#### Abstract

A tagging study was undertaken on the spawning grounds of Scots Bay and German Bank to examine the residency time of herring on the grounds during spawning season. Tagging was attempted on as close to a weekly basis as possible, although weather or a lack of fishing activity sometimes prevented this. A total of 8,580 tags were applied to herring from Scots Bay on four occasions and a total of 5,047 tags were applied to herring on German Bank on five occasions. The overall tag return rate for Scots Bay was $4.5 \%$, whereas the return rate from German Bank was only 0.6\%. Returns from both spawning grounds indicated that, although the majority of tag returns came from within the first three weeks after tagging, some fish remained on the spawning grounds for up to five to six weeks after tagging. The possibility that some herring remain on the spawning grounds for longer than the previously assumed 10 to 14 day interval has implications for the timing of the repeated acoustic surveys of the spawning grounds used in the 4VWX herring assessment in recent years.

## RÉSUMÉ

Une étude de marquage a été entreprise dans les frayères de la baie Scots et du banc German, en vue d'examiner le temps passé dans les frayères par le hareng pendant la période de ponte. On a tenté de procéder au marquage des poissons à toutes les semaines, dans la mesure du possible, mais le mauvais temps ou l'absence d'activité de pêche a parfois rendu la chose impossible. Au total, 8580 étiquettes ont été apposées à des harengs de la baie Scots à quatre reprises et 5 047, à des harengs du banc German, à cinq occasions. Le taux de récupération des étiquettes dans l'ensemble a été de $4,5 \%$ pour la baie Scots, mais de seulement 0,6 \% pour le banc German. À en juger par les retours de harengs des deux frayères, bien que la plupart des étiquettes aient été récupérées au cours des trois premières semaines suivant le marquage, certains poissons sont demeurés dans les frayères jusqu'à cinq ou six semaines après le marquage. La possibilité que certains harengs restent dans les frayères plus longtemps que les 10 à 14 jours présumés antérieurement a des répercussions sur le moment choisi pour les relevés acoustiques répétés dans les frayères qui ont servi à l'évaluation des harengs de $4 \mathrm{VW} X$ ces dernières années.

## 1. INTRODUCTION

The current assessment for herring, Clupea harengus, from the Southwest Nova/Bay of Fundy Spawning Component employs repeated acoustic surveys of the spawning grounds (Power et al., 2005). These surveys are required to be separated by at least 10 to 14 days in an attempt to prevent double counting (Power et al., 2002). Knowledge of the length of time that herring remain on the spawning grounds and whether or not they leave immediately after spawning is therefore of great importance to the survey method, particularly for the major spawning grounds of German Bank and Scots Bay.

## 2. BACKGROUND

The amount of time that herring spend on the spawning grounds and the factors that initiate migration and homing are not clearly defined (Haegele and Schweigert, 1985). Runnstrom (1941) stated that herring move onto the spawning grounds at night and spawn over several weeks, with the oldest fish spawning first. Waves of spawning have been reported in the past (Lambert, 1984, 1987, Hay 1985). Blaxter (1985) stated that it was common for spawning to occur over a period of a few weeks on a given spawning ground. This was supported by Bradford (1991) who found that, with individual populations, spawning is a continuous process throughout the spawning season, although within this there may be single or multiple waves. Spawning waves have been documented for Pacific Herring (Clupea pallasi). These spawning waves are separated by roughly 10 to 15 days and later spawners tend to be younger and smaller (Hay, 1985).

Prior to 1998, the calculation of the Spawning Stock Biomass (SSB) for Southwest Nova Scotia herring was based on a VPA tuned using a fall larval herring survey. (Stephenson et al.,1998). Between 1997 and 2004 the SSB calculation was based on the acoustic estimates from regular surveys conducted on the spawning grounds and in 2005 the acoustic estimates were used as an index to tune the VPA (Power et al., 2004, 2005). The time between acoustic surveys and the turnover rate of herring on the spawning grounds are therefore critical since surveys which are too close together may be counting the same fish.

An analysis of the existing data on turnover rates of herring on the German Bank Spawning grounds was made in 2002 (Clark et al., 2002; Appendix C in Power et al., 2002). This included an analysis of the length and maturity data from 1995 to 2001, previous tagging data, fat content and age information. Four recommendations were made:

1. Sampling of herring on the German Bank spawning ground should be continued at the same level of intensity as in 2001.
2. If tagging is to be used as a method of examining turnover rate, the application of tags at a specific interval (weekly) should be instigated on German Bank.
3. There should be increased acoustic effort to document the behaviour, number and size of schools of herring on the spawning grounds.
4. Herring spawning behaviour should be documented using underwater video equipment.

The first of these recommendations has been addressed. Intensive sampling for maturity stage has been conducted since the 2002 fishing season with the results summarized by Melvin et al. $(2003,2004)$ and Power et al. $(2005)$. These results were used to assist in the evaluation of turnover timing and inclusion or exclusion of specific acoustic surveys (Power et al., 2005) but did not give clear indications of a consistent turnover rate or the residency time of herring on the spawning grounds. The second of the recommendations is addressed by the tagging study reported in this document.

In March, 2005, concerns were again raised regarding turnover rate at the 4VWX Herring Regional Advisory Process (RAP) Meeting. It was noted that, if acoustic survey estimates were taken as absolute estimates of abundance, then there were inconsistencies between the summed survey estimates and the SSB as calculated by a virtual population analysis. The opinion was expressed that these variations necessitated exploration and that further work was required on turnover rate (Neilson, 2005). In order to address this concern, tagging was conducted in the summer and fall of 2005 on the spawning grounds of Scots Bay and German Bank.

As was reported in Paul (1999) and Power et al. (2002), tagging was conducted on spawning fish on German Bank in the past. In 1998 a total of 9,068 spawning herring were tagged and there were 28 within season tag returns from German Bank. Of those 28 returns, eight were caught more than ten days and six were caught more than fourteen days after tagging (Paul, 1999). In 2001 a total of 9,698 spawning herring were tagged on German Bank over a two day period. There were 47 tag returns from the spawning grounds, all within 8 days after tagging but the results were complicated by a large decrease in fishing effort in the second week after tag application.

## 3. METHODS

In July and August, 2005 the Herring Science Council (HSC), Fundy Weir Fishermen Association (FWFA) and the Maine Department of Marine Resources (DMR) conducted four tagging events in Scots Bay using purse seine vessels. In August and September DFO, HSC, FWFA and DMR conducted five tagging events using purse seine vessels on German Bank. The tagging procedure used was identical for all trips. The crew of the vessels loosely pursed the seine leaving the herring in the water. Herring were then transferred by dip net from the seine to a Xactics tank filled with running sea water. Herring were tagged between the fin rays at the base of the dorsal fin using individually numbered external Hallprint tbar tags bearing the dual Canada/U.S.A. address as follows:

The tags were identical to those used in the FWFA weir herring tagging project (fall 2002 to present) and the DMR herring tagging project (2003 to present). Herring were released back into the water as they were tagged and any fish that appeared unhealthy were not tagged.

A random length frequency sample of 100 to 200 herring was collected from each tagging set and a sub-sample was frozen for detailed laboratory analysis of age, sex and maturity.

Tags were returned to the St. Andrews Biological Station where the information was entered into a database and the data were analysed. Names of people who returned tags were entered into an annual draw for \$1,000, funded by industry.

As part of the ongoing weir herring tagging project, a protocol already existed in many processing plants to encourage individuals to return tags and posters were distributed to these plants. A press release about this project was also prepared and articles appeared in local newspapers such as the Sou`wester and The Saint Croix Courier.

## 4. RESULTS

### 4.1 Scots Bay

A total of 5,047 tags were applied in Scots Bay on four separate occasions (Table 1). The weekly landings for Scots Bay in relation to the tagging events are shown in Table 2 and Figure 1. There was fishing after all tagging trips, although the landings dropped considerably after the last tagging event and the fishery concluded on September 9, only two weeks after the final tagging trip (Figure 1).

The maturity data from samples collected during the tagging events on Scots Bay are shown in Figure 2. Samples collected on August 7, 15 and 24 contained primarily stage 6 (spawning) herring (between 64 and 77\%). The percentage of stage 6 herring was much lower ( $9 \%$ ) in the July 28 sample in which $64 \%$ were stage 7 (spent). The high percentage of stage 7 fish was unexpected since it has been proposed in the past that herring leave the spawning grounds immediately after spawning. The maturity data from all samples collected on Scots Bay over the course of the entire fishery are shown in Figure 3 and length frequencies are shown in Figure 4.

To date 228 tags have been returned (Table 3), a tag return rate of $4.5 \%$. To avoid a bias from fish recaptured immediately after tagging, the tag returns from the first 2 days after tagging were removed. When this was done the number of tag returns decreased to 151 , a tag return rate of $3 \%$. The majority of the returns that were caught within 2 days were from the tagging event on August 15 (57 tag returns).

In this project tags were applied at close to weekly intervals. The rationale behind this was that if fish tagged in the first week were not caught on the spawning ground more than seven days after the first tagging event, but fish tagged the following week were being caught, then there would be a stronger basis for concluding that the fish from week 1 had left the spawning ground. In Table 4 the raw tag return data are presented by week. The same data were adjusted by the landings (Table 5 and 6, Figure 5 and 6) to allow comparisons to be made between weeks.

A turnover rate of between 7 to 14 days has been suggested in the past based on anecdotal information from fishers and maturity information. Tag return data is presented in this context in Tables 7 and 8 and Figure 7. It should be noted that there was decreased fishing effort after the final tagging event. Also fishing ended 16 days after the final tagging event and thus, no tag returns are possible after this 16 day period.

During the data analysis, it was noted that there might be differences in tag return rate depending on where and how the fish were processed. The percentage of Scots Bay fish bought and of tag returns by buyer is shown in Figure 8. The major buyers of Scots Bay fish appear to be detecting and returning tags.

## Quantifying Turnover Rate in Scots Bay

There were sufficient tag returns from Scots Bay to compare the proportion of fish that remained on the spawning grounds over time. The tag returns from Scots Bay were adjusted by landings (Table 9) and then standardized in the following manner:
$\mathrm{n}=$ number of tag returns adjusted by the landings
$\mathrm{n}_{\mathrm{wi}}=$ the number returns from a given tagging event $w$, where $\mathrm{i}=1$ is the first week after tagging, $i=2$ is the second week etc
$\mathrm{n}_{\mathrm{w} 1}=$ the number of tag returns from the first week after tagging for tagging event $w$. This is assumed to be the number of tag returns you would get if all the fish are still present on the spawning grounds.
$\frac{N_{\mathrm{wi}}}{\mathrm{n}_{\mathrm{w} 1}}=\begin{aligned} & \text { the proportion of fish in week i from tagging event } w \text { still present on the } \\ & \text { spawning grounds (Table 10). }\end{aligned}$
$\frac{\mathrm{N}_{\mathrm{wi}}}{\mathrm{n}_{\mathrm{w} 1}} \quad \begin{aligned} & \text { This standardizes so that the proportions from different tagging dates } \\ & \text { can be compared and averaged (Table 11, Figures } 9 \text { and 10). }\end{aligned}$
$\frac{\mathrm{N}_{\mathrm{wi}}}{\mathrm{n}_{\mathrm{w} 1}}$
There was a large amount of variation in the proportion of tagged fish present in any given week; this is clearly demonstrated by the high standard errors. Also, as was noted above, there was decreased fishing effort after the August 24 tagging and fishing ended two weeks later so there was no information on long term tag
returns from this event or for tag returns more than 3 weeks after the August 15 tagging event.

## Tag Returns from Areas Other than Scots Bay

A total of 63 tag returns (42\%) came from areas other than Scots Bay (Table 4). Of these, 40 tags ( $26 \%$ ) came from the New Brunswick weirs, some within the first few days after tagging. Fish tagged in the Scots Bay weirs ranged from 22 to 31.5 cm in length and were predominantly in spawning or post-spawning condition (Figures 2 to 4). The length frequency and maturity information for the samples collected from the New Brunswick weirs shows that fish of the same size as those in Scots Bay were present in the weirs, as were spawning and post-spawning fish (Figures 11 and 12).

Small numbers of tag returns also came from other areas, including the Nova Scotia weirs, the Long Island Shore, Northeast Bank, Northwest Ledge and German Bank (Table 4 and 5, Figure 6).

### 4.2 German Bank

A total of 8,580 tags were applied to herring on the spawning grounds of German Bank on five separate occasions between August 30 and October 5, 2006 (Table 12). The weekly landings for German Bank in relation to the tagging events are shown in Table 13 and Figure 13. There were no tag returns from the September 21 tagging event but correspondingly, there were no landings from German Bank between September 24 and October 2. The lack of landings in this time period leaves a hole in the data. The German Bank fishery ended on October 13, only eight days after the last tag applications on October 4 (Figure 13).

The maturity data from samples collected during the tagging events on German Bank are shown in Figure 14. For all but the first tagging event, the samples contained predominantly spawning stage 6 herring (between $89 \%$ and $98 \%$ of the samples). In the sample taken on August 30, $88 \%$ of the herring are stage 5 (hard roe). The maturity and length data from all the samples collected from the German Bank fishery from August 30 onwards are shown in Figures 15 and 16. After August 30 samples contained mostly stage 6 fish and the length frequency mode was around 27 cm .

To date 56 tags have been returned (Table 14), a tag return rate of only $0.7 \%$. Most of these tag returns (42) came from the German Bank fishery. The tag returns from the first 2 days after tagging were removed to avoid a bias from fish recaptured immediately after tagging. This had little effect on the tag return data. The overall number of tag returns decreased to 52 ( 38 from German Bank), a tag return rate of $0.6 \%$.

As with the Scots Bay experiment, it was proposed that tags be applied at weekly intervals for this project. This was accomplished for the first four tagging events, but the lack of fishing between September 24 and October 2 precluded tagging
during that week. In Table 15 the raw tag return data are presented by week. The same data were adjusted by the landings (Table 16 and 17, Figure 17 and 18) to allow comparisons to be made between weeks.

Tag return data are presented in Tables 18 and 19 and Figure 19 in the context of the suggested turnover rate of between 7 to 14 days. The lack of fishing between September 24 and October 2 and the after October 13 precludes long term tag returns from the last two tagging events.

The tag return rate of $0.6 \%$ is considered low. The percentage of Scots Bay fish bought and of tag returns by buyer is shown in Figure 20. Tag returns from the German Bank fishery have been received from only three plants which bought only about $40 \%$ of the German Bank fish. The remaining plants, which bought about $60 \%$ of the German Bank fish, did not return tags.

## Tag Returns from Areas Other than German Bank

There were very few tag returns from areas other than German Bank. Six tags were returned from the Grand Manan area seiner fishery, 2 from the New Brunswick weirs, and 1 from The Patch on the Offshore Scotian Shelf (Table 15).

## 5. DISCUSSION

In the past one of the reasons that the interpretation of tagging data for turnover rates was difficult was because it was confounded by changes in effort. In this project, tags were applied at weekly intervals in attempt to avoid this issue. As was stated in Appendix C of Power et al., (2002):
"If fish tagged in week 1 are not caught on the spawning ground more than seven days after the first tagging event, but fish tagged the following week are being caught and returned, then there would be a stronger basis for concluding that the fish from week 1 had left the spawning ground."

On both Scots and German Bank, the majority of tag returns came from the first 3 weeks after tagging. However some fish remained on the spawning grounds for up to five to six weeks after tagging (Tables 6, 8, 17 and 19, Figures 5, 7, 17 and 19). For the first three tagging events in Scots Bay tagged fish were present on the spawning grounds for at least three weeks after tagging and, in one case, five weeks after tagging. The last tagging event was too late in the season to determine if fish were still around in Scots Bay after two weeks. On German Bank tagged fish were caught five and six weeks after tagging. If acoustic surveys had been conducted at 10 ten day intervals, then some of the fish would clearly have surveyed at least twice.

The attempt to quantify the turnover rate on Scots Bay (Tables 9 to 11, Figures 9 and 10) shows a huge amount of variability. This likely indicates that the residency time of fish on the spawning grounds is variable and therefore hard to quantify and
predict, making it difficult to plan acoustic surveys at fixed intervals, without the possibility of counting the same fish twice.

The tag return rate from German Bank was very low ( $0.6 \%$ ), but this was comparable to the experiments conducted in 1998 (0.3\%) and 2001 (0.5\%)(Paul, 1998, Clark et al., 2002). The results from the 2005 German Bank tagging experiment were similar to those of 1998 when $20 \%$ of the tag returns were from more than two weeks after the tagging event (Paul, 1999).

The data presented in Figures 8 and 20, show that some fish plants are not detecting and returning tags. It appears that the major processors of Scots Bay fish are finding and returning tags, but there were no tag returns from some of the major fish processors of German Bank fish. Tags are often missed in fish that are processed for bait, but tags should be detectable on large spawning fish that are processed for human consumption. The tagging projects have been well advertised with visits to the fish plants, media articles and the distribution of posters but this result indicates that it is necessary to further improve this advertising. For this sort of project to work in the future, plants need to set up their own procedures for tag returns so that workers are encouraged to detect and return the tags. An incentive of a small tag reward for each of the major processors might also be considered in future tagging project planning.

There appears to be an affinity between fish tagged in Scots Bay and the New Brunswick weirs. A total of $26 \%$ of the Scots Bay tag returns came from the New Brunswick weirs, some within the first few days after tagging. The maturity and length frequency information from the weir fishery shows that there are large fish in pre- and post-spawning condition in the weirs, which is consistent with the tagging data. As part of the New Brunswick Weir Herring Tagging Project that was being conducted concurrent to this experiment, 51 tags that were applied to fish in New Brunswick weirs have been returned from the Scots Bay roe fishery. Of these tags, more than fifty percent were from fish tagged in weirs from the Bliss Islands, coastal mainland and West Isles area. Under the current management scheme, fish from the New Brunswick weirs are considered to be predominantly juveniles (mostly ages 2 and 3) from NAFO Subarea 5 (USA) spawning components and these fish have therefore been excluded from the NAFO area 4WX quota (Power et al., 2005). This assumption is challenged by the apparent connection between the Scots Bay spawning grounds and the New Brunswick weirs.

## 6. CONCLUSIONS

Tagging of herring in Scots Bay and on German Bank was conducted in 2005 in order to examine the turnover rate of herring on these spawning grounds. Knowledge of the turnover rate is critical for the timing between acoustic surveys since surveys which are too close together count the same fish. Based on the results of the tagging experiment, the following conclusions can be drawn:

- Some tagged herring remain on the spawning grounds for at least 3 weeks after tagging, and in some cases, up to five to six weeks after tagging. As a result, acoustic surveys that are spaced at two week intervals are surveying some of the same fish.
- The residency time of herring on the spawning grounds appears to be extremely variable.
- There appears to be an affinity between the fish tagged in Scots Bay and the New Brunswick weirs.
- For a project like this to be fully successful, tag returns are necessary from all the major fish processors.
