Monthly Changes in Stomach Contents  
of Demersal Fishes in  
Passamaquoddy Bay, N.B.

by A. V. Tyler

FISHERIES RESEARCH BOARD OF CANADA

TECHNICAL REPORT NO. 288

1971

**FISHERIES RESEARCH BOARD OF CANADA**

*Technical Reports*

FRB Technical Reports are research documents that are of sufficient importance to be preserved, but which for some reason are not appropriate for primary scientific publication. No restriction is placed on subject matter and the series should reflect the broad research interests of FRB.

These Reports can be cited in publications, but care should be taken to indicate their manuscript status. Some of the material in these Reports will eventually appear in the primary scientific literature.

Inquiries concerning any particular Report should be directed to the issuing FRB establishment which is indicated on the title page.

FISHERIES RESEARCH BOARD OF CANADA

TECHNICAL REPORT NO. 288

MONTHLY CHANGES IN STOMACH CONTENTS OF DEMERSAL FISHES  
IN PASSAMAQUODDY BAY, N.B.

BY A. V. TYLER

THIS IS THE FORTY-SIXTH FRB TECHNICAL REPORT FROM THE  
FISHERIES RESEARCH BOARD OF CANADA,  
BIOLOGICAL STATION, ST. ANDREWS, N. B.

MONTHLY CHANGES IN STOMACH CONTENTS OF DEMERSAL FISHES  
IN PASSAMAQUODDY BAY, N.B.

BY A. V. TYLER

SCOPE AND PROCEDURE

This report presents data on monthly transitions in total stomach content, percent of stomachs without food, and quantities of principal prey in the stomachs, for abundant, demersal fishes in Passamaquoddy Bay. Methods of collecting the fishes, and records of their relative abundance are published (Tyler 1971), as are stomach sampling procedures and comparisons of diet among the fishes (Tyler 1972).

To examine seasonal trends in quantity of food in fishes' stomachs, the mean grams of food per kilogram of fish was calculated as follows: the total wet weight (grams) of food in a fish's stomach was divided by the live weight of the fish (kilograms) derived from conversion of fish length to fish weight. Length-weight relationships for Passamaquoddy fish were given in Kohler et al. (1970). The grams per kilogram values were averaged for each sample and the standard error of the mean calculated. Values of zero (empty stomachs) were not included. Values for two times the standard error of the mean were plotted as 95% confidence intervals along with the means. Non-overlap of these intervals would indicate a significant difference at the 5% level. Some species were stratified by size because different sizes had different prey (Tyler 1972).

Mean monthly values of g food per fish were plotted also in case weight changes in the fish obscured trends in stomach content in the g food per kg fish calculation. Trends were found to be the same for both calculations. Plots of g food per fish were dropped in favor of g food per kg fish to put different species on an equitable basis.

Seasonal changes in quantities of principal prey species were initially calculated as mean kg prey per kg fish and then converted to kcal prey per kg fish. Principal prey were considered to be those food organisms that occurred in more than 10% of the stomachs in quantities of more than 1 g

per kg fish on at least one sampling date. The mean was based on only those fish with food. Also, the number of fish that ate each principal prey was expressed as a percentage of the number of fish with food in their stomachs. Data for a few species were graphed here that exemplify the contrast between those fishes that fed largely on nekton and those that fed on the less mobile epi-fauna and in-fauna.

An adiabatic, oxygen-bomb calorimeter with automatic water jacket temperature control (Parr Instruments Inc.) was used for determination of calorific values of prey samples (Table 1). Specimens for calorimetry work were netted or dredged from the bay and deep frozen (-20°C) in small, closed vials or bottles within a few hours of capture. Percent water composition and calorific value was determined within a few months of collection. Specimens were homogenized and then dried for 5 hours in a ventilated oven at 60°C. They were then dried to constant weight in a CaSO<sub>4</sub> desiccator. Calorific determinations were made with 0.5 to 1.0 g samples (dry weight). Appropriate corrections were made for the energy equivalent of the calorimeter, the length of fuse wire consumed, and acid formation. A sulfur correction was not made since this correction would have been less than 0.5% of the otherwise corrected calorific value.

Data were examined from haddock (*Melanogrammus aeglefinus*), cod (*Gadus morhua*), ocean pout (*Macrozoarces americanus*), winter flounder (*Pseudopleuronectes americanus*), thorny skate (*Raja radiata*), little skate (*Raja erinacea*), white hake (*Urophycis tenuis*), and plaice (*Hippoglossoides platessoides*). Data for other species (Tyler 1971) could not be considered in a date-by-date manner, because sample sizes from individual collecting trips were too small. A detailed data listing is given in the Appendix.

## RESULTS

### Total Stomach Content

#### Winter flounder

Flounder had progressively more food in their stomachs after the first spring feeding in April, when the water temperature was between 3 and 4°C (Fig. 1 and 2). The peak in quantity at the end of May was largely composed of quantities of *Nephtys incisa* and *Lumbrineris fragilis* (Fig. 3). Increasing bottom temperature during the summer was accompanied by a gradual decrease in stomach content, the lowest quantity being reached in November, when some individuals ceased feeding.

The water temperature at the November onset of winter fasting had dropped between 5 and 6°C from a peak of 10.1°C in September.

#### Haddock

The quantity of food in haddock stomachs gradually decreased from 12 g food/kg fish in May, when the fish first arrived in the bay (after being absent during the winter), to 2 g/kg the following March (Fig. 2). In April 1966, there was a statistically significant increase in the stomach contents and a greater increase from April to May. This increase was largely due to the presence of the polychaetes, *Praxillella praetermissa* and *Lumbrineris fragilis*, whereas the peak in the previous spring resulted from consumption of polychaetes, *Aphrodite hastana*, *Lumbrineris fragilis*, *Praxillella praetermissa*, and amphipod, *Leptocheirus pinguis* (Fig. 4 and 5).

During January and February, when stomach contents were lowest, there was an increased percentage of empty stomachs.

#### Cod

The quantity of food in cod stomachs increased during the spring and early summer to a peak of 27 g/kg, decreased during late summer and early fall, and levelled in the winter at about 7 g food/kg fish (Fig. 6). The peak in early August was due to quantities of *Meganyctiphanes norvegica* in the stomachs (Fig. 7). Variation in the quantity of food among individuals, as seen through the standard error, was greater in the summer than in the winter. The high degree of variation in the summer, when cod fed almost exclusively on *Meganyctiphanes norvegica*, may indicate that this prey species had a heterogeneous spacial distribution in the study area at this time, and so was not equally available to all cod.

#### American plaice

There are no seasonal trends evident for quantity of food in plaice stomachs (Fig. 6). The isolated peak at the beginning of August was due to feeding on *Meganyctiphanes norvegica* (Fig. 8). The peak at the end of May was due to feeding on 5 and 6 cm herring which move into the bay at this time. The rise in February was due to quantities of *Myctophum stenolepis*.

### Longhorn sculpin

Longhorn sculpin had more food in their stomachs during summer (40 g/kg maximum) than during the winter (14 g/kg maximum) (Fig. 9). The low in early September was due to a drop in quantity of *Meganyctiphanes*, *Hyas*, *Aphrodite*, and *Pandalus montagui* in the stomachs, while the recovery in September was due to an increase in quantity of these same species (Fig. 10). The peak, in May 1966, was due to quantities of small Atlantic herring (*Clupea harengus*).

### Thorny skate

Because thorny skate were not so common as other species, data from adjacent dates had to be combined to achieve samples of between 20 and 30 fish. This combination did not result in large standard errors, and so it is assumed that feeding trends present in the population were not obscured by lumping the data.

Thorny skate between 20 and 40 cm had greater quantities of food in their stomachs during the spring and summer of 1965 (mostly *Nephthys*, *Aphrodite*, and gammarid amphipod), than they did in the spring of 1966 (Fig. 11). The food items missing in the diet on this latter date were *Aphrodite* and gammarid amphipods, particularly *Leptocheirus pinguis*. There were more empty stomachs in the spring of 1966 than at any other time of the year.

Large thorny skate (greater than 40 cm) showed no statistically significant differences in grams per kilogram by date. They ate *Nephthys* and *Aphrodite* throughout the year, *Hyas* in winter, and many small herring in spring.

### Little skate

Little skate were present in the community during winter only. Individuals less than 45 cm showed no differences in quantity of food in the stomach, except for the last date on which they were abundant, when each of the eight fish sampled had empty stomachs (Fig. 12). Skate larger than 45 cm also had a large portion of empty stomachs just before they left the area. The mean quantities of food in the stomachs in December and January are not statistically different at the 5% level, but the mean for February is significantly higher than the mean for January. The increase was due to quantities of *Aphrodite*. Other principal prey were *Nephthys*, *Lumbrineris*, *Hyas*, *Pandalus*, *Meganyctiphanes* and *Lumpenus* (a blenny). The principal prey for smaller individuals were *Nephthys*, *Lumbrineris*, and *Unciula*.

### **White hake**

This species was present during the summer and fall. Statistically significant differences in mean gram food per kilogram fish are evident in white hake, 15 to 26 cm in total (standard) length (Fig. 13). Small white hake had more in their stomachs just before they left the study area than at any other time. As the mean quantity of food increased, the percentage of empty stomachs decreased. The large quantities of food present in December were composed chiefly of *Mysis stenolepis*. It would seem that the small hake did not leave due to lack of food. Other principal prey were *Meganyctiphanes*, *Mysis*, *Leptocheirus*, *Maera*, and *Unciola*.

Large white hake did not show significant differences in mean quantity of food in stomach by date. Principal prey were *Pandalus*, *Meganyctiphanes*, *Mysis*, *Crangon*, and *Lumpenus*.

### **Ocean pout**

A rapid increase in total stomach contents in the spring, after the fish increased their abundance in the study area (Tyler 1971), was followed by steady decline in amount of food present (Fig. 13). In November most of the ocean pout moved out of the area but those few that remained usually had empty stomachs. In May of 1966, the fish had twice as much food in their stomachs as they did in May of 1965. This increase was attributable to particularly large quantities of *Praxillella*. Other principal prey were *Musculus niger*, *Nuculana* sp., *Venericardia borealis*, *Arctica islandica*, *Yoldia sapotilla*, *Ophiura* sp., *Aphrodite*, and *Pandalus*.

Half of the fish ceased feeding when the temperature decreased from 10 to 9°C in October. By November, 90% of the fish had empty stomachs. During this period of 17 days, the temperature decreased from 8.9 to 5.9°C. Most of the ocean pout had left the area by December 14, when the temperature had dropped to 4.4°C.

The fish returned to the area in March at a temperature of 1.5°C but did not begin feeding (75% empty stomachs) until April when the temperature was 2.8°C.

### Seasonal Change of Prey

Predators of in-fauna generally ate the same species throughout the year, but fish feeding on nekton ate different species at different times of the year, probably in response to changing availability of the prey. Haddock was typical of

in-fauna feeders, which included winter flounder, ocean pout, and the skates. All of the haddock's principal prey were eaten in both winter and summer, though in winter, smaller portions of the feeding population had eaten each principal prey and reduced quantities were in the stomachs (Fig. 4 and 5). The same pattern was found for winter flounder (Fig. 3), except that flounders had no food in their stomachs during winter.

Young cod, on the other hand, fed chiefly on nekton. *Meganyctiphanes norvegica* were common in the stomachs in the summer but were largely replaced by *Mysis stenolepis* in winter (Fig. 7). Cod also fed heavily on 5-6 cm Atlantic herring (*Clupea harengus*) for a brief period in May. This is the time of year that the young herring move into Passamaquoddy Bay from open water.

Plaice and longhorn sculpin, like cod, feed principally on *Meganyctiphanes* in summer (Fig. 8 and 10). Young herring are important in the prey list in the early summer. Both fishes turn to *Mysis stenolepis* in winter. Larger portions of the plaice population feed on the polychaete, *Praxillella praetermissa*, in winter than in summer. Principal prey of the sculpin that were not included here (to retain clarity in the graph) were *Leptocheirus pinguis*, *Hyas araneus*, and *Aphrodite haastana*.

#### Change in Feeding Rate versus Quantity in Stomach

Change in quantity of food in the stomach must result from differences of the rate of ingestion and the rate of digestion. As long as both rates are equal, the quantity of food in the stomach will not change. A long-term increase in quantity of food in the stomach can only mean that the average ingestion rate for the period of time was relatively higher than the digestion rate, and similarly, a long-term decrease in quantity of food must mean that the average digestion rate was relatively higher than the ingestion rate.

Seasonal trends for haddock, cod, small thorny skate, ocean pout, and winter flounder were similar in that the quantity of food in the stomach increased during the spring and decreased during the summer and fall, after reaching a peak in early summer. In the spring, when these fishes increased the quantities of food in their stomachs, temperature rose, and so digestion rate should have increased. It is well known from laboratory studies that digestion rate accelerates with increasing temperature. If stomach contents and digestion rate increased, then ingestion rate must also have increased.

During the summer, while the water temperature was still rising, the quantity of food decreased in the stomachs of the above mentioned fish species. On the basis of the temperature change, digestion rate should have increased during this period and decreasing quantities of food in the stomach can be accounted for by either decreasing ingestion rates (food may have progressively become more scarce after the early summer peak in stomach contents), static ingestion rate, or ingestion rates which increased less rapidly than digestion rates increased. Information is thus lacking for any postulation of change of rate of feeding during the summer.

Quantity of food in the stomach decreased as temperature dropped in the autumn. If it is postulated that the temperature drop led to a decrease in digestion rate, then ingestion rate must have decreased more rapidly than digestion rate to produce the progressively smaller quantities of food in the stomach.

#### CONCLUSIONS

1. Most of the fish species examined had more food in their stomachs in summer than in winter (haddock, cod, small thorny skate, ocean pout, and winter flounder). Ocean pout and winter flounder fasted during the cold months.
2. Plaice, longhorn sculpin, and large thorny skate did not show seasonal trends in quantity of food in the stomach.
3. Presence of a seasonal trend is not related to whether a fish had different prey species in different seasons.
4. It is sometimes possible to deduce monthly transitions in relative feeding rate from transitions in quantity of food in the stomach.
