Assessment of cod in Division 4X in 2004

Évaluation de la morue de la division 4X en 2004

ABSTRACT

The TAC from 2000-2004 has been 6,000 t annually and landings dropped to the lowest recorded level in 2003 at 5,600 t. Despite the record low landings, survey biomass indices have not increased. Recruitment indices in both surveys have shown improvement for 1998-2001 year classes over other recent year classes. The 2002 year class, however, appears weak. Rebuilding was expected to be supported by the incoming 1998 and 1999 cohorts but their abundance declined more rapidly than expected and an increase in biomass did not materialize. Prospects for rebuilding are now dependent only on the incoming 2001 year class and it is unlikely that any sustained increase in biomass will be achieved at a TAC of 6,000 t.

RÉSUMÉ

Au cours des années 2000 à 2004, le total autorisé des captures (TAC) de morue de 4X a été fixé à 6 000 t par année, et les débarquements ont chuté pour atteindre la valeur record de 5 600 t en 2003. Malgré les faibles débarquements records, les relevés révèlent que les indices de biomasse n'ont pas augmenté. Les indices de recrutement fondés sur les résultats des deux relevés montrent une amélioration chez les classes d'âge de 1998 à 2001 par rapport à d'autres classes d'âge récentes. La classe d'âge de 2002 semble cependant faible. Le rétablissement des stocks devait être appuyé par les cohortes de 1998 et de 1999, mais l'abondance de celles ci a diminué plus rapidement que prévu et la biomasse n'a pas augmenté. Les perspectives de rétablissement dépendent maintenant uniquement de la classe d'âge de 2001, et il est improbable qu'une hausse soutenue de la biomasse puisse se produire si le TAC demeure fixé à 6 000 t.

INTRODUCTION

Recent assessments of 4X cod have been problematic. The 1999 assessment presented two possible analyses as equally consistent with the data; one estimated a spawning stock biomass of 19,000 t, and the other a biomass of 30,000 t. The higher estimate included high biomass estimates at older ages, but also indicated that older fish did not contribute much to the fishery. The projected $F_{0.1}$ yields were 4,100 t and 5,600 t respectively. In 2000, a single VPA was accepted at RAP. This also had relatively high estimates of biomass at older ages, but indicated they would make very little contribution to the fishery. The $F_{0.1}$ projection for yield in 2002 was about 4,200 t from an estimated spawning stock biomass of 40,000 t.

In the 2002 assessment, this VPA formulation displayed a strong retrospective pattern. Analyses of survey data also showed high total mortality estimates, while comparisons of reported landings and survey catch gave low relative fishing mortality estimates. Since, unlike areas further east, the seal population was not thought to be high in 4X and fish condition showed no decline, it was concluded that increased natural mortality was unlikely to be responsible for this discrepancy. It was suggested that much of this discrepancy could have been caused by unreported landings and discarding in the fishery in 2000 and 2001. In 2003, no VPA formulation was accepted.

Differences in survey trends among regions in 4X were felt to be contributing to problems in the analysis, and further attempts at analytical assessment were forestalled, pending completion of tagging studies and conclusions on how to partition landings to appropriate biological stock components. This work is underway, and is expected to yield results by the spring of 2005. In the interim, survey and fishery data are examined to determine if population biomass has increased to an extent which could permit an increase in TAC, following 5 years at the low TAC of 6,000 t. Available information from landings data and observers are also examined to determine if there is evidence of discarding or misreporting in the fishery.

DISCRIPTION OF THE FISHERY

Landings of cod from NAFO Subdivision 4X (including the Canadian portion of 5Y; Fig. 1) increased through the 1960s as foreign and domestic otter trawler fleets became active in the fishery (Table 1; Fig. 2). Landings declined in 1970, primarily due to restrictions on haddock fishing. Landings peaked again in the early 1980s, due to increases in inshore catches. In 1981 handline landings exceeded 5,000 t, and landings in 4Xo exceeded 12,000 t (Table 2). Recent landings are, in part, a reflection of the TAC which declined from 26,000 t in 1992 to 6,000 t in 2000. The quota has been held at 6,000 t for 5 years as part of a rebuilding strategy for 4X cod. As of November 11th, 2004, 3,652 t of cod has been landed in the current quota year.

The fishery takes place year round, peaking in June and July (Table 3). Landings from the winter declined after 1992, with many fishing sectors treating cod as a by-catch as they pursued other species. Since 2000, the quota year has run from April 1st –March 31st. With this change in fishing year, and the increase in haddock quotas relative to cod, the winter haddock fishery has increased, and winter landings of cod have also increased.

In 2001 and 2002, the cod fishery was reported to have improved in most areas, aside from the coastal hook and line fisheries. The distribution of landings was similar to recent years, with a high proportion of landings in the Bay of Fundy (4Xqrs5Y), and Georges and Crowell basins (4Xp)(Fig. 3). This is a general pattern in the groundfish fishery and reflects shifts in the distribution of abundance for a number of species.

Most groups reported no difficulty in catching their quota despite the fact that many were directing their effort primarily for haddock. Fishermen maintained that cod quota was the most restrictive in the mixed species groundfish fishery, and that they needed to try and avoid cod to remain within their quota while pursuing haddock. This is reflected in annual quota reports, where a larger proportion of the cod quota was caught compared to other species in the fixed gear and small dragger fisheries (Table 4). Fishing in inshore areas of 4Xo, however, was poor for both cod and haddock, with fishermen having to travel further offshore. Landings of cod from 4Xo declined below 1,000 t for the first time in 2002 (Table 2).

In 2003 and in 2004, fishing was reported to have been poor in most coastal areas. Many fixed gear fishers delayed their activity in 2003, reportedly due to the prevalence of dogfish early in the summer and low water temperatures; they were then not able to land their full quota in the fall before switching to lobster fishing. In 2004 poor fishing for both cod and haddock inshore, coupled with low prices for groundfish and high bait costs, led many hook and line fishers to curtail their fishing activity. The number of vessels active in the fishery in 4X continued to decline, particularly for handline, which has all but disappeared (Table 5a), and reported fishing effort for groundfish has dropped in 2004 for hook and line vessels (Table 5b). Landings by the fixed gear fleet to November are lower than for the same period in 2003 and it appears unlikely that they will catch their quota (Table 4).

The small dragger fleet in 2004 appears likely to catch its cod quota, as the proportion caught by early November is higher than in 2003 (Table 4). Gillnet landings are also higher in 2004 than in 2003 (Table 1), as this fleet has not reported any difficulty catching cod.

There were numerous reports of cod being discarded or landed unreported in 2000 and 2001 to avoid exceeding the quota. This was thought to have decreased in 2002. There have been few reports from industry of discarding since 2002, and some have maintained that it was never a serious problem. Given the low proportion of the quota landed so far in 2004, it seems unlikely that discarding is an issue this year.

The majority of landings are subject to dockside monitoring. Monitored trips accounted for 85% of reported cod landings in 2003; thus, it seems unlikely that the potential for misreporting of landings in unmonitored trips could be resulting in a significant underestimate of landings in the fishery as a whole.

Discrepancies in species composition between trips carrying an observer and unobserved trips may be indicative of potential discarding or misreporting of landings. The level of observer coverage in 4X has generally been below 1% (Table 6), too low for any meaningful comparisons. Observer coverage increased in 2004, but much higher coverage,

stratified to account for heterogeneity in the fishery, would be required to make useful comparisons of observed and unobserved trips. Experience with the 5Z groundfish fishery, which is less heterogeneous, suggests that 10% observer coverage may not always be sufficient for detecting potential discarding.

Catch-at-Age

Fishery Samples

Catch-at-age was derived following standard protocols for this stock (Clark et al., 2002). Length frequency samples were aggregated to give catch at length by gear, area and quarter-year, while age-length keys were produced for area and quarter (Table 7a and b).

Landings

The size composition of the catch peaks at a somewhat lower length on the Shelf than in the Bay of Fundy, reflecting differences in growth between these areas (Fig.4). In both areas the peak is consistent with length at age 3, the 2000 year class.

In both 2001 and 2002 the 1998 year class dominated the landings of 4X cod, and the contributions from ages 7+ were very low (Table 8). In 2003, landings were dominated by the 1998 and 1999 year classes; the age range in the fishery showed some expansion, and was similar to the long term average age composition (Fig. 5). In 2004, landings have been dominated by the 2001 year class (Table 8). Ages 7+ were a small part of the fishery in the first half of 2004.

In the 2003 assessment, it was reported that weights-at-age from the commercial fishery appeared to have increased in recent years (Clark and Hinze, 2003; Table 9a). When samples from the deeper water of the Fundian Channel and Gulf of Maine in 4Xp are grouped with the Bay of Fundy, rather than with Browns Bank and the Scotian Shelf, this trend is less pronounced (Table 9b). The increase in landings from these areas, where faster growing cod are found, led to an apparent increase for Scotian Shelf cod.

ABUNDANCE INDICES

The annual DFO Research Vessel (RV) survey, employing a stratified random survey design with about 70 stations sampled annually, and the joint DFO/industry small dragger survey (ITQ), employing a fixed station design with 184 stations, are used for abundance indices for this resource (Clark et al., 2002). The DFO Research vessel survey has been conducted annually since 1970; however, due to uncertainties regarding the appropriate conversion factors to apply in relation to changes in vessel and net, only data after 1982 are used as indices (Clark et al., 2002).

Due to repair work which was ongoing to the CCGS Alfred Needler during the July survey period, the CCGS Teleost was used in its place. The Teleost used a Western IIa trawl which had some slight modifications to its foot gear. These changes in vessel and gear

may have some impact on catchability, although this is not expected to be large. The results for the 2004 survey may not, therefore, be directly comparable to those from other years. Comparative surveys are planned for 2005 following which conversion factors between the two vessels will be calculated.

There were few good catches of cod in the RV survey in 2004 (Fig. 6). The number of sets completed in the Bay of Fundy was lower than in recent years (21 in 2004 versus 37 in 2003 and 29 in 2002); however, sampling remained adequate, with at least 2 stations occupied in each stratum. As in 2003, few cod were caught in the southern and eastern parts of the Shelf in 4X.

The distribution of catches in the ITQ survey in 2003 differed from other years (Fig. 7). There were few good catches in the Bay of Fundy or on German Bank, where the biggest catches are usually made. There were many sets where catch for that location was at or below the five year median for the survey series in the Bay of Fundy (Fig. 8). Most sets where catches were above the median were located around Browns Bank and on the Scotian Shelf.

In the Bay of Fundy, the research vessel (RV) survey biomass index has been variable without any persistent trend since 1983 (Fig. 9). The index in 2002 and 2003 was above the 1983-2003 median but in 2004 was the second lowest. The 2004 index may not be directly comparable to previous years because the survey was conducted by the *Teleost* and conversion factors between it and the *Needler* are not available. The ITQ survey biomass index has shown little variation since 1996, except for the anomalously high value in 2001(Fig. 9). It also declined substantially to its lowest level in 2004.

On the Scotian Shelf, the RV survey biomass index shows a declining trend since 1996 and remained at the lowest level in 2003 and 2004(Fig. 10). The ITQ survey biomass index shows little interannual variability since 1996 and the 2004 biomass was above the median (Fig. 10).

ITQ survey catches-at-length were below the median for most commercial lengths in the Bay of Fundy, and above the median only from 16-28 cm (Fig. 11). The modal length at 55 cm was consistent with what was seen in the fishery, but the low numbers of fish over 65 cm differed from the commercial fishery. The length frequency from the Shelf was similar to the median for most lengths, and above the median from 40-55 cm. This is consistent with the commercial catches for the Shelf.

RV survey catches in 2003 were at or above the median at most lengths in the Bay of Fundy, but in 2004 catches were above the median only from 46-59 cm (Fig. 12). The paucity of fish outside this length range differs from both the ITQ survey and the commercial fishery. RV survey catches were below the median on the Shelf for most lengths. The absence of a mode for the Scotian Shelf size composition is not consistent with the size composition from the ITQ survey or the fishery, and is unlikely to be representative of the population.

Some of the difference in the survey catches is due to differences in catchability-at-length by the gear employed. The ITQ survey uses rock hopper foot gear which leaves little space for escape below the footrope, and has proportionately higher catches of cod less than 50 cm. The differences between the two surveys may also reflect the high variability in survey catches, as is seen in inter-annual variability in the longer RV series, or differences in the completeness of geographic coverage of the 4X area.

RV survey indices in 2004 are low for most ages, except for continued indication of above average abundance for the 2001 year class in the Bay of Fundy (Table 10, Fig. 13). The age range also remains constricted, with no cod caught above age 6 in the Bay of Fundy, or above age 8 on the Scotian Shelf.

ITQ survey catches-at-age in 2004 were high in the Bay of Fundy for age 1, at the median for the series for ages 3 and 6, and low for all other ages. On the Scotian Shelf, catches were among the highest in the series (1996-2004) for ages 3-6 (Table 11, Fig. 14). Indices of abundance from the ITQ survey have consistently indicated that the 1999-2001 year classes are stronger on the Scotian Shelf than any since the1994 year class. There has been little change in catches for ages 7+ in this survey since its inception, and catches in 2004 were near the median for these ages.

Recruitment indices (ages 1-3) in both surveys have shown improvement for 1998-2001 year classes over the previous five year classes; however, initial indications from both surveys are that the 2002 year class is weak for both the Bay of Fundy and the Scotian Shelf.

Lengths-at-age from the RV survey show some variability over time, particularly on the Scotian Shelf, but show no consistent trend across ages (Figure 15). Condition (Fulton's K) has been very stable in the Bay of Fundy (Fig.16). Cod from the Scotian Shelf have shown greater variability in condition. Condition dropped to a low in 1985, but has been fairly stable at average levels recently.

The proportion of RV survey sets where cod are caught (design weighted area occupied) in the Bay of Fundy has varied considerably without trend since 1983 (Fig. 17). On the Scotian Shelf, area occupied has varied considerably, but declined annually from 1999 to 2003 and remained near the lowest in the series in 2004.

For the ITQ survey, there has been a gradual decline in the proportion of sets where cod are caught and a sharp decline in the proportion of fixed stations where the catch in a year was above the median for that location for the Bay of Fundy (Fig. 18). Both the proportion of sets where cod were caught and the proportion > median are low for the Scotian Shelf, but the decline is less severe and it remains within the range seen in other years.

Total mortality (Z), as calculated from the RV survey has high inter-annual variability (Fig. 19). The absence of any apparent trend is not consistent with the reductions in nominal landings and fishing effort; however, the high Z's in recent years in the Bay of Fundy do not suggest there has been any decline in mortality levels in response to the low TAC in recent years.

SOURCES OF UNCERTAINTY

Cod in the 4X/5Y management area have been considered a stock complex comprised of a number of spawning components. Difficulty in separating landings has precluded analyses of discreet components. The similarities in past abundance trends for components had alleviated concerns about treatment as a single management unit. A divergence in population trends among these components would be inconsistent with model assumptions. Efforts to delineate components based on tagging and biological data are underway.

Reports of current and historical discarding and under-reporting indicate that these vary among years. Prior to the mid-1980s misreporting could also have included over-reporting of landings from other species or areas as 4X cod. This uncertainty can potentially be alleviated in future years with additional effort in monitoring, and by following the delineation of stock components. Inter-annual variability in natural mortality must also be considered. An increase in natural mortality would be consistent with the continued high total mortality despite reductions in TAC.

The lack of an analytical assessment compromises the ability to assess the status of the stock, and puts heavy reliance on the survey indices. The survey results are highly variable from year-to-year, and their interpretation is subject for concern. The *Teleost* was used for the RV survey in 2004. Also, bottom temperatures were 2-3^{o} C below average at the time of the summer survey. These lower temperatures delayed fishing activity in 2004.

OUTLOOK

Condition and length-at-age are both about average with little recent variation. This differs from cod further east, and indicates that growth rates are not a concern in 4X. Area occupied has declined in the surveys. The number of sets in which no cod are caught has increased, but there are not broad areas in which cod are consistently not caught. This would seem to reflect the overall low abundance rather than a range reduction.

The 2002 year class appears weak in both surveys. This will enter the fishery in the Bay of Fundy in 2005, and appears unlikely to make a major contribution to landings. Recruitment is strong for the 2001 year class. In 2004 this year class appears dominant in both surveys and the commercial fishery.

While the 2001 year class continues to look strong in both surveys, only the ITQ survey on the Shelf continues to indicate that abundance at older ages may be above even recent averages. Older ages were well represented in the fishery in 2003, but in the first half of 2004 their contribution was much reduced. The paucity of older fish in the fishery, along with the high Z's from the survey, indicates total mortality has remained high.

Survey biomass indices show that overall biomass has not increased since 1999 when the quota was reduced to 6,000 t to promote rebuilding, and may have declined; therefore, an increase in quota is not supported.

Rebuilding was expected to be supported by the incoming 1998 and 1999 year classes, but their abundance declined more rapidly than expected and an increase in biomass did not materialize. Prospects for rebuilding are now dependent only on the incoming 2001 year class. It is unlikely that any sustained increase in biomass will be achieved at a TAC of 6,000 t.

Acknowledgements

I would like to thank Kirsten Clark for her assistance in drafting some of the figures. Kirsten Clark, Heath Stone and Julie Porter all provided useful suggestions in reviewing earlier drafts of the document.
