* This series documents the scientific basis for the evaluation of fisheries resources in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

This document is available on the Internet at:

* La présente série documente les bases scientifiques des évaluations des ressources halieutiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au Secrétariat.

Ce document est disponible sur l'Internet à:

Canadä

#### Abstract

The Pacific cod stocks off the west coast of Vancouver Island (3CD) and in Hecate Strait (5CDE) were assessed using the available commercial fisheries research survey data. A delay-difference stock productions analysis was used to synthesize these data. For the 3CD stock, indicators of biomass and recruitment are currently very low, but have been increasing slightly in recent years. Fishing mortality and fishing effort on the stock have been reduced and this should aid stock recovery. The current Total Allowable Catch (TAC) plus carry over is 893 t . Catches in this range in 2002 would result in a decline in stock biomass and further compromise stock rebuilding. However, the TAC for this stock has never been caught. If catches continue to be similar to those in recent years, i.e. less than 200 t , there may be improvement in stock biomass.

An index of sea level height in Prince Rupert was incorporated in the assessment model for the area 5CD stock. High sea levels during January-March have been associated with high transport through the Hecate Strait area and reduced recruitment for the stock. Conditions have been unfavorable for recruitment through most of the 1990s, however, sea levels have declined in the past 2 years and recruitment may be improving. Stock biomass is estimated to be very low. Fishing mortality and fishing effort had been relatively high prior to 2001, however these were reduced in 2001 due to the reduced TAC, and this should aid stock recovery. If the current TAC of 200 t is maintained for 2002, the stock biomass may increase by between $25-35 \%$ and allow some stock rebuilding.

## Résumé

Nous utilisons les données de relevés de recherche disponibles sur les pêches commerciales, mises en rapport à l'aide d'une analyse de production à retardement des stocks, pour évaluer les stocks de morue du Pacifique de la côte ouest de l'île de Vancouver (3CD) et du détroit d'Hécate (5CDE). Dans le cas du stock de 3CD, les indicateurs de la biomasse et du recrutement sont actuellement très faibles, bien qu'ils aient légèrement augmenté au cours des dernières années. La mortalité par pêche et l'effort de pêche exercé sur le stock ayant diminué, le stock devrait se rétablir. L'ensemble du TAC actuel et du report de quota se chiffre à 893 t . Des prises de cet ordre en 2002 résulterait en un déclin de la biomasse et compromettrait davantage le rétablissement du stock. Par contre, le TAC fixé pour ce stock n'a jamais été récolté. Si les prises restent aux mêmes niveaux que par les années passées, c'est-à-dire qu'elles se chiffrent à moins de 200 t , la biomasse augmentera peut-être.

Nous avons inclus un indice du niveau de la mer à Prince Rupert dans le modèle d'évaluation du stock de 5 CD . Un niveau de la mer élevé de janvier à mars signifie que l'espèce transite rapidement à travers le détroit d'Hécate et que le recrutement au stock est réduit. Les conditions n'ont pas été favorables au recrutement pendant la plupart des années 1990, mais comme le niveau de la mer a diminué au cours des deux dernières années, le recrutement s'améliorera peut-être. La biomasse estimée du stock est très faible. La mortalité par pêche et l'effort de pêche étaient relativement élevés avant 2001, mais comme ils ont diminué cette année-là en raison d'une réduction du TAC, le stock devrait se rétablir. Si le TAC actuel de 200 t reste inchangé en 2002, la biomasse du stock augmentera peut-être de 25 à $35 \%$, ce qui permettra au stock de se rétablir dans une certaine mesure.

## 1. Introduction

Pacific cod (Gadus macrocephalus) are harvested in relatively shallow waters ( $<150$ m ) all along the BC coast. Coastwide landings peaked in the mid-1960s at close to $15,000 \mathrm{t}$, again in the mid-1970s at just over 12,000 t and again in the late 1980s and early 1990s. Landings have been highly variable and have tended to follow changes in recruitment. Landings declined in the 1990s and have been below the long term average of 6,400 t since 1994 with landings from 1996-2000 being the lowest on record (Fig. 1, Table 1).

Four stocks of Pacific cod are defined for management purposes on the BC coast, Strait of Georgia (4B), west coast Vancouver Island (3AB), Queen Charlotte Sound (5AB), and Hecate Strait (5CDE). The species is fished almost exclusively with trawl gear. The most recent assessment of the Hecate Strait stock is given by Sinclair (2000), for the west coast Vancouver Island stock by Haist and Fournier (1995), and for the Strait of Georgia by Westrheim and Foucher (1987). No assessments have been made of the Queen Charlotte Sound stock.

This Research Document will focus on the west coast Vancouver Island and Hecate Strait stocks. The objective is to address the questions asked in the "Request For Working Paper" given in Appendix I. Specific objectives are:

1. To review surveys, biological, sampling, catch records, logbooks, observer reports, and fishing practices for Pacific Cod to provide a basis for management for the 2002/2003 fishery in Hecate Strait and west coast Vancouver Island;
2. To provide an assessment of Hecate Strait and west coast Vancouver Island pacific cod stock status;
3. To provide stock projections based on various yield options;
4. To recommend appropriate yield options;
5. To recommend a stock monitoring program for Hecate Strait pacific cod.

The Research Document is divided in 2 main sections, one for each stock. Stock status indicators are reviewed and summarized in a "Report Card" format. A delaydifference stock production model is used for each stock. An environmental covariate is introduced in the Hecate Strait model and the consequences of environmental variation on biological reference points and stock projections are investigated.

## 2. Methods

### 2.1 Data Sources

### 2.1.1 Fishery data

Catch and effort data from the Canadian groundfish trawl fishery were obtained from 2 sources. The GFCATCH database (Rutherford 1999) contains landing slip, interview, and logbook information for fisheries between 1954-1995. These 2 sources of information were combined to form "fishing event" records. From 1954-1990, these events were aggregations of individual fishing sets where the aggregation was done by
fishing locality and depth zone within individual fishing trips. Fishing events consisted of individual fishing sets between 1991-1995. For 1994 and 1995, fishing locations were recorded by latitude and longitude instead of larger fishing localities. The PacHarvTrawl database (1996 to present) consists of set-by-set data collected by either fisheries observers (the vast majority) or captured from logbooks, and trip landings data collected through dockside monitoring. These data are combined in such a way that the landings data, considered to be the most accurate data on total catch, are prorated according to the set-by-set catch estimates. Non-Canadian total annual catch data were taken from previous assessments of the stocks. These catches occurred between 1954-1978 and they were inferred by subtraction of the Canadian annual catch from the total catches provided in Haist and Fournier (1998). The catch and effort data were used as the source for describing the spatial and seasonal distribution of the fishery and for developing a catch per unit effort abundance index for the stocks.

Historical size composition data for the commercial catches of Pacific cod were obtained from V. Haist, the lead author of previous assessments of these stocks. For the west coast Vancouver Island stock, this included data from 1956-1995. For the Hecate Strait stock, this included the years 1956-1998. The time series were brought up to date using sample data from recent years. The samples were obtained either in port by DFO port samplers or at sea by fisheries observers. Samples were combined by quarter after weighting individual samples by the ratio of catch divided by sample weight. For sea samples, the catch weight was the weight of the individual fishing set catch from which the sample was drawn. For port samples, the catch weight was the weight of the landing.

### 2.1.2 Hecate Strait groundfish survey

A trawl survey of the Hecate Strait area was conducted on the CCG vessel W.E. Ricker in May-June, 2001. The objective of the survey was to collect biological data on commercial groundfish stocks in the area as well as to collect other data for hydrographic and geological purposes. In addition, several fishing sets were allocated to areas designated as being good places to find Pacific cod. The designation was done by knowledgeable fishermen from the Prince Rupert area. This survey was not an extension of the Hecate Strait groundfish assemblage survey time series, results of which are given in Sinclair 2000. Nevertheless, some qualitative comparison of results in terms of catch rate and size composition were made.

### 2.1.3 Shrimp survey index

A shrimp trawl survey has been conducted off the west coast of Vancouver Island beginning in 1973. The spatial coverage of the survey varied among years. The greatest coverage was in Pacific Fisheries Management Area (PFMA) 124 (Fig. 2) which was sampled annually with the exception of 1974, 1984, and 1986. PFMA 125 was not sampled in 1974, 1984, 1986, 1989 and 1991. PFMA 123 was sampled in 1996-2001. PFMA 23, which is inshore in Barkley Sound, was surveyed with a net equipped with a fish exclusion device and thus the results were of little interest as an index of fish biomass. The weights of Pacific cod catches were recorded throughout the time series.

The survey followed a systematic design with stations located along Loran lines, e.g. Y lines, 20 microseconds apart; and Z lines, 10 microseconds apart. Inner and outer boundaries were determined by fishing this grid system until shrimp catches were negligible or the bottom became too rough to trawl. Steps were taken to maintain sampling gear and fishing effort comparable between surveys. However, changes in gear were unavoidable. From 1973 to 1976 the survey was conducted using a semi-balloon trawl with wood flat doors, and fitted with a bobbin and roller groundline (Butler et al. 1973). In 1976 the trawl was changed to a National Marine Fisheries Service (NMFS) high-rising shrimp sampling trawl fished with steel Vee Doors (Boutillier et al. 1976). During the 1976 survey, comparative tows between the high rise and the semi-balloon trawl were made and the NMFS trawl was found to be 1.4 times more efficient in catching shrimp per unit area swept (Boutillier et al. 1976). Because the efficiency of the nets have not been calculated for catching efficiency of fish species such as cod, the historical data have NOT been adjusted to reflect the use of the NMFS trawl as the standard sampling gear. This would if anything tend to bias the indices for fish species towards under-estimates for 1973 and 1975. The gear may have changed over-time due to repairs, stretching etc., there is no information at the present time to determine how this would effect the standardized effort. However, over the last 10 years a net sonar on the headline of the trawl has been used to monitor trawl dimensions and performance during almost every tow. Any substantial changes in the trawl opening dimensions are readily picked up and appropriate actions and adjustments can be readily made.

Most of the offshore surveys (121, 123, 124, and 125) have been conducted using the research vessels G.B.Reed (1973-1985) and W.E.Ricker (1987-present). Exceptions to this were a multiple vessel survey in the fall of 1977 aboard the F.V. Gypsy Traveller, Deliverance, Pacific Trident and Crino D'Oro, a fall survey in 1978 aboard the F.V. Ocean King and a spring survey in 1989 aboard the F.V. Sharlene K. Differences in fishing power that may have occurred because of differences in vessel power, warp size, etc. have not been measured or adjusted for in any way.

All tows were of 30 minutes duration, unless shortened due to snags, etc. The distance traveled was calculated using the technology of the day. In the early years, this was start and stop loran locations while today a much more accurate differential global positioning systems (DGPS) is used. This has resulted in a trend towards a shorter distance traveled for a 30 minute tow over the years. At this time no attempt has been made to account for the errors or differences between the surveys to reflect this increase in accuracy of distance towed. Surveys were always conducted during daylight hours to reduce the problems associated with the known diurnal vertical migration of some shrimp species at night.

The density of cod by weight per square meter was calculated for all tows. This data along with the latitude and longitude of the center point of each tow was then imported into Arc View GIS system. The cod biomass indices were modeled for the offshore areas in question by interpolating the distribution from the sample tow density using an inverse distance weighted interpolation procedure. The total area of fishable shrimp grounds for each survey area was masked off and the area was divided into $300 \times 300$ meter (90,000 $\mathrm{m}^{2}$ ) grids. The center point of a tow was assigned to the appropriate grid cell along with the weight densities. The blank grid cells were then filled in with interpolated values and
the biomass indices were then calculated by summing the values in each grid within the larger masked boundaries of each survey area. All the biomass index calculations were made within the Arc View GIS software package.

### 2.2 Catch per unit effort analysis

Commercial catch per unit effort indices were calculated for each stock in the following manner. The depth range where Pacific cod are commonly found in each area was determined and data from outside this range were eliminated from the analysis. There have been important changes in the depth distribution of fishing effort in each stock area, with an expansion of the fishing grounds toward deeper depths in more recent years. Pacific cod tend to be found in relatively shallow water, therefore including data from deeper zones in more recent years would bias the catch per unit effort series downward. There have also been a number of fishery closures over the years based on area and season. These closures were considered when selecting data for analyses. The measurement of the central tendency of the data was also considered. In previous assessments, the median of the non-zero event-specific catch per unit effort was used. Two factors weigh against this approach. First, this approach eliminates all non-zero catches from the index. Second, the more recent observer data tends to contain more small catches of individual species than the earlier logbook data. This is the likely consequence of fishing captains not recording small by-catches in their logbooks. As an alternative, I used an effort weighted mean catch per unit effort, i.e. the ratio of the sum of catch divided by the sum of effort. Specific details on the areas and seasons used in each stock index are given in the respective results sections.

### 2.3 Swept area biomass index

Catch per unit effort is a density measure. When catch per unit effort is treated as a biomass index, an assumption is made that the area over which this density is measured remains constant from year to year. An alternative approach is to calculate both the density and the area fished. The product of density and area would be a more accurate index of biomass, provided the total area occupied by the stock is sampled (Beverton and Holt 1957). This is the basis of swept area measures of fish abundance and biomass (Walters and Bonfil 1999, Schnute and Haigh 2000, Sinclair 2000). The availability of precise fishing location data from logbooks (1994-95) and observers (1996-2000) allows such calculations to be done.

The approach taken here was to divide the stock area into a rectangular grid of 0.05 degrees latitude and longitude. The effort weighted mean catch per unit effort in each rectangle was calculated and assumed to represent the mean fish density in the grid. The fish biomass index for the area was then calculated as the sum of the densities in each rectangle. The stock area was calculated as the number of rectangles that contained the upper $95 \%$ of the biomass index.

### 2.4 Delay-difference production analysis

A delay-difference stock production model (Hilborn and Walters 1992) was used to estimate stock parameters relevant to management. The model uses 2 age groups,
recruits and spawners. A stochastic Ricker stock-recruitment function was used to link the 2 groups. Recruitment to the spawning population and the fishery was assumed to be knife edged at age 2. Growth was assumed to follow a constant von Bertalanffy function and the length-weight relationship was assumed constant. Input parameters for growth were obtained from Westrheim (1996). The model is conditioned on fishing effort, estimated as the ratio of catch divided by catch per unit effort. The objective function includes terms for predicted vs. observed catch, predicted vs. observed mean weight of individuals, and recruitment anomalies. A non-equilibrium surplus production model was used in the previous assessment of the 5CD Pacific cod stock (Sinclair 2000). The delay-difference model used in the current assessment was considered to be an improvement because it allowed for a stochastic stock-recruitment relationship.

An environmental covariate was included in the stock/recruitment relationship for the Hecate Strait stock. Fournier (1983) reported a negative effect of sea level height on Pacific cod recruitment success in Hecate Strait. Tyler and Crawford (1991) tested several possible environmental stock recruitment functions for this stock including circulation, temperature, herring as prey for young cod, and herring as prey for spawners. They concluded that the circulation hypothesis was the most effective in explaining recruitment anomalies for the stock. Sea level at Prince Rupert during the spawning period (January-March) was used as an index of circulation. High sea levels indicated high circulation through Hecate Strait and this resulted in low recruitment success. The hypothesis being that eggs and larvae were removed from the area by strong currents. Based on these analyses, the effect of sea level on stock production model was introduced as an effect on the slope at the origin of the stock recruitment curve. Sea level data were available since 1962 with the exception of 1986. The sea level was assumed to be average in years when data were missing. The data were transformed into standard deviates from the overall mean.

The model formulation was as follows.
Estimated Parameters
$B_{0}$ - unfished population biomass
$\gamma$ - ratio $B_{1} / B_{0}$, population size in year 1 relative to unfished population size
$\delta$ - steepness of stock-recruitment curve, multiplier between slope at unfished equilibrium and at the origin of the stock recruitment curve
$q$ - fishery catchability
$\phi_{t}$ - recruitment anomolies in year t
M - natural mortality rate
$\tau$ - sea level effect on recruitment
Input parameters from other sources
$L_{\infty}=89.48$ - maximum length in von Bertalanffy growth equation
$k=0.307$ - growth rate parameter in von Bertalanffy growth equation
$t_{0}=-0.116$ - time at $\mathrm{L}=0$ in von Bertalanffy growth equation
$a=7.38 \mathrm{E}-06-$ slope of length - weight relationship (kg)
$b=3.0963$ - exponent of length - weight relationship
$r=2$ - age of knife edge recruitment to fishery and spawning population
Annual Input Data
$E_{t}$ - fishing effort in year t
$P_{t}$ - sea level at Prince Rupert in year t
$C_{t}$ - weight of catch in year t
$w_{t}$ - mean weight of individuals in the population in year t

Parameters Derived From Leading Parameters
$\rho=0.836$
$\alpha=1.41$
$w_{r}=a\left(L_{\infty}\left(1-e^{-k\left(r-t_{0}\right)}\right)\right)^{b}$
$S=e^{-M}$
$\bar{w}=\frac{\left(S \alpha+w_{r}(1-S)\right)}{1-\rho S}$
$N_{0}=\frac{B_{0}}{\bar{w}}$
$R_{0}=N_{0}(1-S)$
$s_{0}=\frac{\delta R_{0}}{B_{0}}$
$\beta=\frac{-\ln (1 / \delta)}{B_{0}}$

## Model Equations

$F_{t}=q E_{t}$
$N_{t}=N_{t-1} e^{(-M-F)}+R_{t-r}$
$B_{t}=\left(\alpha N_{t-1}+\rho B_{t-1}\right) e^{(-M-F)}+w_{r} R_{t-2}$
$\hat{w}_{t}=\frac{B_{t}}{N_{t}}$
$R_{t}=s_{0} B_{t} e^{\left(-\beta B_{t}\right)} e^{\left(\tau P_{t}\right)} e^{\left(\phi_{t}\right)}$
$\hat{C}_{t}=\frac{B_{t}\left(1-e^{(-M-F)}\right) F}{M+F}$
slope of the Ford-Walford plot, age 2-20
intercept of Ford-Walford plot, age 2-20
weight at the age of recruitment
natural survival rate
average body weight in the unfished population
unfished equilibrium population numbers
unfished equilibrium recruitment
maximum recruitment survival, slope at the origin of stock recruitment curve recruitment capacity
instantaneous fishing mortality in year $t$
population numbers in year $t$
population biomass in year $t$
predicted mean weight of individuals in the population in year t
recruitment in year t
predicted catch in year $t$

Objective Function: minimize

$$
n \ln \sigma_{\phi}+\frac{1}{2 \sigma_{\phi}^{2}} \sum\left(\phi^{2}\right)+n \ln \sigma_{C}+\frac{1}{2 \sigma_{C}^{2}} \sum\left(\ln C_{t}-\ln \hat{C}_{t}\right)^{2}+n \ln \sigma_{w}+\frac{1}{2 \sigma_{w}^{2}} \sum\left(\ln w_{t}-\ln \hat{w}_{t}\right)^{2}
$$

The residual standard deviations for weighting the three components of the objective function were arbitrarily set to $\sigma_{\phi}=0.4, \sigma_{w}=0.2$, and $\sigma_{C}=0.2$ for the recruitment anomalies, mean weights, and catch respectively. It was reasoned that the recruitment process error should have the highest variability of the three. The variation in mean weight at age may reflect, to a large extent, observations error while the variation around predicted catch would reflect mainly process error in catchability.

## Equilibrium Predictions

$S_{e}=e^{-M-F}$
$w_{e}=\frac{S_{e} \alpha+w_{r}\left(1-S_{e}\right)}{1-\rho S_{e}}$
$B_{e}=-\ln \left(\frac{\left(w_{e}-S_{e} \alpha-S_{e} \rho w_{e}\right)}{w_{r} s_{0} w_{e}}\right) / \beta$
$N_{e}=\frac{B_{e}}{w_{e}}$
$Y_{e}=\frac{B_{e}\left(1-e^{(-M-F)}\right) F}{M+F}$
survival rate with fishing average weight
population biomass
population numbers
yield

The model parameters were estimated using the Solver Add-in in Microsoft Excel '97.

### 2.5 Report card

Information from various sources for each stock are summarized in a Report Card similar to that discussed in Richards and Schnute (2000). The report card is presented as a summary of information and interpretation and is not meant to replace yield forecasts and prognoses derived from the assessment model. The indicators are separated into primary and secondary ratings. Among the primary ratings are indicators of biomass, recruitment, recruits per spawner, mortality, fishery, production, and industry input. These indicators may be interpreted directly in terms of stock status. Among the secondary indicators are size structure, maturity, growth, spatial distribution, predators, prey abundance, and oceanography. The interpretation of these indicators may be ambiguous or there may be so little information available that no interpretation is possible. For example, if the size composition is dominated by small fish, this could mean either good recruitment or a lack of large fish. Such indicators need to be interpreted in relation with others. The knowledge status of each indicator is evaluated with respect to the amount of data available, it's reliability, and relevance. The individual observations are described, interpreted, and comments on uncertainties are included where appropriate. Then, each indicator is ranked in 4 categories in terms of stock status, danger (among the lowest observed), low (below target but above danger), neutral (close to target or ambiguous), healthy (above target or beneficial to stock production).

## 3. Area 3CD, West Coast Vancouver Island

### 3.1 Description of the Fishery

Pacific cod are taken as part of the mixed-species groundfish trawl fishery off the west coast of Vancouver Island. Pacific cod ranked among the top 4 species in volume landed from the 3CD management areas in each decade from the 1950s to the 1990s. However, this ranking dropped to $17^{\text {th }}$ in 2000-2001. Detailed interview and logbook data describing fishing locations and catch composition of Canadian vessels participating in this fishery are available since 1954. The trawl fishery was initially concentrated in the $0-199 \mathrm{~m}(0-109 \mathrm{fm})$ depth zone where almost all of the fishing effort was exerted until the early 1980s (Fig. 3). Total fishing effort varied between a low of 2300 hr in 1958 and a high of 8300 hr in 1972. The fishery expanded into the 200-699 m (109-384 fm ) depth zone in the mid to late 1980s. The precise timing of this transition is unclear because a large amount of fishing effort was reported from unknown depths during this period. This uncertainty was reduced in 1992 when the proportion of total effort reported from unknown depths was greatly reduced. Fishing effort in 3CD was split almost equally between the 0-199 m and 200-699 m depth zones in 1992. Total fishing effort increased by a factor of 4 between 1987 and 1992 when it reached an all time high of $22,500 \mathrm{hr}$ in the area. Fishing effort expanded into the $>=700 \mathrm{~m}(>=384 \mathrm{fm})$ depth zone in the mid-1990s. This was accompanied by a decline in effort in the 2 shallow depth intervals.

Most of the Pacific cod landings come from the 0-199 m depth zone. Between 19541995 , over $95 \%$ of the reported landings that could be attributed to a depth zone were reported from 0-199 m. This declined to roughly $85 \%$ between 1996-1999, but increased to over $90 \%$ in 2000 and the first half of 2001.

Canadian landings data for Pacific cod were obtained from the GFCatch (1954-1995) and PacHarvTrawl (1996-2001) databases. Total landings data, including USA and foreign catches prior to the extension of jurisdiction, were obtained from Haist and Fournier 1998 (Table 1). Canadian and total landings are compared in Fig. 4. The fishery became exclusively Canadian in 1979.

Total landings of Pacific cod were highly variable. The historic maximum occurred in 1972 at 5600 t . Other peaks occurred in 1966, 1989, and 1992. Landings declined considerably between 1993 and 1996, and have remained below previously reported lows ever since.

Annual TACs for Pacific cod were introduced in this area in 1994. These were managed on a calendar year basis until 1996. Beginning with the 1997-98 period, the fishing year was changed to April 1 to March 31. None of the TACs were attained (Table 2). Provisions exist in the Groundfish Trawl Management Plan to carryover up to $37.5 \%$ of the uncaught portion of individual vessel quotas (IVQ) to the following year. Since the TACs were never caught, this resulted in carryovers of $205 t$ and $200 t$ in the 2000/01 and 2001/02 fishing years respectively. In 1994, $56 \%$ of the TAC was taken, in 1995 $50 \%$ was taken. Since then, less than $20 \%$ of the annual TACs plus carryover were taken. A voluntary increase in mesh size was suggested for this fishery in 1991 and was then regulated in 1995.

The majority of landings have been made in the first half of the year. For several years, more than $50 \%$ of the annual landings came from the first quarter of the year, the spawning period, and from spawning grounds on Amphitrite Bank. Concern about the possible harmful effects of an intensive fishery during the spawning season led to the implementation of spawning closures of various duration in the first quarter of the year between 1978-1983 and 1985-1988 (Tyler and Foucher 1990). In general, landings from the spawning grounds during spawning were lower in years in which these closures were in effect. The closures were lifted in 1989 and the highest spawning season landings were recorded thereafter. Concern over the status of the stock and the potential effect of intensive fishing during spawning led to a reinstitution of the spawning closure in 1999.

The majority of landings off the west coast of Vancouver Island came from management area 3C. In general, over $80 \%$ of the annual landings were from 3C. This declined to around $70 \%$ in the late 1960s and again in the mid-1990s. Within area 3C, the landings came from the Swiftsure, Amphitrite, and Big Banks (Fig. 2).

### 3.2 Commercial Catch per Unit Effort

The commercial catch per unit effort index was calculated in a manner similar to previous assessments. Only data from April-December were included in the index. Most previous assessments have restricted the catch per unit effort data to these months to avoid potential bias caused by the numerous spawning closures in the area (Stocker et al. 1995). As has been the practice in all previous assessments, data from 3C only were included in the index. The index was also restricted to fishing events from the $0-199 \mathrm{~m}$ depth zone. This was because of the large increase in fishing effort in deeper depth zones where Pacific cod have not been found in any abundance in previous years. The index was calculated as an effort weighted mean of all observations, i.e. the sum of catch divided by the sum of effort. The new catch per unit effort series was highly correlated with the previous series presented by Haist and Fournier (1995) ( $\mathrm{r}=0.90$ ).

The catch per unit effort series had several peak periods, in the mid-1960s, the early 1970s, the late 1970s, and the late 1980s (Fig. 5). The series declined in the early 1990s and reached an historic low in 1998. Since then, there has been an increase to 2001. The most recent value is less than half the long-term average.

### 3.3 Swept Area Biomass Index

A "swept area" biomass index was calculated from the set-by-set commercial data available since 1994. Data from area 3C between April-December were used. No attempt was made to correct for the width of the trawl or the catchability of the gear. Therefore, this is an index of biomass rather than an absolute estimate. The biomass index showed a very similar trend to the catch per unit effort index, declining from 1994 to 1998 and increased thereafter (Fig. 5). There was a decline of approximately $25 \%$ of the stock area between 1994 and 2000.

### 3.4 Commercial Catch Size Composition

Sampling levels for the stock have varied considerably over the years (Table 3). An average of close to 5000 fish were measured annually between 1956 and 1979. This declined to less than 1000 measurements annually between 1980 and 2000. Sampling was particularly low when there was an average of 300 fish measured per year and there was no sampling in 1997. Sampling increased considerably in the second quarter of 2001 when over 2000 fish were measured.

The size composition of commercial landings from recent years were examined for evidence of improved recruitment. In earlier years, when a large year-class appeared in the population, it was possible to follow a strong mode in the length frequency distribution for a number of years. An example is for the period 1988-1990 when the large 1985 year-class recruited to the population (Fig. 6). The mode in the distributions moved from 55 cm range in 1988 to 71 cm in 1990. The length frequencies for 19992001 are presented for comparison. In these length frequencies, the modes were 47 cm in 1999, 69 cm in 2000, and 47 cm in 2001. This qualitative comparison of length frequency data does not indicate that there has been a significant recruitment event in this stock during the period 1998-2000. However, the low sampling levels in 1999 and 2000 may mean that the size compositions were not well estimated making the detection of a change difficult.

Trend in mean weight of fish in the catch was quite variable and this may also reflect the low sampling levels (Fig. 7). The mean weights in 1994,1996, 1998, 1999, and 2001 were among the lowest observed since 1956.

### 3.5 Shrimp Survey Index

The cod biomass index from the shrimp surveys off the west coast of Vancouver Island indicate a general agreement with the commercial catch per unit effort index (Fig. 8). A combined index was made by summing the indices for areas 124 and 125 in the years in which both were surveyed. The shrimp survey combined index increased sharply in the late 1980s, declined rapidly in the early 1990s, then had moderate increases in the late 1990s until 2001. This trend was similar to that in the commercial catch per unit effort series. There was poorer agreement between the shrimp survey and commercial index in the early years of the survey (1973-1980). Area 123 was only surveyed since 1996. It also indicated an increase in biomass in the most recent years.

### 3.6 Analysis

### 3.6.1 Delay Difference Production Analysis

Input observations and model predictions for the production analysis are given in Table 4 and key parameter estimates are given in Table 5. The catch time series had a high dynamic range and the model fit to the time series was reasonable (Fig. 9). The catch residuals had a relatively low serial correlation ( $\mathrm{r}=0.33$, lag $=1$ ). There was lower dynamic range in the mean weight time series and the model fit to this series was weaker than to the catch time series. The main contribution of the mean weight data to the model was to improve the estimate of the natural mortality rate. The recruitment anomalies had
high serial correlation ( $\mathrm{r}=0.73, \mathrm{lag}=1$ ) as is often seen for recruitment time series. Of note are the series of negative anomalies in 1991-1994.

The initial predicted stock biomass was $12,773 \mathrm{t}$. There were 3 main peaks in biomass, in 1965 ( $17,000 \mathrm{t}$ ), 1972 ( $25,000 \mathrm{t}$ ) and 1989 ( $12,000 \mathrm{t}$ ) (Fig. 10). Biomass declined following the third peak and reached an historical minimum of 2, 123 t 1996. The predicted biomass increased somewhat thereafter, reaching 4,511 t in 2001, but this remains below previous minima in the 1980s and 1960s. The peaks in biomass were all preceded by peaks in recruitment. Predicted F varied between 0.1-0.4 from 1956-1990 then increased sharply to between 0.7-0.9 from 1991-1995. This period of high fishing mortality corresponded with a series of low recruitment anomalies. In combination, this resulted in very low stock biomass and recruitment in recent years.

A retrospective analysis of model estimates was done to investigate the influence of the most recent catch per unit effort data on the solution. The model was calibrated using data up to and including 1995. Stock biomass was predicted forward to 2001 using the observed catches. Two projections were done. One set the recruitment anomalies to 0 . The second used the recruitment anomalies estimated in the analysis that included all years. The key parameter estimates are given in Table 5. There was little difference in parameter estimates. The main difference was that the initial biomass, natural mortality, and productivity ( $s_{0}$ ) were higher in the retrospective analysis. There was a greater increase in biomass in the most recent years in the retrospective analysis than in the analysis using the entire catch per unit effort time series (Fig. 11). There was little difference between the biomass projections with and without recruitment anomalies. Thus, the higher projected biomass from the retrospective analysis was likely the result of a higher productivity estimate.

The results of the production analysis were compared with those from the last analytical assessment of this stock (Haist and Fournier 1995) (Fig. 11). The trends in biomass were highly correlated $(\mathrm{r}=0.93)$ and the estimates were of similar scale.

An advantage of the production model assessment is that biological reference points such as stock biomass associated with maximum sustainable yield ( $B_{m s y}$ ), the fishing mortality associated with maximum sustainable yield ( $F_{m s y}$ ), and the unsustainable fishing mortality ( $F_{\text {crash }}$ ) are outputs of the model. Sinclair (2000) discussed a management framework that included various zones of stock biomass and fishing mortality. A target zone was where stock biomass was above $B_{m s y}$ and fishing mortality below $F_{m s y}$. Overfishing would occur if fishing mortality exceeded $F_{m s y}$. The stock would be overfished if biomass was below $B_{m s y}$. It would be undesirable and potentially dangerous to the stock if biomass was less than $0.5 B_{m s y}$ or fishing mortality was above $F_{\text {crash }}$. This approach is similar to a framework for implementing the precautionary approach to fisheries management proposed in Richards and Schnute (2000).

Where has the stock been relative to these biological references points? The model predictions indicate that for much of the time series (1956-1990) the fishing mortality
was above $F_{m s y}$ and the biomass above $0.5 B_{m s y}$ (Fig. 12). In 8 years the biomass was above $B_{m s y}$. Fluctuations in biomass during this period were largely due to variation in the recruitment anomaly. Fishing mortality increased considerably in 1991 to values not seen before and the stock biomass declined sharply. There has been little increase in biomass in recent years despite a large reduction in fishing mortality. The point estimate of biomass in 2000 is approximately $25 \%$ of $B_{m s y}$.

### 3.6.2 Report Card

Information from the various sources presented above are summarized and interpreted in a Report Card format in Table 6. Indicators of biomass were in the danger and low categories. Recruitment has also been in the danger category for several years. While recent recruitment anomalies have been average, spawning biomass is very low leaving little production for stock recovery. Fishing mortality and fishing effort on the stock have been reduced in recent years and this should aid stock recovery. Cod are taken largely as by-catch in other fisheries. There have been some reports of increased abundance in 2001, however there have been no requests for increases in TAC to allow higher catches in other fisheries.

There are few data available on secondary indicators. The size composition of commercial catches have not indicated a large mode passing through the population. This may be due in part to a low level of sampling in recent years. There has been a small reduction in fishing area in recent years, but some fishermen have indicated that Pacific cod are being found over a larger area then in past years. Information is lacking on changes in growth, maturity and condition.

### 3.6.3 Current Status and Prognosis

The results of deterministic catch projections are summarised in Fig. 13. A range of 2002 catches of $0-900 t$ was used. The catch in 2001 was assumed to be 200 t . This was considered reasonable given the reported catch to date (Table 2). Three criteria were investigated. The first was the change in biomass between the beginning and end of 2002. With no catch in 2002 , stock biomass is predicted to increase by $18 \%$. A catch of approximately 180 t would allow a $10 \%$ increase in biomass while a catch of 390 t would result in no change in biomass. A catch of $600 t$ would result in a $10 \%$ decline in biomass and a catch of $900 t$ would cause a $25 \%$ decline in biomass. The second criterion was to compare the 2002 fishing mortality to $F_{m s y}$. A catch of 250 t would result in $F_{m s y}$ while a catch of 480 t would generate a fishing mortality approximately $2.0 F_{m s y}$. The third criterion was how close the surviving biomass would be to $B_{m s y}$.
With no catch in 2002, the surviving biomass would be approximately $25 \%$ of $B_{m s y}$ and a catch of 900 t would leave a biomass of $14 \% B_{m s y}$.

Current stock biomass is well below the $B_{m s y}$ target and recruitment is low. The current TAC plus carry over is 894 t . Catches in this range in 2002 would result in a decline in stock biomass and further compromise stock rebuilding. The TAC for this
stock has never been caught. If catches continue to be similar to those in recent years, i.e. less than 200 t , there may be improvement in stock biomass.

### 3.6.4 Uncertainties

The analytical portion of the assessment is based largely on the commercial catch per unit effort time series. There may be several problems with such indices given recent changes in fishing strategies and management practices. However, the trend in Pacific cod biomass indicated by the fishery independent shrimp survey on the west coast of Vancouver Island supports the commercial index. This increases our confidence in the overall assessment results.

The production analysis presented here could benefit from further investigation. Time constraints precluded investigation of the statistical properties of the various estimates. This additional work could be undertaken in the near future. Of particular interest would be the robustness of the biological reference point estimates. Of all the model outputs, these may be the most uncertain. Various trial runs indicated the trends in biomass and fishing mortality were fairly robust, but the biological reference points, which depend largely on estimates of M and $s_{0}$, were quite variable. Thus, one should use these with caution.

## 4. Area 5CD, Hecate Strait

### 4.1 Description of the Fishery

Annual landings of Pacific cod show considerable variability (Fig. 14). There were major peaks in landings in the mid-1960s ( 9519 t in 1966), the mid-1970s ( 5036 t in 1975), in 1987 ( 8870 t ) and 1991 ( 7655 t ). The minimum annual landing was recorded in $2000(504 \mathrm{t})$, and landings since 1994 have been among the lowest on record.

Annual total allowable catches (TACs) were introduced in the Hecate Strait area in 1992. These were managed on a calendar year basis until 1996. Beginning with the 1997-98 period, the fishing year was changed to April 1 to March 31. The original TAC was $3,400 \mathrm{t}$ and landings exceeded this figure by about $50 \%$ (Table 7). The TAC was increased to 5,100 t in 1993, and then reduced in steps to 1000 t in 1998/99. The low catch in relation to the TAC in 1999/00 led to a carryover of 283 t in 2000/01. With the exception of 1992, the landings have been below the TAC plus carryover with between $39 \%(2000)$ and $85 \%(1998 / 1999)$ being landed. The TAC was reduced to 200 t in 2001/02 due to very low stock biomass. No carryovers were allowed. So far in the current fishing year, $31 \%$ of the 200 t TAC has been landed (as of Oct. 15). A voluntary increase in mesh size was suggested for this fishery in 1991 and was then regulated in 1995.

The groundfish trawl fishery in area 5CD occurs from Dixon Entrance in the north, through Hecate Strait and into Moresby Gully in the south (Fig. 15). A large number of species are exploited and each is distributed widely throughout the area. Pacific cod ranked second in total catch during 1996-2001 in this multispecies groundfish fishery. Other species in the top 6 were arrowtooth flounder, rock sole, walleye pollock, English
sole, and Dover sole respectively. Cod density, measured by commercial catch per unit effort, is highest over the Two Peaks, Butterworth, White Rocks, Bonilla, and Horseshoe fishing grounds (Fig. 16).

A substantial quota reduction was implemented for Pacific cod in area 5CD in the fishing year 2001-2002, from 1283 t to 200 t . This reduction was made because of very low stock biomass estimated in the November 2000 stock assessment (Sinclair 2000). At that time, there was a substantial portion of the 2000-2001 fishing year TAC that was not caught. In order to avoid fishing this up during the remaining months of the fishing year, an agreement was reached between DFO and the groundfish trawl fleet to close all of the above mentioned fishing grounds, with the exception of the northern edge of Two Peaks, between February 6-April 30, 2001.

The low TAC in 2001-2002 had a noticeable effect on the distribution of fishing effort. During the second quarter of 2001, there was little fishing over the sections of the Butterworth, White Rock, Bonilla, and Horseshoe grounds which had given the highest cod catch per unit effort in previous years (Fig. 16). Reports from the industry indicate that the good cod fishing grounds had to be avoided to preserve cod quota for by-catch in other fisheries.

Given the large closure in Hecate Strait during the first quarter of 2001 and the shift in fishing away from cod grounds during the second quarter, it was decided not to use catch per unit effort or swept area biomass indices from these months in any further stock analysis.

Additional analyses of seasonal depth distributions of cod catches are given in Sinclair (2000).

### 4.2 Input Data

### 4.2.1 Commercial CPUE

Pacific cod are caught at depths less than 150 m . A commercial catch per unit effort index was calculated using all trawl data for the $0-150 \mathrm{~m}$ depth range. An annual index was calculated as the sum of catch divided by the sum of effort. This new series is very similar to that used last year (correlation between series 0.96 ). Three major peaks occurred in Pacific cod density (Fig. 17), in the mid-1960s, the mid-1970s, and the late 1980s. Catch per unit effort declined since the last peak and reached an historic low value in 2000.

### 4.2.2 Swept Area Biomass Index

An annual swept area biomass index was calculated for Hecate Strait in a similar manner as for the west coast of Vancouver Island. Data from all months of the year were used. However, the data from 2001 were not included for reasons described above. The swept area biomass index indicated a declining trend from 1994-2000. The 2000 value was the lowest in the series.

### 4.2.3 Size Composition

The size composition of commercial landings of Pacific cod were examined for evidence of improved recruitment. Sample size per quarter is summarized in Table 8. Quarterly length frequencies for 1999 - 2001 were compared to those from 1987, the last time a significant year-class appeared in the stock. The 1987 length compositions showed a large abundance of small fish, with a dominant mode in the high 40 and low 50 cm length classes (Fig. 18). The 1999, 2000, and 2001 length compositions were more broadly distributed. They were bi-modal in the latter periods of each year, indicating some recruitment. However, the lower mode was never dominant in the length composition. It should be noted that the commercial mesh size used in 1987 was smaller than in 1999-2001, and this would result in a shift in the commercial length compositions to larger lengths in recent years. But, it is doubtful that this change in mesh size would result in the suppression of a length frequency mode caused by the arrival of a large yearclass. This qualitative comparison of length frequency data indicates that there has not been a significant recruitment event in this stock during the period 1999-2001.

The mean weigh of fish in the catch varied between $2.0-2.5 \mathrm{~kg}$ from the mid-1950s until the late 1980s (Fig. 7). The mean weights then increased to approximately 3.0 kg in the 1990s.

### 4.2.4 Research Vessel Survey

Pacific cod catches in the 2001 groundfish biological survey were in general smaller than in previous years. An exceptionally large catch was made in the Horseshoe area (Fig. 19). The fishing captain spent 30 minutes scouting the area using the echo sounder searching for indications that cod were present before making the set. In a normal assemblage survey, the fishing captain does not scout an area looking for fish before setting. This one set dominated the total catch of the survey, making up $84 \%$ of the average (Fig. 20). The fish in this set were quite large, averaging 76 cm in length.

The size composition of the total survey catch showed a peak in the high 20 cm range, which were most likely 1 year old fish (Fig. 21). This peak was larger than in 1996 and 2000, comparable to that in 1991, and smaller than in other years. Consequently, the survey does not indicate that a large year-class is entering the population.

### 4.2.5 Sea Level at Prince Rupert

Winter (Jan.-Mar.) sea level data for Prince Rupert were supplied by W. Crawford, Institute of Oceans Science, DFO, Sidney, BC. The data are corrected for atmospheric pressure and general sea level rise. There were 3 high sea level years in the 1990s, 1992, 1993, and 1998 (Fig. 22). Sea level in 2000 was about average and the most recent value in 2001 was below average. The 5 -year running mean sea level was about 0.5 standard deviations below average during the early 1970s and late 1980s. The 5 -year running mean was about 0.5 standard deviations above average in the early 1980 s and most of the 1990s. The implications of these variations in sea level on stock production are discussed in the following section.

### 4.3 Analysis

### 4.3.1 Delay Difference Production Analysis

Two main effects were explored with the delay difference model, the effect of sea level on recruitment and the influence of the most recent biomass index data (1995-2000) on the solution. The first effect was explored by comparing model output with and without the sea level covariate. Input observations and model predictions for these 2 production analysis are given in Table 9 and key parameter estimates are given in Table 10 and 11.

The potential effect of sea level on recruitment and stock production was investigated by comparing model estimates with and without the sea level covariate. The objective function was $7 \%$ lower when sea level was included in the model than without (Table 12). The recruitment anomaly component was $25 \%$ lower, the catch residuals $22 \%$ lower, and the mean weight residuals $3 \%$ higher with the sea level effect than without. The model without sea level had higher $B_{0}$ and lower $\gamma$ estimates than the model with sea level, but the net result was similar initial biomass estimates of $6,780 \mathrm{t}$ and 6183 t respectively. The model without sea level produced a lower productivity estimate, i.e. $s_{0}$, had a higher $B_{m s y}$ and lower $F_{m s y}$ estimates than the model with sea level. The estimated recruitment anomalies were negative for most of the 1990s in both models and the mean weight residuals were positive for the same time period (Fig. 23). No attempt was made to adjust for changes in mesh size used in the trawl fishery that occurred during the early 1990s. This change may explain the anomaly and residual patterns. If so, it is possible that recent recruitment estimates are biased downward.

Predicted trends in biomass and fishing mortality were very similar between the 2 models (Fig. 24). The main difference was that the model with sea level produced more variable recruitment estimates. Another important difference were the reference point estimates, illustrated in Fig. 25. In particular, the $B_{m s y}$ reference point was lower in the model with sea level, and this essentially shifted the management goal posts while not affecting the estimated stock trajectory.

The effect of variation in sea level height on production of area 5CD Pacific cod was investigated by estimating equilibrium yield curves when sea level was +-0.5 standard deviation of the mean sea level. When sea level was 0.5 standard deviation above the mean, $B_{m s y}$ was estimated as $11,131 \mathrm{t}, F_{m s y}$ was estimated as 0.19 , and $F_{\text {crash }}$ was estimated as 0.48 (Fig. 26). When sea level was 0.5 standard deviation below the mean, $B_{m s y}$ was estimated as $14,911 \mathrm{t}, F_{m s y}$ was estimated as 0.32 , and $F_{c r a s h}$ was estimated as 0.94 . These results indicate that if sea level anomalies persist over several years, as has been observed (Fig. 22), it may be prudent to shift target fishing mortality and biomass accordingly.

A retrospective analysis of model estimates was done to investigate the influence of the most recent catch per unit effort data on the solution. The model with sea level was calibrated using data up to and including 1995. Stock biomass was forecast forward to 2001 using the observed catches and the sea level covariate. Two options were used for
the recruitment anomalies in the forecast period, either set to 0 or set to the values estimated in the full analysis .

The key parameter estimates are given in Table 12. The main difference in parameter estimates between the models was that the productivity was higher in the retrospective analysis. There was a substantial predicted increase in biomass in the most recent years in the retrospective analysis that had recruitment anomalies set to 0 (Fig. 27). About half of the increase was due to the higher productivity estimate and the other half to the difference in recruitment anomaly.

The results of the delay difference production analysis were compared with those from the length-based assessment of Haist and Fournier (1998) (Fig. 28). The trends in biomass tended to be higher in the delay difference models than in the multifan analysis. One major difference between the models was that a higher natural mortality ( $\mathrm{M}=0.6$ ) was used in the multifan analysis. The main features were similar among the different models. Each predicted peak biomasses in the mid-1960s, mid-1970s, and late 1980s. The main differences among models are in the most recent years. The retrospective analysis suggests the stock size increased considerably in the late 1990s. This trend is opposite to the catch per unit effort series, the research vessel surveys, and all reports received from the industry. The last assessment indicated an increasing trend from 19941998. However, it is likely that this trend would have changed if the same analysis was run with the most recent data. The 2 production models using all available data indicate that the stock size is at an all time low.

The previous assessment of this stock (Sinclair 2000) used a non-equilibrium surplus production analysis. The current model, which includes a stochastic stock-recruitment relationship, resulted in a greatly improved fit to basically the same data. The residual mean square error about the main tuning index was considerably lower in the current model ( 0.08 ) than in the former model (0.19). The serial correlation of these residuals was also lower in the current model ( 0.29 ) than in the former model ( 0.53 ). This improvement in fit justifies moving to the new model.

### 4.3.2 Report Card

Indicators of biomass were in the danger and low categories (Table 13).
Recruitment is at a low level but may be increasing. Fishing mortality and fishing effort on the stock were reduced in 2001 due to the reduced TAC, and this should aid stock recovery. Cod were taken entirely as by-catch in other fisheries in 2001. There have been some reports of increased recruitment in the third quarter of 2001, however there have been no requests for increases in TAC to allow higher catches in other fisheries.

There are few data available on secondary indicators. The size composition of commercial catches have not indicated a large mode passing through the population. This may be due in part to a low level of sampling in recent years. There has been a small reduction in fishing area in recent years, but some fishermen have indicated that Pacific cod are being found over a larger area then in past years. Information is lacking on changes in growth, maturity and condition. An environmental index which has been related to cod recruitment success, sea level at Prince Rupert, has become average to
favorable in the past 2 years following several years of unfavorable values. This may indicate improved recruitment conditions.

### 4.3.3 Current Status and Prognosis

The results of deterministic catch projections from the production models without and with sea level as a covariate are summarised in Fig. 29. A range of 2002 catches of 01500 t was used. The catch in 2001 was assumed to be 200 t . This was considered reasonable given the reported catch to date (Table 7). Three criteria were investigated. The first was the change in biomass between the beginning and end of 2002. With no catch in 2002, stock biomass is predicted to increase by between $30 \%$ and $40 \%$ in the 2 respective models. A catch of 1000 t and 1200 t would result in no change in biomass in the respective models. The second criterion was to compare the 2002 fishing mortality to $F_{m s y}$. Catches of 600 t and 750 t would result in $F_{m s y}$ in the 2 models. The third criterion was how close the surviving biomass would be to $B_{m s y}$. With no catch in 2002, the surviving biomass would be approximately $20 \%$ and $40 \%$ of $B_{m s y}$.

Current stock biomass and recruitment is well below target. If the current TAC of 200 t is maintained for 2002, the stock biomass may increase by between $25-35 \%$ and allow some stock rebuilding.

### 4.3.4 Uncertainties

This assessment depends to a large extent on the commercial catch per unit effort series as an index of stock size. It has been suggested on many occasions that recent changes in fishing strategies and management practices have introduced serious biases into the series possible making it an unreliable index of stock size. Indeed, it is clear that the fishery in the second quarter of 2001 was conducted in areas of low cod abundance. In anticipation of this trend continuing, it is very important to establish a fishery independent index of stock size in this area.

The Hecate Strait groundfish assemblage survey offers an alternative fishery independent index of stock size. However, it has proven to be a very imprecise index and of little use in following changes in stock size.

As was the case for the area 3CD stock, the possible the most serious weakness of the production analysis is in the estimation of biological reference points. There were the least robust to changes in model formulation. A second weakness is failure to account for changes in mesh size in the model and the effect this may have on recruitment estimates. These aspects warrant further investigation.

## 5. Acknowledgement

We would like to thank Jon Schnute for his suggestions on formulating the delaydifference production model.

## 8. Figures

Figure 1: Annual landings of Pacific cod off the BC coast.

Figure 2: Groundfish trawl catch per unit effort of Pacific cod off the west coast of Vancouver Island. Shaded rectangles are where cod were caught, shading is on a $\ln$ scale. The total fishing area is outlined. Depth contours are shown for 100,500 , and 1500 m . Selected groundfish management area boundaries are also shown.

Figure 3: Distribution of trawl fishing effort by depth zone off the west coast of Vancouver Island, 1954-2000.

Figure 4: Annual landings of Pacific cod off the west coast of Vancouver Island (Area 3CD), 1954-2000.

Figure 5: Catch per unit effort and swept area biomass indices of Pacific cod abundance off the west coast of Vancouver Island.

Figure 6: Size composition (proportions) of commercial catches of Pacific cod off the west coast of Vancouver Island. Samples were from the first quarter of 1988, 1989, and 1990 and the second quarter of 1999, 2000, and 2001.

Figure 7: Mean weights of individuals in the commercial catches of Pacific cod off the wesc coast of Vancouver Island (WCVI) and hecate Strait.

Figure 8: Indices of Pacific cod biomass obtained from shrimp surveys off the west coast of Vancouver Island. The survey areas $(123,124,125)$ are shown in Fig. 2.

Figure 9: Recruitment anomalies, mean weight residuals, and catch residuals from the delay difference production analysis of west coast Vancouver Island Pacific cod.

Figure 10: Predicted biomass, recruitment, and fishing mortality for west coast Vancouver Island Pacific cod.

Figure 11: Comparison of predicted biomass from 3 analyses of Pacific cod off the west coast of Vancouver Island. Biomass projections in the retrospective analysis were done with and without recruitment anomalies predicted in the analysis with all years' data.

Figure 12: Phase plot of predicted biomass and fishing mortlaity for west coast Vancouver Island Pacific cod. The vertical lines begin at $B_{m s y}$ and $0.5 B_{m s y}$ and terminate at $F_{\text {crash }}$. The horizontal line is at $F_{m s y}$ and terminates at $B_{0}$. The final 2 years $(2000,2001)$ are indicated by solid circles.

Figure 13: Summary of catch forecasts for west coast Vancouver Island Pacific cod. Three criteria are presented relative to the catch in 2002. The solid line with tick-marks gives the proportional change in stock biomass between 2002 and 2003. The dashed line indicates the proportion of $F_{m s y}$ that will result from the given catch. The solid line indicates the fraction of $B_{m s y}$ that will be present in 2003.

Figure 14: Landings of Pacific cod from the Hecate Strait stock, 1956-2000.

Figure 15: Major groundfish trawl fishing grounds in areas 5CD. The 100 m depth contour is shown.

Figure 16: Distribution of Pacific cod during quarter 2 of 1997-2000 (left panel) and 2001. The rectangles are shaded to represent catch per unit effort $\left(\ln t \cdot h r^{-1}\right)$.

Figure 17: Catch per unit effort and swept area biomass indices of Pacific cod abundance in Hecate Strait, area 5CD, 1954-2000.

Figure 18: Quarterly length frequencies (percent) for Pacific cod in area 5CD, 1987, 1999-2001.

Figure 19: Catches of Pacific cod during the Hecate Strait groundfish assemblage surveys, 1984-2000 and a biological sampling survey in 2001. The symbols represent catch rates $\left(\mathrm{t} \cdot \mathrm{hr}^{-1}\right)$. The $100 \mathrm{~m}, 500 \mathrm{~m}$, and 1500 m depth contours are shown.

Figure 20: Mean catch per unit effort (kg•hr-1) of Pacific cod in the Hecate Strait groundfish assemblage surveys (1984-2000) and the 2001 groundfish biological survey. The distributions of the means were determined by bootstrapping. The vertical lines give the $95 \%$ confidence limits. The data labeled 2001 include all sets in the survey. The data labeled 2001a exclude one exceptionally large set made in the Horseshoe area.

Figure 21: Length composition of Pacific cod in the groundfish assemblage surveys 1984-2000 and the 2001 groundfish biological survey. The graphs are scaled to numbers per hour fished and indicate both size coposition and relative abundance. Note that the scale of the 1989 panel is different that the others.

Figure 22: Average winter (Jan.-Mar,) sea level (cm) in Prince Rupert, adjusted for air pressure and sea level rise. The annual data are plotted as standard deviates from the overall mean of $1402 \mathrm{~cm}(\mathrm{st} . \mathrm{dev}=5.4 \mathrm{~cm})$. Data supplied by W. Crawford, Institute of Ocean Sciences, DFO, Sidney, BC.

Figure 23: Recruitment anomalies, mean weight residuals and catch residuals from delay difference production models of area 5CD Pacific cod. The right side give results fro a model with sea level as a covatiate.

Figure 24: Predicted biomass, recruitment, and fishing mortality from delay difference production models of area 5CD (Hecate Strait) Pacific cod. The panels on the right are from a model that includes sea level height as a covariate.

Figure 25: Trajectories of biomass and fishing mortality for area 5CD Pacific cod, estimated with delay difference models without (upper) and with (lower) sea level as a covariate. The vertical lines begin at $B_{m s y}$ and $0.5 B_{m s y}$ and terminate at $F_{\text {crash }}$. The horizontal line is at $F_{m s y}$ and terminates at $B_{0}$. The final 2 years $(2000,2001)$ are indicated by solid circles.

Figure 26: Predicted effects of variation in sea level height on production of area 5CD Pacific cod. Equilibrium yield curves are presented for +-0.5 standard deviation of sea level height.

Figure 27: Comparison of biomass predictions for area 5CD Pacific cod made using all years data and a retrospective analysis using data up to 1995. The stock biomass was projected forward from 1995 in the retrospective analysis in 2 ways, one with no recruitment anomalies and the second using the estimated recruitment anomalies from the full analysis.

Figure 28: Comparison of biomass estimates for Pacific cod in area 5CD from 4 different models. These are delay difference production models using all years and no sea level, all years and sealevel, calibrated to 1995 and sea level, and a multifan catch at length analysis presented by Haist and Fournier 1998.

Figure 29: Summary of catch forecasts for area 5CD (Hecate Strait) Pacific cod from delay difference productions models without (upper) and with (Lower) sea level as a covariate. Three criteria are presented relative to the catch in 2002. The solid line with tick-marks gives the proportional change in stock biomass between 2002 and 2003. The dashed line indicates the proportion of $F_{m s y}$ that will result from the given catch. The solid line indicates the fraction of $B_{m s y}$ that will be present in 2003.

## 9. Appendix I: Request for Working Paper

Date Submitted: June 26, 2001

Individual or group requesting advice: Groundfish Management Unit
Proposed PSARC Presentation Date: November 2001

## Subject of Paper (title if developed):

Hecate Strait and WCVI Pacific Cod Assessment and Recommended
Yield Options or 2002
Stock Assessment Lead Author: Alan Sinclair

## Fisheries Management Author/Reviewer: <br> B. Ackerman

## Rational for request:

A stock assessment was conducted in 2000 for Hecate Strait Pacific Cod that indicated a conservation concern for this stock. As a result, significant changes have been implemented in the 2000 management plan; including, spawning closures and quota reductions.

PSARC recommended that improvements to the stock assessment model, incorporating more of the stock dynamic of Pacific cod, be added to the 2001 Assessment.

No advice has been provided for WCVI stock and, in light of the conservation concerns for Hecate Strait, an assessment of WCVI stocks is warranted.

## Question(s) to be addressed in the Working Paper:

1. What is the current biomass and stock size structure of Pacific Cod Hecate Strait and WCVI Pacific cod and how does this relate to historical stock conditions.
2. What is the expected trajectory of the HSS and WCVI Pacific cod to the end of 2002/2003 fishing season and how will this be affected by a range of annual TAC's.
3. What range of TAC's in Hecate Strait that would be consistent with PSARC direction for stock conservation and rebuilding.
4. What is an appropriate design for a monitoring program for Hecate Strait Pacific Cod given the reduced commercial fishing activity and the need to track stock status.
5. What were the impacts of the spawning closures for Hecate Strait in 2000 on catch compared to previous years.
6. Given conservation concerns in 2001, carryforward/overage provisions were revoked for the 2001 fishing plan. Is carryforward/overage provisions appropriate for Pacific Cod and how would this affect yield advice for 2002?

Objective of Working Paper: (StAD staff to develop further jointly with management)
6. To review surveys, biological, sampling, catch records, logbooks, observer reports, and fishing practices for Pacific Cod to provide a basis for management for the 2002/2003 fishery in Hecate Strait and WCVI.
7. To provide an assessment of Hecate Strait and WCVI pacific cod stock status.
8. To provide stock projections based on various yield options.
9. To recommend appropriate yield options.
10. To recommend a stock monitoring program for Hecate Stratic pacific cod.

StAD staff may want to take above questions and develop more explicit objectives these are a mix of general and specific objectives.
