autumn survey.)

Fig. 14. Indices of abundance (top), biomass (middle) and spawner biomass of cod from autumn bottom-trawl surveys in inshore strata of divisions 3KL in 1996-1998 and 2000. The abundance index is calculated from mean catch per tow at age, the biomass index is the abundance index with commercial Jan. 1 weights-at-age applied, and the spawner biomass index is the biomass index with the proportions mature at age applied. (The Jan. 1 weights-at-age and proportions mature at age were moved back one age and one year to correspond to the timing of the autumn survey.)

Fig. 15. Cod distribution (number per standard tow) during the autumn surveys in divisions 2J3KL in 1987 and 1988.

Fig. 16a. Cod distribution (number per standard tow) during the autumn surveys in divisions 2J3KL in 1995 and 1996.

Fig. 16b. Cod distribution (number per standard tow) during the autumn surveys in divisions 2J3KL in 1997 and 1998.

Fig. 16c. Cod distribution (number per standard tow) during the autumn surveys in divisions 2J3KL in 1999 and 2000.

Fig. 17. Indices of abundance and biomass of cod from spring bottom-trawl surveys in Division 3L. Estimates for 1985-1995 are based on Campelen equivalents and those for 1996-2000 are based on actual catches.

Fig. 18a. Geographic distribution (number per standard tow) during the spring surveys in divisions 3LNO in 1984-1987.

Fig. 18b. Geographic distribution (number per standard tow) during the spring surveys in divisions 3LNO in 1988-1991.

Fig. 18c. Geographic distribution (number per standard tow) during the spring surveys in divisions 3LNO in 1992-1995.

Fig. 19a. Geographic distribution (number per standard tow) during the spring surveys in divisions 3LNO in 1992-1995.

Fig. 19b. Geographic distribution (number per standard tow) during the spring surveys in divisions 3LNO in 1996-1999.

Fig. 20. Geographic distribution (number per standard tow) during the spring survey in divisions 3 LNO in 2000.

Fig. 21a. Cod distribution (number per standard tow) during spring and autumn surveys in southeastern 3K and eastern 3L in 1995 and 1996. The spring 1995 data are Engel trawl catches converted to Campelen equivalents.

Fig. 21b. Cod distribution (number per standard tow) during spring and autumn surveys in southeastern 3K and eastern 3L in 1997 and 1998.

Fig. 21c. Cod distribution (number per standard tow) during spring and autumn surveys in southeastern 3K and eastern 3L in 1999 and 2000.

Fig. 22. Standardized catch rates from sentinel surveys in 3 KL combined.

Fig. 23. Standardized catch rate at age for three gear types fished by the sentinel surveys in 19952000.

Fig. 24. Median gillnet catch rates by statistical section (Fig. 1c) from the gillnet fisheries for cod by vessels $<35$ feet during the 1998 and 2000 index fisheries and the 1999 commercial fishery.

Fig. 25. Standardized catch rates from the gillnet fisheries for cod by vessels $<35$ feet in 3 KL combined during the 1998 and 2000 index fisheries and the 1999 commercial fishery.

Fig. 26. Mean lengths at ages 2-8 of cod in Divisions 2J, 3K and 3L in 1978-2000, as determined from sampling during bottom-trawl surveys in autumn. Values calculated from fewer than 5 aged fish are not plotted. There were no surveys in Division 3L in 1978-1980 and 1984.

Fig. 27. Mean weights at ages 2-8 of cod in Divisions 2J, 3K and 3L in 1978-2000, as determined from sampling during bottom-trawl surveys in autumn. Values calculated from fewer than 5 aged fish are not plotted. There were no surveys in Division 3L in 1978-1980 and 1984.

Fig. 28. Mean lengths and weights at ages 4 and 6 of cod in Divisions 2J, 3K and 3L in 19782000, as determined from sampling during bottom-trawl surveys in autumn. Values calculated from fewer than 5 aged fish are not plotted. There were no surveys in Division 3L in 1978-1980 and 1984.

Fig. 29. Mean Fulton's condition (gutted weight) at ages 3-6 of cod in Divisions 2J, 3K and 3L in 1978-2000, as determined from sampling during bottom-trawl surveys in autumn. Values calculated from fewer than 5 aged fish are not plotted. There were no surveys in Division 3L in 1978-1980 and 1984.

Fig. 30. Mean liver index at ages 3-6 of cod in Divisions 2J, 3K and 3L in 1978-2000, as determined from sampling during bottom-trawl surveys in autumn. Values calculated from fewer than 5 aged fish in 1995-1997 are not plotted. There were no surveys in Division 3L in 1978-1980 and 1984.

Fig. 31. Estimated percentage mature at ages 4, 5 and 6 for female cod in divisions 2J3KL combined (1982-2001). The percentage mature at age estimated from sampling during the autumn research bottom-trawl survey in year t is displayed for spawning in year $\mathrm{t}+1$.

Fig. 32. Age at $50 \%$ maturity ( $\pm 95 \% \mathrm{CI}$ ) by year for female cod in divisions 2J3KL combined (1982-2001). The A50 estimated from sampling during the autumn research bottom-trawl survey in year $t$ is displayed for spawning in year $t+1$.

Fig. 33. Age at $50 \%$ maturity ( $\pm 95 \% \mathrm{CI}$ ) by cohort for female cod in divisions 2 J 3 KL combined based on sampling during the autumn research bottom-trawl surveys in 1981-2000.

Fig. 34. Estimates of the proportion of single-tagged fish that still retain their tag, versus time-at-liberty.

Fig. 35. Weekly estimates of the fully selected exploitation rates (\%) in 2000 by gear type for 3 K . The mid-week date is shown for every fourth week.

|  | gillnet handline linetrawl |  | other ottertrawl | (mownols | trap unknown |
| :---: | :---: | :---: | :---: | :---: | :---: |

Fig. 36. Weekly estimates of the fully selected exploitation rates (\%) in 2000 by gear type for northern 3L. The mid-week date is shown for every fourth week.

Fig. 37. Weekly total catch, exploitation, and biomass estimates for three inshore regions in 3 KL . The panels in the top row show weekly landings, for weeks when the landings exceeded 50 tonnes. Exploitation and biomass estimates corresponding to these weeks are shown in the middle and bottom panels. The weeks are numbered from the beginning of the year.

Fig. 38. Mortality rates on fish aged 1 to 14 as calculated from catch rate per tow at age during the autumn research bottom-trawl surveys in 2J3KL in 1983-2000.

Fig. 39. Mortality rates on fish aged 4 and 6 as calculated from catch rate per tow at age during the autumn research bottom-trawl surveys in 2J3KL in 1983-2000. The smoother is a two year forward moving average.

Fig. 40. Standardized year-class strength derived from modelling 30 survey/age indices (see Section 4.4.3).

Fig. 41. Estimates of population biomass (3+), spawner biomass (7+), and recruitment (at age 3 ) in the $2 \mathrm{~J}+3 \mathrm{KL}$ cod stock (from Baird et al. MS 1992).

Fig. 42. Estimates of recruits (at age 3) and spawner biomass (7+) in the $2 \mathrm{~J}+3 \mathrm{KL}$ cod stock (from Baird et al. MS 1992).

Fig. 43. Semi-annual cod length frequencies calculated from the sizes of otoliths found in harp seal stomachs in NAFO divisions 2J, 3 K and 3L combined, for each year in the period 1986-1998.

Fig. 44. Mean weights of cod consumed and the number of cod consumed by harp seals in NAFO divisions 2J, 3K and 3L combined, by half-year and year in the period 1986-1998.

Fig. 45. Estimates of the number of cod at age consumed by harp seals each year during 1986-1998.

[^0]:    ${ }^{1}$ Not all strata in the depth range have been fished. Strata not fished in the $<=\mathbf{5 0 0}$ meter depth range have been filled using a multiplicative model using data to 1992. Std are for strata fished in the depth range.

[^1]:    changes below were made before 1997 fall survey
    ${ }^{1}$ Area of strata 788 was increased by 9 sq. n. mi and the area of strata 789 was decreased by 9 sq.n. mi.
    2 Strata 791 in the 100-200 depth range was divided into two separate strata 791 101-150
    with area $=227$ sq. n. mi.and strata $800151-200$ area $=81$ sq. n.mi.
    ${ }^{3}$ Strata 611 area was decreased by 27 sq. n. mi.
