Preliminary Report on Maturity Spawning Season and Larvae Identification of Rockfishes (Scorpaenidae) Collected During 1970

by

W. R. Harling, M. S. Smith and N. A. Webb

Biological Station, Nanaimo, B.C.

April 1971

INTRODUCTION

During 1970, field studies continued on the maturation, spawning season and larvae identification of rockfish (Scorpaenidae) species. These studies began in 1967 (Westrheim et al., MS, 1967), and continued in 1968 (Westrheim et al., MS, 1968) and 1969 (Harling et al., MS, 1969).

The 1970 studies were directed primarily at the Southeast Alaska region for comparison with the data collected off southwest Vancouver Island during 1967-69 (Fig. 1). However, data were actually collected from five areas -- La Pérouse Bank (southwest Vancouver Island), Queen Charlotte Sound, Langara Island (northwest Queen Charlotte Islands), Southeast Alaska, and off Icy Bay, Alaska.

MATERIALS AND METHODS

Collection of samples

All samples were collected during G.B. REED groundfish cruise no. 70-1 (Harling et al., MS, 1970), 70-2 (Westrheim et al., MS, 1970) and 70-3 (Harling et al., MS, 1970) using standard otter trawls or experimental off-bottom trawls.

Processing of specimens

Procedures used for determining maturity and spawning season, and classifying pre-extrusion larvae were the same as those reported for 1967-69. One exception was the preservative for larvae. Larvae stored in 5% formalin shrivelled and turned opaque after prolonged storage. In 1970, larvae were successfully fixed and stored in a modified Davidson's "A" solution¹. While the new preservative maintained the larvae in better shape, an unforeseen problem arose. The preservative leached tannin from the vial corks, and the tannin stained the larvae so that melanophore patterns could not be distinguished. Fortunately, only a few samples were affected before the leaching was discovered, and corks were replaced with plastic caps.

Shrinkage tests were undertaken for *S. alutus* larvae stored in both formalin and Davidson's solutions (Table 1). Shrinkage ranged from 7 to 11% after 5-12 days in storage. The relatively low mean length (7.80 mm) for the control lot in formalin sample no. 2 was probably caused by the death of some of the larvae prior to measurement. Larvae were observed to visibly shrink immediately after death.

¹Counts of: 20 parts, 40% unbuffered formalin; 20 parts, glycerin; 30 parts, 95% ethanol; and 30 parts, NaCl solution (30%).

RESULTS

General

A total of 20,520 specimens, comprising 24 species, were examined for gonad development (Table 2). Size composition, by sex, for each species is shown in Appendix Table 1. (A further division is shown for those species which exhibited a significant variation in size composition by geographic area.)

A total of 60 larvae samples, comprising 11 species, were collected during GBR 70-1 and examined later in the laboratory to evaluate the worth of melanophore patterns in species identification.

Shipboard rearing experiments, initiated in 1968 (Westrheim et al., MS, 1968), were continued during GBR 70-1. A total of 139 time-series samples, from 10 species, were collected during this cruise. No larvae were encountered during GBR 70-2 or 70-3.

Maturity

Descriptions of the maturity stages of gonads are listed in Table 3. The numbers of specimens examined, by area, month, species, sex and gonad condition are listed in Appendix Table 2.

Table 4 gives the size interval, by sex, area and month, for each species in which 50% or more of the fish were mature. As in previous years, condition-9 males and condition-2 females have arbitrarily been deemed immature.

No species were examined in sufficient quantity in any one month or area to determine ovary condition by 20-fm depth interval. However, during cruise no. 70-3 an attempt was made to determine variations in the degree of testes development for mature *S. alutus* males with depth. Table 5 summarizes the results. In general, shallow water (<160 fm) specimens were developing more quickly than fish in intermediate (160 fm-200 fm) or deep (>200 fm) water. This variation in development may be related to water temperatures (temperatures decreased with depth during 70-3).

Spawning season

Table 6 lists the estimated spawning time, by area, of selected species collected during 1970. In general, the principal spawning time for each species was later in the year for fish taken in northern waters.

Larvae identification

Table 7 summarizes the pigment characters for each species collected by geographic area during 1970.

Figure 2 shows the melanophore patterns for three species (S. ciliatus, S. entomelas; S. variegatus) not described in earlier reports. In addition, two previously described species (S. ruberrimus and S. zacentrus) are shown to illustrate variations in melanophore patterns within species.

Variations of melanophore patterns often occurred within species collected during 1970 by geographic area, by time, and by sample collected at the same time within a single geographic area.

Variations of pigment patterns by geographic area in S. alutus specimens (Table 7) occurred in the dorsal pigment row (presence or absence of melanophores). Minor differences also occurred in the head and hypural region. A further difference, in the ventral pigment row, is noted between S. alutus specimens collected in 1970 off S.E. Alaska and those collected in 1968 off southwest Vancouver Island (Westheim et al., MS, 1968). Unlike the 1970 specimens, none of the 1968 S. alutus specimens had less than 16 melanophores in the ventral row.

Two other species (S. ruberrimus and S. zacentrus) collected from Queen Charlotte Sound in 1970 differed from specimens collected off southwest Vancouver Island in 1968. The 1970 S. ruberrimus specimens possess a greater number of (and more distinct) ventral melanophores (Fig. 1). Samples of S. zacentrus collected in 1968 are entirely different from S. zacentrus (A) shown in Fig. 1, but agree very well with S. zacentrus (B).

Table 8 shows the variation among samples, within species, captured in a single geographic area. Of the species examined, S. alutus displayed the greatest variation, primarily in the presence or absence of a dorsal pigment row. Not only were these S. alutus samples from the same area, they were captured in the same tow.

The two S. zacentrus diagrams in Fig. 1 also demonstrate differences in melanophore patterns from specimens captured in the same geographic area (Queen Charlotte Sound) at the same time (June 10-12). S. zacentrus (A) differs from S. zacentrus (B) in the following characters:

- 1) it possesses a dorsal pigment row
- 2) the ventral pigment row does not stop short of the anus by four myotomes
- 3) considerable pigment encircles the yolk sac
- 4) a large melanophore is situated midway between the dorsal and ventral rows
- 5) a greater amount of pigment is evident in the hypural region

Temporal changes in melanophore patterns within species, by geographic area, are shown in Table 9. S. aleutianus, S. entomelas, and S. zacentrus exhibited little or no change, but the remaining seven species displayed varying degrees of change. Most common character variation occurred in the head. Variations also occurred in the dorsal pigment row and hypural region.

Table 10 shows the temporal variation in pigment pattern for larvae sampled from three parent specimens of S. alutus and two of S. helvomaculatus captured in the same geographic area. Again, the variation with time, both within a single parent specimen and among parent specimens is evident.
