Stock structure, life history, fishery and abundance indices for spiny dogfish (*Squalus acanthias*) in Atlantic Canada

Structure du stock, cycle biologique, pêche et indices d'abondance de l'aiguillat commun (*Squalus acanthias*) dans l'Atlantique canadien

Canada

Abstract

In 2003, an intensive 5-year research program on Canadian dogfish was initiated by the Department of Fisheries & Oceans (DFO), conducted in cooperation with the dogfish fishing industry through a Joint Project Agreement (JPA). This report is an overview of all new and published work done to date to better understand the stock structure, migration patterns, abundance trends and current state of the Canadian portion of the Atlantic spiny dogfish population. The information and advice provided is expected to be used in the management of the fishery and to guide future discussions with the U.S.

Spiny dogfish have many characteristics of a metapopulation, whereby some dogfish aggregations colonize or depart Canadian waters *en masse* at periodic multi-year intervals, and then remain resident in those waters for many years at a time. For the most part, dogfish tagged in Canadian waters have remained in Canadian waters, and those tagged in U.S. waters have remained in U.S. waters. However, there is some movement (10-20%) between Canadian and U.S. waters, with the Gulf of Maine region being the primary mixing ground. The existence of a metapopulation would imply that managing northwest Atlantic dogfish as a single, well-mixed stock would be inappropriate.

In the absence of a viable population model, it was not possible to estimate the exploitation rate for spiny dogfish in Atlantic Canada. However, biological studies indicate that the Atlantic population of spiny dogfish is more productive than is the northwest Pacific population. However, the long gestation period (~ 2 years), late age of sexual maturation and slow growth rate for spiny dogfish means that the species is relatively unproductive compared to other fish species.

Spring minimum trawlable biomass estimates for spiny dogfish in Canadian and U.S. waters show similar trends, increasing from the early 1980s to the early 1990s, then declining somewhat to the present. Mean values for both indices were around 500,000 mt in the early 1990s, declining to about 300,000 mt in 2007 for the Canadian index. The Canadian spring index is considered to be a better indicator of total adult biomass than is the summer index.

It is not currently possible to estimate trends in mature female biomass for spiny dogfish in Atlantic Canada. However, mature female biomass in the U.S. spring RV survey has declined to much lower values in recent years, albeit with an upturn in the last two years. Without knowing the extent that Canadian spawners contribute to the health of northwest Atlantic dogfish metapopulation, it may not be wise to increase the exploitation rate on mature females.

Résumé

En 2003, un programme quinquennal de recherches intensives sur l'aiguillat canadien a été entrepris par le ministère des Pêches et des Océans (MPO), en collaboration avec l'industrie de la pêche de l'aiguillat, dans le cadre d'une entente relative à un projet conjoint (EPC). Le présent rapport donne un aperçu de tous les travaux, nouveaux et publiés, à ce jour, permettant de mieux comprendre la structure du stock, les habitudes migratoires, les tendances de l'abondance et l'état actuel de la portion canadienne de la population d'aiguillat commun de l'Atlantique. L'information et les conseils fournis seront probablement utilisés pour la gestion de la pêche et pourraient guider les discussions futures avec les É.-U.

L'aiguillat commun affiche un bon nombre des caractéristiques d'une métapopulation en ce que certains groupes d'aiguillats colonisent ou quittent les eaux canadiennes en masse, à intervalles périodiques de plusieurs années, puis résident dans ces eaux pendant de nombreuses années. De façon générale, des aiguillats marqués dans les eaux canadiennes sont demeurés dans les eaux canadiennes et d'autres, marqués dans les eaux américaines, sont demeurés dans ces eaux. Toutefois, on constate certains déplacements (de 10 à 20 %) entre les eaux du Canada et des États-Unis, la région du golfe du Maine étant le principal lieu de mélange. L'existence d'une métapopulation porterait à croire que la gestion de l'aiguillat commun de l'Atlantique Nord-Ouest en tant que stock unique mixte est inappropriée.

En l'absence d'un modèle de population viable, il n'a pas été possible d'estimer le taux d'exploitation de l'aiguillat commun dans l'Atlantique canadien. Cependant, des études biologiques montrent que la population de l'Atlantique est beaucoup plus productive que celle du Pacifique Nord-Ouest, mais la longue période de gestation (~ 2 ans), la maturation sexuelle tardive et le lent taux de croissance de l'aiguillat commun font en sorte que l'espèce est relativement peu productive comparativement à d'autres espèces de poisson.

Les estimations de la biomasse minimale chalutable d'aiguillat commun au printemps dans les eaux canadiennes et américaines présentent des tendances similaires, augmentant à partir du début des années 1980 jusqu'au début des années 1990, pour diminuer quelque peu par la suite, jusqu'à aujourd'hui. Les valeurs moyennes des deux indices étaient d'environ 500 000 tm au début des années 1990, diminuant jusqu'à environ 300 000 tm en 2007 pour ce qui est de l'indice canadien. L'indice canadien printanier est considéré comme un meilleur indicateur de la biomasse adulte totale que l'indice d'été.

Il n'est pas possible actuellement d'estimer la tendance de la biomasse des aiguillats femelles matures dans l'Atlantique canadien. Toutefois, la biomasse de femelles matures, selon le relevé du printemps du navire de recherche aux É.-U., a diminué jusqu'à des valeurs beaucoup plus faibles, ces dernières années, quoiqu'on ait constaté une reprise ces deux dernières années. Sans connaître la mesure dans laquelle les géniteurs canadiens contribuent à la santé de la métapopulation d'aiguillats de l'Atlantique Nord-Ouest, il n'est peut-être pas avisé de hausser le taux d'exploitation des femelles matures.

Background

Most Atlantic Canadian landings of spiny dogfish are taken in directed handline, longline, and gillnet fisheries. Catches were unrestricted prior to 2002. Since 2002, precautionary directed catch quotas based on past catches have been in place for the Scotia-Fundy region. The quota since 2004 has been set at 2500 mt. Quotas to this point have not been based on scientific advice, and there are no restrictions on discarding and bycatch in other fisheries.

In recognition that spiny dogfish stock components are found on both sides of the Canada/U.S. border, an information exchange forum was held at the Bedford Institute of Oceanography in 2003 so that science, fisheries management and industry from both the U.S. and Canada could exchange information and views about spiny dogfish biology, management and fisheries. The meeting was recognized as the first step in a process to work towards more integrated management of spiny dogfish.

In 2003, an intensive 5-year research program on Canadian dogfish was initiated by the Department of Fisheries & Oceans (DFO), conducted in cooperation with the dogfish fishing industry through a Joint Project Agreement (JPA). The JPA provided for the collection of large numbers of at-sea and landed samples of dogfish catches that were used in analyses of commercial catches and dogfish biology.

This report is an overview of all work done to date to better understand the stock structure, migration patterns, abundance trends and current state of the Canadian portion of the Atlantic spiny dogfish population. The information and advice provided is expected to be used in the management of the fishery and to guide future discussions with the U.S.

Distribution and Habitat

Spiny dogfish (*Squalus acanthias*) are small squaloid sharks common both on the bottom and in the water column of coastal temperate oceans around the world. Dogfish populations are known to be present in the waters off of Europe, Argentina, New Zealand and Japan, as well as in the northeast Pacific and northwest Atlantic. In the northwest Atlantic, dogfish are common from North Carolina to southern Newfoundland, and can be found further to the south and north (Fig. 1).

Dogfish on the Scotian Shelf are usually associated with bottom water temperatures between 0 and 12 ^{0}C throughout the year, although 6-11 ^{0}C appear to be the preferred temperatures (Fig. 2). The species has been collected at depths from 0-350 m on the Scotian Shelf, although it is most commonly observed at depths of 50-200 m (Fig. 2). At the northern limit of their range, Kulka (2006) reported that dogfish in Newfoundland waters (NAFO 3LNOP) were most commonly associated with water temperatures of >5 ^{0}C and water depths of 100-250 m.

Reproduction

Spiny dogfish are ovoviviparous, with the young feeding and growing off a yolk sac in utero before being born alive (Jensen 1966; Ketchen 1975; Nammack et al. 1985; Hanchet 1988; Jones and Ugland 2001; Henderson et al. 2002). In maturing females, immature eggs turn yellow and grow to a diameter of 20-45 mm. The mature eggs pass through the shell gland, where they are fertilized and become enclosed in a protective capsule (candle) prior to passing through to the uterus. Candled embryos break free of the capsule after about a year, living as free embryos feeding off the yolk sac within the uterus for the remainder of the gestation period.   The embryos

continue to grow as the yolk sac shrinks, but embryos that have completely resorbed the yolk sac may remain in the uterus for some time before being born. This reproductive cycle takes 22-24 months, making it one of the longest gestation periods known for any vertebrate.

As part of an intensive study of dogfish conducted in cooperation with the commercial dogfish fishery, we studied the sexual maturation and growth of dogfish collected on research surveys and as part of the commercial fishery (Campana et al. in press). Sexually mature and pregnant females were distributed throughout the waters of southwest Nova Scotia and the Bay of Fundy during the summer and fall, but moved offshore to deeper waters in the winter (Fig. 3). Females of mature size have also been observed in the southern Gulf of St Lawrence and off southern Newfoundland. The fork length at 50% maturity for males was 55.5 cm (= 63.6 cm total length (TL)) at age 10, while that for females was 72.5 cm (= 82 cm TL) at age 16 (Fig. 4). Free embryos were observed in 62% of all pregnant females (n=1491). The number of free embryos in any given female ranged between 1 and 14 with a mode of 5 (Fig. 5). Larger females tended to have significantly more free embryos, such that a 90-cm FL female had on average four times as many free embryos as a female 60 cm FL (Fig. 5). Free embryos first became apparent in June at a fork length of 16 cm, and would be expected to reach their birth size of 22-25 cm during the winter. Our results confirmed that the dogfish gestation is around 2 yr, thus making the species relatively unproductive.

Pupping grounds have not been observed in either Canadian or U.S. waters. However, large aggregations of mature females occur in deep warm waters off the edge of the continental shelf and in the deep basins of the central shelf throughout their range in the winter. Based on the presumed birth months in late winter, pupping occurs in these deep offshore areas. Small juveniles are seldom collected in either Canadian or U.S. research surveys, but those that are collected are found in the same areas as the mature females in winter. It appears likely that the small juveniles pursue a largely pelagic existence for the first few years of their lives before moving onto the continental shelf. Based on the presence of mature females and young juveniles in offshore waters each winter, pupping most probably occurs in both Canadian and U.S. waters.

Age and Growth

The accuracy of dogfish age interpretations using spine growth bands has been confirmed using bomb radiocarbon dating (Campana et al. 2006). To determine the age structure of Canadian Atlantic dogfish, a total of 525 spiny dogfish were aged with a mean precision (CV) of 12% and a longevity of 31 yr. Males and females grow at similar rates until the size and age of male maturity, after which male growth rate slows considerably (Fig. 6). Two-parameter von Bertalanffy growth equations using a fixed size at birth (=25 cm) gave $L_\infty = 78.0$ and $K = 0.099$ for the males, and $L_\infty = 119.5$ and $K = 0.042$ for the females. Northwest Atlantic dogfish appear to grow more quickly, mature at a younger age, and die at a younger age than do northeast Pacific dogfish. Thus the Atlantic population is more productive than is the northwest Pacific population.

The relationship between dogfish length and weight is shown in Fig. 7. Although fork length is a more accurate measure of length for dogfish (since it does not involve depressing the upper lobe of the tail), some authors have used total length in their reports. The inter-conversion equations are as follows:

Fork Length = -1.5 + 0.90 • TL
Total Length = 3.1 + 1.09 • FL

Stock Structure and Migration

Genetics

To test for evidence of population structuring in Canadian dogfish, tissue samples were analyzed for microsatellite DNA from dried muscle on dogfish spines (n=307) collected around Nova Scotia and Newfoundland (Fig. 8). Samples were collected from six locations in three different years, with the majority of the samples having been collected in 2006. Only the Upper Bay of Fundy (UBF) sample set included collections from multiple years (2005 and 2006). Additional samples were requested from U.S. waters, but these have not yet arrived. Seven microsatellite loci developed for dogfish (McCauley et al. 2004) were used for the microsatellite analysis. The analysis was conducted by the Aquatic Biotechnology Lab at the Bedford Institute of Oceanography by Lorraine Hamilton and Koren Spence.

The amplification success rate at each of the six loci varied between the sample collections. For the UBF samples the majority of the failures occurred in the 2005 UBF samples. That sample set had the highest number of failures (at least one failed amplification at 21 out of 23 samples) and, as that was the sample set of the lowest size, this resulted in a very high failure rate. The failure rate was not associated with the age of the samples as the Sambro samples were the oldest (2003 collection) and had the lowest failure rate. The 2005 UBF sample was dropped from further analysis due to the high sample failure rate combined with the low sample size.

Summary statistics for all loci at each sampling location indicate that deviations from Hardy-Weinberg expectations were significant for nine of the sample location and locus combinations (Table 1, HWE rows), and the overall probability of the combined sample set deviating from Hardy-Weinberg expectations was highly significant with all loci included (Table 1). As the number of loci and their level of polymorphism were limited, analyses could not be run with and without loci suspected of having null alleles.

The pairwise comparison of the FST values (measured as Weir and Cockerham's Θ) were all very small (Table 2). Of these values, only one was significant, the Sambro and Upper Bay of Fundy samples (P=0.01646±0.0019). This is the only significant difference seen in this sample set.

This study did not find evidence of dogfish population structuring in Canadian waters based on the loci used. However, it is possible that a larger sample size and a larger number of polymorphic loci, or sampling of mating aggregations, would have detected population structuring. U.S. samples will be analyzed for differences from the Canadian samples when they become available.

Tagging Studies

Several studies have been published which report on recapture and movement of tagged spiny dogfish in the northwest Atlantic. However, there have been significant numbers of recaptures post-publication, plus two studies which have never been published. To this point, no one has attempted to summarize these various studies in a single analysis. To do so, we start by presenting tagging and recapture locations for each study individually (including any unpublished results), then analyzing all of the studies together.

Templeman (1954, 1984) tagged 2657 dogfish at various inshore and offshore locations in southern Newfoundland between 1942 and 1965 (Table 3). Of the 232 recaptures, 216 were recaptured in Newfoundland waters, 12 were caught around NS or NB, and 4 were caught in U.S.

waters (Fig. 9). An addition, Templeman (1976) reported that two tagged dogfish made trans-Atlantic migrations, one to Iceland and one to Scotland.

Moore (1998) tagged 995 dogfish in the Minas Basin of the Bay of Fundy (Canada) in 1996. There were 39 recaptures from this study, 21 of which were reported in Moore (1998), and 18 of which are reported here for the first time (Table 3). Many of the recaptures were made many years after release. Of these recaptures, 29 were made in Nova Scotian waters, and 10 were in and around Cape Cod (USA) (Fig. 10).

Register (unpublished) tagged 743 dogfish in the Bay of Fundy in 2005-2006, recapturing 10, all in Canadian waters (Table 3; Fig. 11). Of the 10 recaptures, 8 were in the Bay of Fundy and 2 were off of southern Newfoundland.

Jensen (1961, 1966, 1969) tagged 999 dogfish at 4 sites in northeastern U.S. waters between 1956 and 1961 (Table 3). A total of 25 recaptures were made, most of which were in the northeastern U.S. and 2 of which were in southwestern N.S. (Fig. 12). He also tagged an additional 50 fish on Browns Bank (Canada), obtaining 2 recaptures in Canada.

Myklevoll (1993) tagged 500 dogfish on Georges Bank (U.S.) in 1968 (Table 3), but few North Americans are aware of this publication written in Norwegian. There were 14 recaptures, 11 of which were in U.S. waters as far south as North Carolina, and 3 recaptures in southwest N.S. (Fig. 13).

Shafer (1970) tagged 649 dogfish off North Carolina in 1967, and an additional 2934 dogfish in northeastern U.S. waters between 1966 and 1969 (Table 3). Of the 60 recaptures, 53 were made along eastern seaboard of the U.S. and 7 were in southwest N.S. (Fig. 14).

In the largest study of its kind, Rulifson (unpublished) tagged 36,604 dogfish in North Carolina waters between 1997 and 2006 (Table 3). Of the 285 recaptures, 269 were made along the eastern seaboard of the U.S. (many in the northeastern U.S.) and 16 were made off southwestern N.S. (Fig. 15).

A visual synthesis of all of the tagging studies except those of Rulifson (unpublished) is shown in Fig. 16. In all, over 46,000 dogfish have been tagged, with 667 recaptures. For the most part, dogfish tagged in Canadian waters remained in Canadian waters, and those tagged in U.S. waters remained in U.S. waters. However, there was clearly some movement between countries, with the Gulf of Maine region being the primary mixing ground. Overall, 346 of 384 (=90%) of recaptures from U.S. tagging sites were recaptured in U.S waters, and 267 of 283 (=94%) recaptures from Canadian tagging sites were recaptured in Canadian waters (Table 3). Restricting the analysis to the Gulf of Maine, 75/86 (=87%) of U.S. tagged fish and 41/51 (=80%) of Canadian tagged fish remained within their host country (Table 3). A more rigorous analysis of tag movements would weight recaptures by fishing effort. Although fishing effort data for all but the recent studies were unavailable, an attempt was made to weight by a proxy for effort: catch. However, catch weighting was confounded by huge landings by foreign fleets in unknown waters (Table 3). In the one study where proper catch weighting was possible (Moore 1998), the analysis reinforced perceptions that most tagged dogfish remained in their host country.

To test the hypothesis that large-scale or trans-boundary migrations are limited to mature females, we tested for sex-specific differences in distance of recapture from tagging site or cross-border movement. Unfortunately, virtually all dogfish tagged in all studies were large females. We noted that none of Shafer's 12 recaptured males (out of 160 tagged) migrated to Canada, but the

4

difference from females was not significant (chi-square test, $P > 0.1$). Similarly, the fact that only one of Rulifson's (unpublished) 13 recaptured males was recaptured in Canada was not significant ($P > 0.1$). Nor did any of the tagging studies that presented information on sex and length at tagging and recapture (Moore 1998; Register unpublished; Rulifson unpublished) show a significant relationship between length of dogfish and distance of migration ($P > 0.1$). Although these results suggest that there is no evidence that migration is linked to large (mature female) dogfish, the statistical power of the test was weak.

An analysis of each of the individual tagging studies indicated a strong seasonal pattern in direction of movement, particularly among dogfish south of the Gulf of Maine. In most studies, dogfish tended to be recaptured in more northerly waters in the summer, peaking in August (Fig. 17). To some extent, this pattern is forced by spatial patterns in fishing effort, since there is little or no fishing for dogfish in winter months in northerly waters, and thus no recaptures are possible there during the winter. Nevertheless, the fish tagged in North Carolina waters (Rulifson unpublished) clearly migrated north to the southern Gulf of Maine during the spring and returned in late fall, given that there were few recaptures in southerly waters during the summer (Fig. 17).

In summary, analysis of all available dogfish tagging data supports the view that there are several non-independent dogfish stock components in the northwest Atlantic. Dogfish movements between Canadian and American waters are not the predominant pattern, accounting for only 10-20% of tag recaptures.. Large-scale annual migrations occur along the east coast of the U.S., but are primarily limited to the area between North Carolina and the Gulf of Maine. Cross-border mixing does occur, but its extent (10% on average) is on the same scale as that observed with groundfish stocks such as 4X cod. Therefore, there appears to be both migratory and resident components, as Templeman (1976) hypothesized for Newfoundland dogfish populations.

To determine if a mix of migratory and non-migratory components is consistent with other spiny dogfish populations around the world, the published literature from the well-studied British Columbia and European populations was reviewed. After tagging >70,000 dogfish in BC, McFarlane and King (2003) reported that the majority of recaptures were made close to the release site; however extensive migrations did occur, including across the Pacific Ocean. About 85% of the coastal dogfish stayed in the Strait of Georgia, apparently forming a non-migratory component, but most of those tagged offshore or in northern BC migrated considerable distances. Interpretations were less clear in European waters, but Vince (1991) and other European studies reported significant movements throughout and around the North Sea, including one trans-Atlantic migration (Holden 1967).

An important question remains though: do dogfish move south to U.S. waters each fall to overwinter, then return to Canadian waters each spring?   The next section will test this hypothesis by examining evidence of dogfish overwintering in Canadian waters.

Seasonal Migrations in Canada: Inshore/Offshore or North/South?

If dogfish migrate south out of Canadian waters each year, the migration should be evident in terms of reduced winter/spring biomass prior to the return migration. There are only a few areas and periods where matching seasonal RV surveys exist, and these will be examined in turn.

Fig. 18 compares the RV survey distribution of dogfish between summer and early spring on the Scotian Shelf, southern Gulf of St Lawrence and off southern Newfoundland. The same period (1979-1984) was used throughout, although dogfish had not yet arrived in the southern Gulf of St Lawrence by 1984, so the 1985 4T distribution was used instead. Note that coverage of 3Ps in

5

the Newfoundland fall RV survey was minimal. Summer distributions tended to be throughout coastal waters, including on shallow banks (Fig. 18). In contrast, spring distributions were almost entirely in deep basins and off the edge of the continental shelf. In all areas, spring distributions were further offshore (or deeper) than summer distributions, with no evidence of net migration out of the area. Indeed, spring biomass was consistently greater than that in the summer (see legend, Fig. 18). This perception was confirmed by comparing the total stratified abundance and biomass of the spring and summer RV surveys in 4VWX. The summer biomass ranged between 20,000-95,000 mt annually while the spring biomass ranged between 53,000-344,000 mt (Table 4). In all years, spring abundance and biomass exceeded summer abundance and biomass by an average of 2-5 (Table 4).

A similar pattern of higher winter/spring abundance and biomass, and no evidence of migration to other areas, was observed in other regions. A comparison of 4VW spring and summer RV surveys demonstrated that spring abundance and biomass exceeded that of summer by a mean factor of 26-58 (Table 5). The higher biomass ratio in the spring survey was particularly accented in the high-abundance years prior to 1992, but spring biomass continued to match or exceed summer biomass in low-abundance years as well.

There was no evidence that spring biomass on the Scotian Shelf was high due to overwintering of dogfish from Newfoundland. A comparison of spring vs fall abundance in NAFO 3LNO indicated parity between the two surveys (Table 6). Since most of the dogfish in Newfoundland waters in spring are found in 3Ps (Table 11 of WP 2007/29), it is possible that spring biomass in Newfoundland waters would also have exceeded that in the fall, but fall RV surveys of 3Ps are not carried out.

The analysis of seasonal RV surveys in Canadian waters described above do not support the hypothesis that dogfish move south out of Canadian waters for the winter. Indeed, the higher stratified abundance and biomass in the early spring surveys suggests that additional fish have appeared from somewhere else. Could they have moved north from U.S. waters? A comparison of spring versus fall RV surveys indicates that spring abundance and biomass in U.S. waters exceeds that in the fall by an average factor of 2.7 (Table 7), comparable to what was observed in Canadian waters. In the past, some have interpreted the greater abundance in the U.S. spring RV survey compared to their fall RV survey as evidence of additional overwintering fish which had migrated in from Canada. Our results reject this interpretation. In other words, spring biomass appears to be higher in both Canadian and U.S. waters. Since it is obvious that fish cannot appear out of nowhere, the apparent increase in spring biomass must be due to a change in catchability. That is, spring aggregations of dogfish in deeper, offshore waters must be easier to catch in the RV gear, perhaps due to the position of dogfish in the water column or lower swimming speed. A more likely explanation is that a significant proportion of the summer distribution is concentrated in shallow nearshore waters not surveyed by the RV gear. Whatever the cause, the fact that catchability increases by a comparable factor between Canadian and U.S. waters suggests that there is little in the way of net southern migration out of Canada for the winter. Seasonal migrations appear to be exclusively (or at least mostly) inshore-offshore.

A comparison of the length composition between the seasonal RV surveys provides some insight into the nature of the early spring aggregations offshore. The sex-specific size compositions of the summer (July) and fall (Oct-Nov) RV surveys between 1979-1984 are very similar, indicating that there is no appreciable sex- or size-specific migration out of the survey area before mid-fall (Fig. 19). In contrast, there are large and significant differences between the sex-specific length compositions between spring and summer, such that large males and in particular large mature females are much more represented in the offshore spring aggregations. Thus it seems likely that

6

these spring aggregations are mating or pupping aggregations. The fact that the offshore spring aggregations comprise both sexes suggests that they may be mating aggregations (Fig. 20).

An analogous comparison of length compositions on the eastern Scotian Shelf (NAFO 4VW) during years of high dogfish abundance (1986-1991) shows a similar pattern with respect to the females: many more large mature females were present in the spring survey than in the summer survey (Fig. 21). Interestingly however, modes corresponding to young juveniles were evident in the summer survey, but not in the spring survey. If those juveniles were indeed present in the spring, their catchability must have been very low. An alternative explanation is that they migrated onto the Scotian Shelf from U.S. waters for the summer, then returned before winter.

The length composition of the eastern Scotian Shelf (NAFO 4VW) during years of low dogfish abundance (1994-2003) presented a somewhat different pattern (Fig. 22). In those years, the relative abundance of young males was higher in the spring than in the summer, while that of young females was spread over a greater size range. In keeping with the other analyses though, large mature females were relatively more abundant in the spring compared to the summer.

The fact that spring RV surveys in various regions consistently catch more large females than are captured in the summer can only be explained by one of three possible mechanisms:

1) Mature females present in offshore waters in spring subsequently migrate south out of Canadian waters into U.S. waters before the time of the summer survey. This option does not seem likely since it would require a southward migration in the late spring, when all available tagging and migration data suggests that migration should be northward at that time of year.

2) Mature females arrive offshore in Canadian waters in fall or winter from somewhere other than inshore waters. This option also does not seem likely, since it would require either a northward migration from the U.S. in the fall (when all known migration is proceeding southward) or a southward migration from more northerly waters (where there is no evidence of large-scale migration at all).

3) Mature females are not really more abundant compared to smaller dogfish in the spring. Rather, their catchability is higher in the spring, or to turn it around, their catchability is low in the summer. This hypothesis seems most likely. A comparison of the summer RV size composition in 4X for the years 2002-2006 with that of commercial longline and gillnet catches over the the same time period in the same area indicates that the summer RV catches relatively few (< 5%) females of mature size (Fig. 23). In contrast, the catch of mature females in commercial gear exceeds 45% of the catch numbers. Therefore, the mature females are definitely there in the summer; they're just not easily caught or available to the RV otter trawl gear. Consistent with this hypothesis are observations by fishermen and others (Moore 1996) that large females are most common inshore in shallow regions not surveyed by research vessels, such as the upper Bay of Fundy.

To summarize, all evidence indicates that spring RV surveys provide the best available view of the dogfish size distribution, and that mature females are too far inshore during the summer to be adequately surveyed by the RV gear. Alternative explanations for the apparently increased abundance of mature females during the spring, and their absence during the summer, are not viable. Summer RV surveys demonstrate that the mature females do not show up further north. And tagging results indicate that they do not move south in the late spring. Therefore, it seems most reasonable to accept that the relatively high biomasses estimated by RV surveys in the spring are due to high catchabilities, and that the spring catchability of large females is enhanced

over that of smaller dogfish. The conclusion is that spring RV surveys are a better representation of sub-adult and adult abundance than are summer RV surveys. Thus large females remain on the Scotian Shelf throughout the year, moving well inshore during the summer and offshore during the fall and winter.

Dogfish as a Metapopulation

A metapopulation can be defined as a group of spatially separated groups or populations of the same species which interacts at some level. Range expansions can bring one group into contact with another, or re-populate areas vacated by another group. As a result, periodic mixing can prevent the development of genetic differences. Although it is not clear that spiny dogfish fit the exact definition of a metapopulation, there do appear to be some characteristics in common:

- There are several more or less well-defined 'groups' of dogfish, such as those occupying the southern Gulf of St Lawrence, around Newfoundland, the eastern and central Scotian Shelf, Bay of Fundy and SW Nova Scotia, Massachusetts and North Carolina.
- The groups remain largely separate, and engage in seasonal onshore-offshore migrations. Some groups undertake seasonal north-south migrations, particularly those in the south. The migrations may be an evolutionary adaptation to remain in a "preferred" temperature range of 5-12 degrees C throughout the year.
- There is occasional mixing between groups, particularly those in the Gulf of Maine.
- Although genetic studies are incomplete, there are unlikely to be genetic differences among groups.
- At least one of the groups – that in the southern Gulf of St Lawrence – is almost certainly a "sink" population. That is, it was colonized abruptly in 1985, and the same group has resided there ever since, growing larger in size but smaller in numbers, with no evidence of outside immigration or recruitment. The mean length in the population increased by an average of 0.47 cm/yr (SE=0.02) between 1985 and 2002, slightly less than the growth rate of 1.22 cm/yr expected of 4X dogfish of comparable size. It seems likely that the generally cooler water temperatures present in the Gulf would have slowed growth compared to 4X, in which case the observed increase in size may be explicable solely on the basis of growth.
- The Eastern Shelf dogfish component appears to have remained resident for many years in NAFO 4VW, then abruptly disappeared in 1992. At around the same time, the Georges Bank component disappeared. These dogfish, whose minimum trawlable biomass was about 300,000 mt, apparently moved to another area, since the abrupt decline cannot be explained by fishing or discarding.

A spiny dogfish metapopulation presents some interesting implications for fisheries management. First of all, it would suggest that Canadian dogfish cannot be viewed in isolation. At a minimum, if some of the dogfish that currently reside in Canadian waters actually originated in U.S. waters, it means that at least some of the recruitment is dependant on the U.S. stock. Secondly, the existence of a metapopulation would imply that managing North American dogfish as a single stock would be inappropriate. If, as seems likely, some dogfish aggregations colonize or depart Canadian waters *en masse* at periodic multi-year intervals, and then remain resident in those waters for many years at a time, alternate management strategies may be more appropriate. Finally, without knowing the extent that Canadian spawners contribute to the health of the northwest Atlantic dogfish metapopulation, it is possible that a fishery on mature females in either Canadian or U.S. waters could impact the abundance in all areas.

The Fishery

Landings

The fishery for spiny dogfish in the Northwest Atlantic began long before commercial catch statistics came to be reported. Reported landings prior to extension of jurisdiction in 1977 were dominated by USSR (Russia) and other European countries, and peaked at about 25,000 mt annually (Table 8; Fig 24). Unfortunately, the country where fishing took place was not recorded. After 1977, U.S. commercial landings accounted for most of the reported catch, peaking at more than 27,000 mt annually. Canadian landings have been a relatively small proportion of the total catch until 2000, at which point the introduction of quotas in the U.S. made Canadian landings a significant portion of the total (Table 8).

Canadian landings have averaged about 2500 mt annually since 2000, with the majority of that being directed catch by handline and longline, followed by gillnets (Table 9). The vast majority of landings were reported from Nova Scotia (Table 10). Almost all of the dogfish were caught in the Bay of Fundy, southwest Nova Scotia and off Halifax (Fig. 25). Summer is the principle time for dogfish fishing (Fig. 26). Although incidental landings have been reported by several fleets, the only gear sector responsible for a significant proportion of Canadian landings other than longlines/handlines has been by gillnets (Table 9). Catches were unrestricted prior to 2002. From 2002 onwards, precautionary directed catch quotas based on past catches were put in place. The 2002 quota of 3200 mt was exceeded by 384 mt, but directed catches in subsequent years have not exceeded the quota (Table 9). The quota since 2004 has been set at 2500 mt. Quotas to this point have not been based on scientific advice. There are no restrictions on discarding and bycatch in other fisheries.

Discards

Unintended and unwanted bycatch of dogfish by Canadian fisheries is substantial, and has achieved an almost legendary status over the years. To quantify the bycatch, observer records of dogfish catch relative to target catch were calculated by fishery, NAFO area, season and year. Observer coverage varied among regions, years and fisheries, but averaged 12% (Table 11). The proportion of dogfish in each observer cell was then multiplied by the total reported landings (from ZIF until 2002, and from MARFIS and other regional statistics after 2002) of the target catch in each cell to obtain the estimated dogfish catch in each cell. The resulting dogfish bycatch by fishery and NAFO area, aggregated by year, varied widely among gear sectors and areas (Table 12). The largest bycatch was associated with the groundfish (OTB, LL, gillnet) and OTB redfish fleets in 4X5Y, although all areas and most fleets reported large dogfish bycatches at some times (Fig. 27). Total discards have averaged 2,000-3,000 mt annually in recent years, although discards of up to 10,000 mt were estimated for some years in the 1990s (Table 12).

Spiny dogfish are relatively hardy, so it is only reasonable to assume that discard mortality is not 100%. Unfortunately, there are few available estimates for dogfish discarding mortality. Revill et al. (2005) reported 2% mortality for OTB-caught lesser-spotted dogfish (*Scyliorhinus canicula*), although Rodriguez-Cabello et al (2005) reported 22% mortality for the same species under more rigorous experimental conditions. Mandelman and Farrington (2007) reported a maximum of 29% mortality for discarded spiny dogfish, but their results were confounded by a relatively high mortality in their control fish. Nevertheless, they suggested that mortality in large tows (>200 kg) would be expected to be even higher. The best available discard mortality estimates come from Rulifson (2007), who reported a 55% mortality rate for dogfish caught in gillnets, and 0% for small numbers caught in otter trawls. All of these mortality estimates are

considerably different than are assumed by than are assumed by the U.S. National Marine Fisheries Service, who used estimates of 50% for OTB discards and 30% for gillnets (NFSC 2006). The basis for the U.S. estimates are unclear.

Dogfish discard mortality in Canadian waters was calculated as per the following: 25% for OTB catches > 200 kg, 0% for OTB catches < 200 kg, 55% for gillnet catches, 10% for longline catches, and 25% for purse seine catches. The exact values are debatable, although all appear to be consistent with the experimental values reported above and observer observations of the manner in which fishers and their gear treat dogfish catch. To estimate the proportion of the OTB catches which exceeded 200 kg, observer data in 4X5Y for the years 2002-2006 were analyzed. Of the OTB redfish sets, 66% of the sets but only 5.4% of the landed catch was less than 200 kg. For silver hake OTB, 10% of the sets but only 0.1% of the landed catch was less than 200 kg. For groundfish OTB, 77% of the sets corresponding to 15% of the landed catch was less than 200 kg. Therefore, these proportions were those that were used in the discard mortality calculations of Table 12.

Estimated dogfish discard mortality has averaged about 850 mt annually since 1986 (Table 12). Discard mortality often exceeded reported catch prior to 1999, but recent landings have greatly exceeded discard mortality (Table 12; Fig 28).

Age and Size Composition of the Commercial Catch

The length composition of the commercial catch over the years 2002-2006 in 4X indicated that females ranged in length from 46-112 cm total length (TL), while males ranged from 36-94 cm (Fig. 29). Most of the catch was of sub-adult and adult size. Median size of females in the catch was 81 cm TL, while that of males was 74 cm. In terms of catch numbers, 66% consisted of females, and 26% of the catch consisted of mature females. These numbers are much lower than those present in the U.S. commercial catch, where median body size of females in the catch was 86 cm TL and females made up 91% of the catch numbers between 2002-2005 (NFSC 2006).

There are some markets where large dogfish are valued more highly than smaller dogfish. In order to test if this preference might have encouraged 'highgrading' at sea (discarding smaller dogfish in preference for larger dogfish), the size composition of the at-sea and landed catch was compared for each of the two major gear types (longline/handline and gillnets) in each of two years (Fig. 30). Landed dogfish were not significantly larger than at-sea (pre-discarding) dogfish, indicating that any highgrading of the catch would have to have been of small scale.

Dogfish in the commercial catch tended to be fairly old, with a mean age of 16 yr for males (n=450) and 18 yr for females (n=1085) (Fig. 31).

Abundance Indices

There are a number of RV surveys and industry surveys in Atlantic Canada that catch significant numbers of dogfish. Although these surveys together do not cover the entire range of spiny dogfish, they can be used to provide an index of relative abundance across years. In this section, the distribution, size composition (where available) and relative abundance of dogfish in each of these surveys is considered in turn. Where possible, relative abundance has been calculated in terms of minimum trawlable biomass so as to allow comparison of relative biomasses among regions. However, differences in gear catchability between surveys may scale the total biomasses differently.

The July RV survey of the Scotian Shelf shows no obvious changes in dogfish distribution or size composition between 1970 and 2006 (Figs. 32 and 33). In contrast, overall abundance increased markedly after 1984 and has remained high, albeit variable, to the present (Table 13; Fig. 34). Note that in the absence of information to the contrary, the catchability of the Western IIA survey gear being towed by the RV Needler has been considered equivalent to that of the same survey gear being towed by the RV Teleost (2004, 2006).

Spring (Mar-Apr) RV surveys of the Scotian Shelf were carried for 5 years between 1979-1984 as part of a seasonal comparison. The spring RV distribution was centred offshore and in deeper waters than was the summer RV distribution (Fig. 35). Size composition and relative abundance varied significantly across years, with no obvious trend (Table 14; Fig. 35).

Fall (Oct-Nov) RV surveys of the Scotian Shelf were carried out for 6 years between 1978-1984 as part of a seasonal comparison. The fall RV distribution was similar to that of the summer distribution (Fig. 36). There was no apparent trend in size composition, and relative abundance fluctuated, with a strong increase in the last year (Table 14; Fig. 36).

March RV surveys for 4VW cod also also collected information on dogfish since 1986. Dogfish distribution in the 4VW cod survey was centred offshore and in the deeper basins of the Scotian Shelf (Fig. 37). The size composition has been variable, but has tended to be dominated by larger fish (Fig. 38). Relative abundance remained high but variable until 1992, after which it dropped abruptly to about 15% of its previous level (Table 15; Fig. 38).

February surveys of Georges Bank have been conducted since 1986. Dogfish distribution at that time of the year is concentrated at the edge of the bank in deeper water (Fig. 39). Size composition has varied over the years, but has sometimes shown a bimodal distribution corresponding to small juveniles and mature adults (Fig. 40). Relative abundance peaked in 1993, then declined abruptly to very low levels, where it has remained since (Table 16; Fig. 40).

Deepwater surveys for redfish on the Scotian Slope were the only survey of this area in the fall (Oct-Nov) (Fig. 41). However, despite their abundance in this same area during the spring, dogfish were seldom caught in this survey between 1982-1988, and those that were caught were of sub-adult size.

The 4VsW cod sentinel longline survey operated each fall (Sept-Oct) between 1995-2005. Dogfish were caught throughout the survey area, although they tended to be uncommon on the shallow offshore banks (Fig. 42). There was no obvious trend in the size distribution across years, although relative abundance declined through the time series (Table 17; Fig. 42).

Longline surveys for halibut have been conducted on the Scotian Shelf and off southern Newfoundland each June since 1998. Dogfish have been caught throughout the survey area, but have been much more concentrated off central and southern Nova Scotia (Fig. 43). Length frequency data were not collected. Relative abundance in this series has been variable, but has increased (Table 17; Fig. 43).

Sentinel longline surveys for 4Vn cod were carried out in 4Vn during September each year between 1994 and 2001. Dogfish were collected throughout the survey area (Fig. 44). No length frequencies were recorded. Relative abundance declined markedly after 1994 and never recovered (Table 17; Fig. 44).

September groundfish RV surveys of the southern Gulf of St Lawrence recorded no spiny dogfish whatsoever between 1971-1983. Once they appeared, they became widely distributed near shore and along the edge of the Laurentian Channel (Fig. 45). The size distribution was uni-modal, and increased gradually in modal length across years, consistent with the increase expected of growth (Fig. 46a). The mean length in the population increased by an average of 0.47 cm/yr (SE=0.02) between 1985 and 2002, slightly less than the growth rate of 1.22 cm/yr expected of 4X dogfish of comparable size, but consistent with the generally cooler water temperatures present in the Gulf which would have slowed growth compared to 4X (Fig. 46b). Relative abundance was greatest in the 1980s and has declined ever since (Table 18; Fig. 45). The sudden appearance, progressive increase in size composition, and gradual decline in abundance are all consistent with that of a 'sink population' – a pulse of dogfish that arrives from somewhere else, then never leaves. The subsequent presence of dogfish in the deep warmer waters of the Laurentian Channel in January RV surveys confirms that at least some of the dogfish remained resident all year round (Fig. 47).

Spiny dogfish have been collected in summer RV surveys of the northern Gulf of St. Lawrence. However, analysis of these data indicated that there were substantial numbers of records for dogfish < 20 cm TL, which is below the birth length. Since black dogfish (*Centroscyllium fabricii*) are common in the northern Gulf, it appears likely that at least some of the spiny dogfish records are actually black dogfish. Accordingly, these data were not considered further.

Spring (Feb-May) RV surveys of southern Newfoundland (NAFO 3LNOP) have been carried out each year since 1972. Dogfish distribution at that time of year is concentrated in the deeper waters at the edge of the Laurentian Channel and continental shelf (Fig. 48). Size frequency data were not collected. Relative abundance between 1972-2005 has been variable with no obvious trend (Table 19; Fig. 48).

A comparison of minimum trawlable biomasses from all Atlantic Canadian RV surveys gives a relative indication of the stock proportion present in each area (Fig. 49). Given the large differences in RV catchability between spring and summer, it is appropriate to compare trawlable biomass only within a given season. The comparison of the various summer/fall RV surveys (summer 4VWX5Z, fall 4VWX and 4T) indicates that the fall and summer trawlable biomasses are roughly comparable, and show similar trends. However, the trawlable biomass in the southern Gulf of St Lawrence is roughly 10% of that on the Scotian Shelf, and thus is small by comparison.

A comparison of the spring RV surveys shows that the spring 4VWX, spring 4VW and the Feb Georges Bank trawlable biomasses are all comparable, although the spring 4VWX survey does not overlap in time with any other spring survey (Fig. 49). Interestingly, the abrupt decline in the 4VW spring survey in 1993 occurred one year after an abrupt increase in the Georges Bank survey, but 1-2 yr before the abrupt decline on Georges. Thus there was no obvious link between areas in the changing abundances. Nor was there any apparent change in the summer 4X biomass in or around 1993, indicating that the 4VW dogfish did not migrate to 4X. The trawlable biomass in Newfoundland waters was negligible compared to the other regions prior to 1997, but the biomass in the other regions subsequently declined so that the Newfoundland biomass is now comparable.

A comparison of the relative abundance indices among the various industry surveys (included both longline and mobile gear surveys) provides no strong insights and therefore was not used (Table 18; Fig. 50).

12

In light of the differing seasons for RV surveys across regions in Atlantic Canada, it is difficult to prepare a single within-season index that covers all regions and time periods. Nevertheless, an approximation was prepared. A spring estimate of minimum trawlable biomass was calculated by summing the biomasses from the February Georges (1986 onwards), spring 4VWX (1979-1984 only), March 4VW (1986 onwards) and spring Newfoundland surveys. Aside from gaps prior to 1979 and in 1985, the glaring problem with this estimate is the absence of any spring survey value from 4X after 1984. Given that 4X accounts for most of the dogfish in Atlantic Canada, any viable Canadian spring index must contain a value for 4X in spring. As a proxy value for spring 4X, we used the dogfish biomass in 4X (only) from the summer RV survey for 1985 onwards. By doing so, we have necessarily assumed that summer 4X biomass is comparable to spring 4X biomass. We were able to test this assumption by comparing spring and fall 4X biomasses between 1979-1984, when seasonal surveys were available. On average, spring 4X biomass exceeded summer 4X biomass by a factor of 3.8, while spring 4X abundance exceeded summer 4X abundance by a factor of 2. Therefore, it seems reasonable to conclude that use of summer 4X biomass as a proxy for spring 4X biomass would, if anything, result in a conservative estimate of total biomass. Accordingly, our estimate of total Atlantic dogfish spring trawlable biomass is the sum of the biomasses from the February Georges (1986 onwards), spring 4VWX (1979-1984 only), March 4VW (1986 onwards), spring Newfoundland, and summer 4X (1985 onwards) surveys. This index does not include estimates from 4T, and is probably a gross underestimate for years prior to 1979. However, it probably provides a reasonable approximation of the minimum trawlable adult biomass summed across areas.

The estimate of summer minimum trawlable biomass in Canadian waters was calculated as the sum of the summer 4VWX5Z and 4T surveys. Therefore, the index does not include an estimate for Newfoundland waters, for which no RV survey is available for the 3Ps area most populated by dogfish. Since the summer RV surveys do not adequately represent the abundance of mature females, the summer index is probably a better representation of sub-adult biomass than adult biomass.

A comparison of the spring minimum trawlable biomass between Canadian and U.S. waters is shown in Fig. 51. Neither of these indices is completely accurate, since the U.S. surveys cover parts of NAFO 4X and the Canadian side of Georges Bank, while the Canadian index includes the U.S. side of Georges Bank. To a rough approximation, these two biases may cancel each other out. Both time series show comparable trends, increasing from the early 1980s to the early 1990s, then declining somewhat to the present. Mean values for both indices were around 500,000 mt in the early 1990s, declining to about 300,000 mt in 2007 for the Canadian index. Across the time series as a whole, the U.S. minimum trawlable biomass estimate (NFSC 2006) has been slightly greater than the Canadian minimum trawlable biomass estimate.

The summer/fall minimum trawlable biomass trends for both countries are more variable than are those from the spring (Fig. 51). Both indices show a consistent upward or stable trend from about 1985 to the present. Once again, the U.S. minimum trawlable biomass estimate slightly exceeds the Canadian estimate. The most recent Canadian biomass value is about 350,000 mt, corresponding to about 200 million fish.

A preliminary calculation of overall mature female biomass for Canadian waters was calculated as the sum of the mature female biomasses from the February Georges (1986 onwards), spring 4VWX (1979-1984 only), March 4VW (1986 onwards), spring Newfoundland, and summer 4X (1985 onwards) surveys, thus requiring the same assumption as that required of the total biomass calculation. To test the assumption that 4X summer mature female biomass is comparable to that of spring 4X, two tests were done. In the first test, mature female biomass in 4X was compared

13

between spring and summer in the period 1979-1984, when seasonal surveys were available. Mature female biomass in the spring exceeded that in the summer by an average of 10X. As a second test, we compared spring and summer mature female biomass in 4VW for periods of high (before 1992) and low (after 1992) dogfish abundance. For the period of high dogfish abundance, spring mature female biomass greatly exceeded (~50X) that present in the summer. However, during the period of low abundance, the spring:summer mature female biomass ratio was ~1:1. Given all of these results, we concluded that use of summer 4X summer mature female biomass as a proxy for spring 4X could underestimate actual spring biomass by a very large amount, and thus should not be used. In addition, values for 4T and 3LNOP were not available due to absence of spring surveys (4T) and length frequency data (3LNOP).

Mature female biomass in the various spring RV surveys generally exceeded 25,000 mt in the 1980s, but has declined to lower values in recent years (Table 20). A comparison of U.S. and Canadian mature female biomass across years was not possible because of the unavailability of a spring 4X mature female biomass index. In addition, the U.S. index is based on females > 80 cm total length, while the Canadian indices are based on 82+ cm. However, mature female biomass in the U.S. spring RV survey has declined to much lower values in recent years, albeit with an upturn in the last two years (NFSC 2006; Fig. 52). Without knowing the extent that Canadian spawners contribute to the health of NW Atlantic dogfish metapopulation, it may not be wise to increase the exploitation rate on mature females.

It was not possible to estimate exploitation rate in the absence of a viable population model. However, it did not appear that the apparent recent decline in total Canadian spring biomass can be attributed solely to commercial exploitation (Fig. 51). Total catch (including dead discards) between 1990 and 2006 accounted for about 3,000 mt per year, while the apparent decline in total biomass was closer to 18,000 mt per year. It is unknown if this is an actual loss to the population, and if a loss, if it was temporary or permanent. Emigration to unsurveyed areas and/or unexplained natural mortality could account for this loss, among other factors.

Population Model

A preliminary population model has been developed for dogfish (Appendix 1). This model is an age- and sex-structured, forward projecting population model, which estimates a starting population size and age structure (in 1960), and projects the population forward by adding recruits (age-1 fish) to the population and subtracting catches and natural mortality. Both foreign and domestic landings are included in the model. The model is fit to the abundance indices obtained from research surveys as well as the proportions-at-length in the surveys and commercial catch. Some of the data series used in the model are short and highly variable, and although the summer RV survey potentially indicates a stable or slightly increasing population, some of the other surveys indicate a declining trend. As a result, the model in its present form does not provide robust estimates of abundance. Three variants of the model were used to estimate abundance, each with a different assumed reproductive scenario. The variants were fit to the summer RV survey data alone, and in another iteration to six research surveys. These variants illustrated several problems with the model in its present form, including several aspects of the fishery, dogfish biology and/or data collection process that are not adequately captured. Recommendations for the next iteration of the model included a recompilation of the commercial catch and survey data on the same spatial scale so that spatial structuring within the population and movement can be examined, further separation of the two sexes in the model, examination of sample sizes to ensure that data is weighted appropriately, and further development of a relationship between variability of length-at-age and age. If possible, immigration and emigration

should be incorporated. Robustness of the model estimates with respect to the length of the time series incorporated into the model should also be examined.

Sources of Uncertainty

There is uncertainty surrounding the conclusions of the genetic analysis of spiny dogfish conducted to date at the Bedford Institute of Oceanography. Small sample size, the number of polymorphic loci, and lack of samples from mating aggregations contribute to uncertainty. Lack of U.S. samples is an additional source of uncertainty.

Surveys do not cover the entire range of spiny dogfish in Atlantic Canada. In particular, lack of a spring RV survey in 4X and summer surveys in inshore areas and the upper Bay of Fundy hampers calculations of mature female biomass.

The accuracy of some historic foreign landings has been questioned. The size composition of foreign landings was not reported.

Tagging of males and juveniles has been limited. Limited Canadian fishing effort in winter months complicates the interpretation of winter recaptures.

Bycatch and discarding estimates were based on observer coverage that was limited or absent in some fisheries and years, for which mean values from adjacent years were used. This undoubtedly introduced some error into the discarding estimates.

Some observations from the fishing industry indicate that there might be large females that remain in the Bay of Fundy throughout the winter. This needs to be explored.

Spiny dogfish have been collected in the northern Gulf of St. Lawrence by RV surveys, but the likely presence of black dogfish in amongst the spiny dogfish records confounded attempts to prepare an abundance index for the region.

Conclusions and Advice

For the most part, dogfish tagged in Canadian waters have remained in Canadian waters, and those tagged in U.S. waters have remained in U.S. waters. However, there is some movement (10-20%) between Canadian and U.S. waters, with the Gulf of Maine region being the primary mixing ground. To date, there has been no evidence that migration is associated with a particular sex or size of dogfish.

Spiny dogfish have many characteristics of a metapopulation, and thus presents some interesting implications for fisheries management. First of all, it would suggest that Canadian dogfish cannot be viewed in isolation. At a minimum, if some of the dogfish that currently reside in Canadian waters actually originated in U.S. waters, it means that at least some of the recruitment is dependent on the U.S. stock. Secondly, the existence of a metapopulation would imply that managing northwest Atlantic dogfish as a single stock would be inappropriate. If, as seems likely, some dogfish aggregations colonize or depart Canadian waters *en masse* at periodic multi-year intervals, and then remain resident in those waters for many years at a time, alternate management measures may be more appropriate. Finally, without knowing the extent that Canadian spawners contribute to the health of the northwest Atlantic dogfish metapopulation, it is possible that a fishery on mature females in either Canadian or U.S. waters could impact the abundance in all areas.

Based on analysis to date, median size of females in the catch was found to be 81 cm TL, while that of males was 74 cm TL. In terms of numbers, 66% of the catch consisted of females and 26% consisted of mature females. These numbers are much lower than those present in the U.S. commercial catch, where median body size of females in the catch was 86 cm TL and females made up 91% of the catch numbers between 2002-2005. Dogfish in the Canadian commercial catch tended to be fairly old, with a mean age of 16 years for males and 18 years for females. There was no evidence of "highgrading" at sea.

Estimated dogfish discard mortality has averaged about 850 mt annually since 1986. Discard mortality often exceeded reported catch prior to 1999, but recent landings have greatly exceeded discard mortality.

In the absence of a viable population model, it is not possible to estimate the exploitation rate for spiny dogfish in Atlantic Canada. However, it does not appear that the apparent decline in total Canadian spring biomass can be attributed solely to commercial exploitation. Total catch (including dead discards) between 1990 and 2006 accounted for about 3,000 mt per year, while the apparent decline in total biomass was closer to 18,000 mt per year. It is unknown if this an actual loss to the population and, if a loss, if it was temporary or permanent. Emigration to unsurveyed areas and/or unexplained natural mortality could account for this apparent decline, among other factors.

The Atlantic population of spiny dogfish is more productive than is the northwest Pacific population. However, the long gestation period (~ 2 years), late age of sexual maturation and slow growth rate for spiny dogfish means that the species is relatively unproductive compared to other fish species.

Spring minimum trawlable biomass estimates for spiny dogfish in Canadian and U.S. waters show similar trends, increasing from the early 1980s to the early 1990s, then declining somewhat to the present. Mean values for both indices were around 500,000 mt in the early 1990s, declining to about 300,000 mt in 2007 for the Canadian index. The Canadian spring index is considered to be a better indicator of total adult biomass than is the summer index.

The trends in summer/fall minimum trawlable biomass estimates for spiny dogfish in Canadian and U.S. waters show more variability than do those from the spring. Both indices show a consistent upward or stable trend from about 1985 to the present. The most recent Canadian biomass value is about 350,000 mt (corresponding to about 200 million fish). The summer index is considered to be a better indicator of sub-adult biomass than adult biomass.

It is not currently possible to estimate trends in mature female biomass for spiny dogfish in Atlantic Canada. However, mature female biomass in the U.S. spring RV survey has declined to much lower values in recent years, albeit with an upturn in the last two years. Without knowing the extent that Canadian spawners contribute to the health of northwest Atlantic dogfish metapopulation, it may not be wise to increase the exploitation rate on mature females.

Other Considerations

A spring RV survey of 4X would greatly improve the ability to monitor mature female biomass in Canada, as would a summer survey in shallow inshore waters and the upper Bay of Fundy.

Research to identify the habitat for pupping and the juvenile pelagic stage, and to quantify pup abundance, would aid in predicting stock abundance and determining stock composition.

Further research on stock structure and cross-border movements is required, perhaps through acoustic tagging of both adult and juvenile stages.

Notes: Canada for 1960 - 85 is from NAFO
Canada for 1986 - 02 is from DFO ZIF
Canada for 2003 - 07 is from DFO MARFIS
Northwest Atlantic Data (US/ 1962-2005) is from US 2006 spiny dogfish assessment
Northwest Atlantic Data (US/ 1960-1961) is from NAFO
Germany for 1960 - 05 is from NAFO
Poland for 1960 - 05 is from NAFO
Japan for 1960 - 05 is from NAFO
Spain for 1960 - 05 is from NAFO
USSR for 1960 - 05 is from NAFO
Other countries for 1960 - 80, 04, 05 is from NAFO
Other countries for 1981 - 03 is from IOP non-Canadian kept catch

42
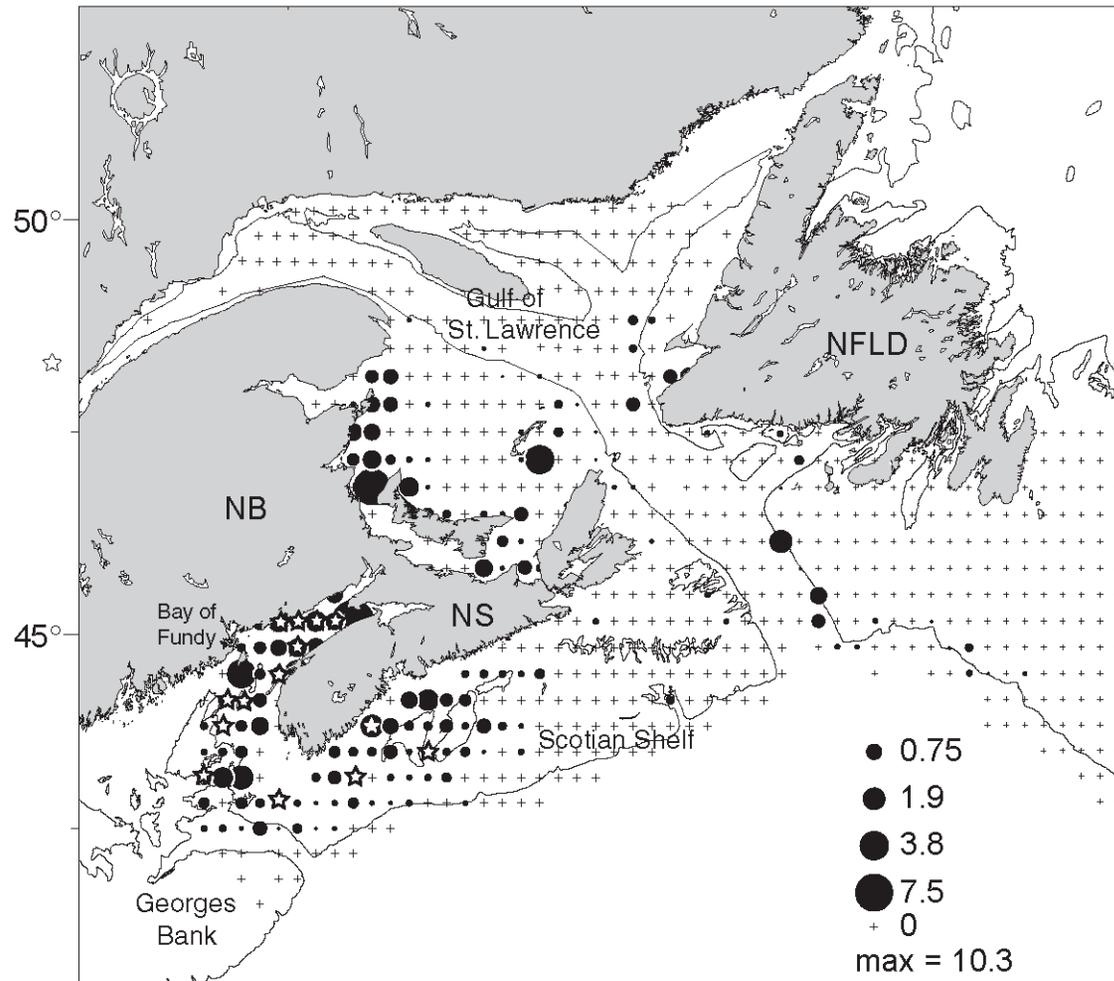

Fig. 3. Distribution of female spiny dogfish of mature size (FL > 73 cm) in summer research surveys of the Scotian Shelf and Gulf of St. Lawrence. Symbols are proportional in size to the mean number of mature dogfish collected within each 20-minute square between 1979 – 2005 inclusive. Survey coverage of the northern Gulf of St. Lawrence and around Newfoundland was 1993 – 2005 (August) and 1971 – 2004 (all months) , respectively. Crosses represent survey sets where mature females were absent. Starred symbols show capture locations of pregnant females in 2003 – 2005 surveys of the Scotian Shelf; maturity examinations were not made in the Gulf or around Newfoundland. The 200-m depth contour is shown. NFLD = Newfoundland; NS = Nova Scotia; NB = New Brunswick.
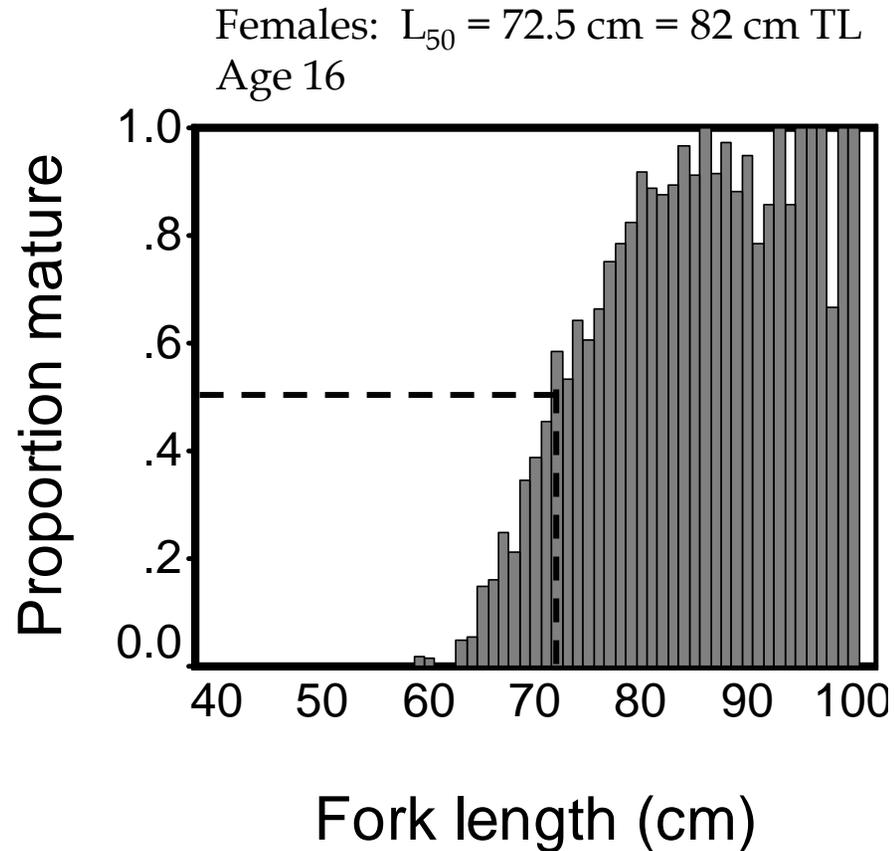

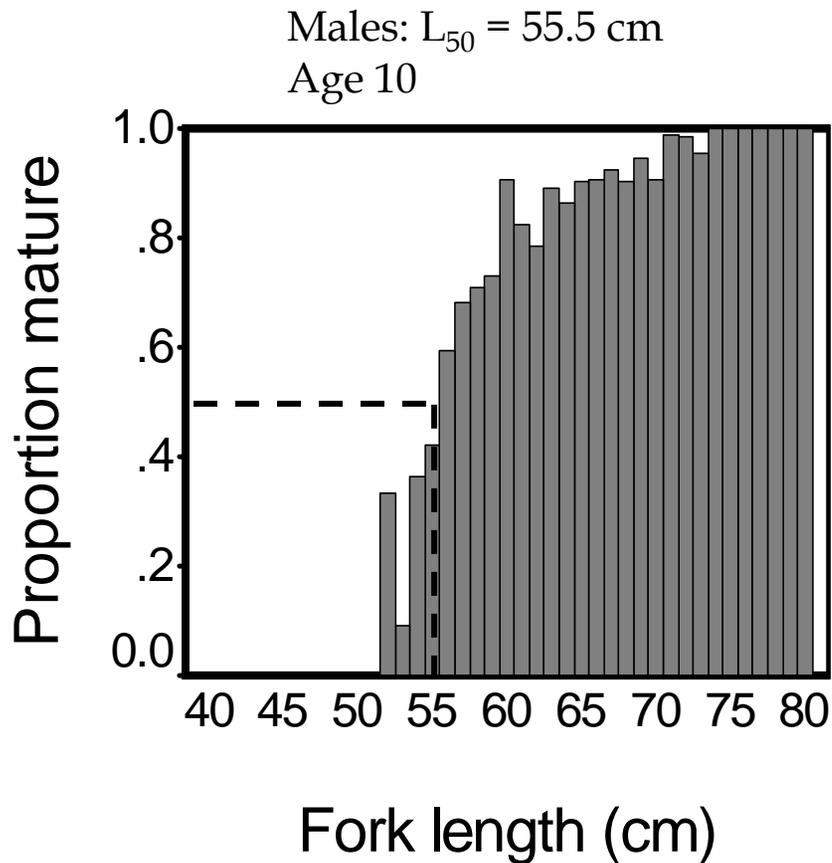

Fig. 4. Maturity ogives for male (n=1723) and female (n=3101) spiny dogfish off southwest Nova Scotia. Dashed lines show the fork length at 50% maturity (L_{50}) as defined by logistic regression.

APPENDIX 1: POPULATION MODELLING

Population Modeling: Methods

Following the approach used by Gibson and Campana (2006) for porbeagle, we used a forward-projecting age- and sex-structured population dynamics model to estimate abundance-at-age, exploitation rates and fishery reference points for this population. Within this model, the population is projected forward from an equilibrium starting point by adding recruitment and removing catches. Model parameter estimates (e.g. selectivity parameters, catchability coefficients, productivity parameters) are obtained fitting the available datasets using maximum likelihood. Nine Canadian fisheries (1986-2006) as well as the total landings of seven countries from 1960 to 2006 were included in the model. Further details of the data collections are provided in the main text of this report. A spawner-recruit function (a Beverton-Holt function) was parameterized using the asymptotic recruitment (R_{asy}) and slope at the origin (α) and was used to model reproduction.

Population dynamics

Of primary interest is the number of fish in year t, of sex s and of age a, denoted $N_{t,s,a}$. The number of fish in each age class in the next year is given by an exponential decay model. Here, the total mortality rate is given by the sum of the sex and age specific instantaneous natural mortality rate ($M_{s,a}$) and the fishery (g) specific exploitation rate in each year, sex and age class ($u^g_{t,s,a}$).

$$N_{t+1,s,a+1} = N_{t,s,a} e^{-M_{s,a}} \prod_g (1 - u^g_{t,s,a}).$$

The spawner-recruit relationship is expressed in terms of the number of females rather than biomass. Using the letter F to denote the female sex category, the number of female spawners in year t (SSN_t) is a function of $N_{t,F,a}$ and the probability that a female fish of age a is mature at that age ($m_{F,a}$):

$$SSN_t = \sum_a N_{t,F,a} m_{F,a}$$

The life cycle is closed by modeling the number of age-1 fish of each sex in the year $t+1$ as a function of SSN_t using a Beverton-Holt spawner-recruit (Hilborn and Walters 1992) relationship:

$$N_{t+1,s,1} = \frac{\alpha SSN_t}{1 + \dfrac{\alpha SSN_t}{R_{asy}}} e^{(\varepsilon_t - \sigma^2/2)} * 0.5$$

Here, α is the slope at the origin, and in the deterministic model is the maximum rate at which female spawners can produce age-1 recruits at low population sizes (Myers et al. 1999); R_{asy} is the asymptotic recruitment level, expressed as the number of age-1 recruits. R_{asy} is the limit approached by R_t as S_t approaches infinity (Beverton-Holt models are often written in terms of the half saturation constant, K, which is related to R_{asy} by: $R_{asy} = \alpha K$). A 1:1 sex ratio at birth is assumed. The model is written so that recruitment can vary around the fitted relationship through

the log of a recruitment deviate for each year (ε_t), in which case a correction for transformation bias based on the standard deviation of the log recruitment deviate (σ) is applied to each deviate, however attempts to estimate deviates to date have not been successful. As written, a lognormal error structure for recruitment (Myers et al. 1995) is assumed. In comparison with the other commonly used 2-parameter SR model, the Ricker model, the Beverton-Holt model has the advantage that R_{asy} can be rescaled and interpreted as an estimate of carrying capacity (Myers et al. 2001), but typically provides estimates of α (and its related reference points) that are higher than those from the Ricker (Myers et al. 1999). Reference points provided by this model are therefore not precautionary with respect to SR model selection.

Commercial fisheries

The influence of commercial fisheries are included in the population dynamics through $u_{t,s,a}^{g}$. This term consists of two separable components: the gear (or fishery) and sex specific selectivity of the commercial fisheries $s_a^{g,s}$ and the exploitation rate of the fully exploited age class by each gear in each year, u_t^g:

$$u_{t,s,a}^{g} = s_a^{g,s} u_t^g$$

Selectivity was assumed to follow a double half Gaussian selectivity curve:

$$s_a^{g,s} = \begin{cases} \exp\left(\dfrac{-(a - s_{full}^{g,s})^2}{v_L^{g,s}}\right) & \text{if} \quad a \le s_{full}^{g,s} \\[4mm] \exp\left(\dfrac{-(a - s_{full}^{g,s})^2}{v_R^{g,s}}\right) & \text{if} \quad a \le s_{full}^{g,s} \end{cases}$$

where g refers to the commercial fishery. In this model, the age at which fish are fully selected by the fishery is denoted $s_{full}^{g,s}$. The steepness of the decline away from the age at full selectivity is governed by the v parameters for the left and right sides of the curve. Note that selectivity includes both the retention selectivity of the gear as well as contact selectivity (the probability that fish come into contact with the gear). Length-frequency data was not available for all fisheries and some assumptions are made about the selectivity of the fisheries. All foreign landings are assumed to have been removed by trawling with a selectivity equal to the more recent summer research vessel (RV) trawl survey. The selectivity of the trawl fisheries is also assumed to match the summer RV survey. Selectivity is estimated for the gillnet and the directed longline/handline fisheries as length-frequency data is available for these fisheries. Nearly all recent landings come from these fisheries.

We assume the catch is taken during a short time period half way through the year, an approximation attributed to Pope (Quinn & Deriso 1999) and that the total catch (biomass) in each year by each fishery (C_t^g) is known without error. The exploitation rate (proportion of the vulnerable biomass removed) in each fishery in each year is then:

$$u_t^g = \frac{C_t^g}{N_{t,s,a} s_a^{g,s} w_{s,a} \sum_{s,a} e^{-0.5 M_{s,a}}}$$

where $w_{s,a}$ is the sex specific weights at age.

Initial conditions

Two approaches were used to estimate the population size and age structure at the start of the time period (1960). The first approach involved estimating two parameters: $N_{1960,1}$ and Z_{start}. The first parameter is the number of age-1 dogfish in 1960 and the second is used to estimate the abundance of dogfish in other age classes in 1960 using an exponential decay function. The second approach adopted for the model runs presented here was to estimate $N_{1960,1}$ and to assume an unfished equilibrium age structure (reported landings in the early 1960's were quite low).

Predictions from the model

Parameter estimates are obtained from the model by minimizing the discrepancies between the observed data and predictions from the model. The model is fit to research survey catches, survey proportions-at-age and the proportions-at-age in some of the commercial fisheries. Constants used in the model are listed in Table A1.1. Thus we want to obtain predictions of the survey catches (I_t^i) where the superscript i is used to index the survey, and to obtain the predicted length composition of the catch in the fisheries and the length composition of the survey catches.

Under the assumption that the survey catch is proportional to abundance, the predicted catch is given by:

$$I_t^i = q^i \sum_{s,a} e^{-\gamma (M_{s,a} + F_{t,s,a})} s_{s,a}^i N_{t,s,a}$$

Here γ is the proportion of the mortality that occurs prior to the survey, set equal to 0.25 for surveys occurring in the spring, 0.5 for surveys occurring in the summer and 0.75 for surveys occurring in the fall. None of the surveys cover the full range of the population, so the catchability of each survey, q^i, included both the catchability of the gear as well as the proportion of the population in the area covered by the survey. Thus, with the exception of the summer groundfish survey which is broken into two parts to reflect a vessel change, an assumption exists that the distribution of dogfish has not changed systematically during the period covered by the surveys.

The sex-specific predicted length compositions in the catches, $P_{t,l}^{g,s}$, are a function of the population age composition, the selectivity curves and the distributions of length at age:

$$P_{t,l}^{g,s} = \frac{\sum_a s_a^{g,s} f_{l|a}^s N_{t,s,a}}{\sum_a s_a^{g,s} \sum_l f_{l|a}^s N_{t,s,a}} \cdot$$

The sex-specific length proportions at age ($f_{l|a}^s$) is given by:

$$f_{l|a}^s (l_a^s, \sigma_a^s) = \frac{\delta}{\sqrt{2\pi}\sigma_a^s} \exp\left[\frac{-\left(x_l^s - l_a^s\right)^2}{2\left(\sigma_a^s\right)^2}\right]$$

where δ is the size of the length increment (3 cm in this analysis). We used a von Bertalanffy growth model to model the relationship between length and age (Figure A1.1), and examined the relationship between the standard deviation of length and age to determine their relationship. No simple relationship was evident (Figure A1.2), so σ_a^s was assumed constant over ages with separate values for each sex. Constants are provided in Table A1.1.

The predicted length compositions in the surveys, $P_{t,l}^{i,s}$ were found similarly.

Likelihood equations

The model was fit to the data by minimizing an objective function (*O.F.V.*) that is the sum of the negative log likelihoods for the survey series (ℓ_{SURVEY}), the length compositions in the catches ($\ell_{catch-comp}$) and the length compositions of the surveys ($\ell_{survey-comp}$). We used lognormal error structures for the total survey catch time series and a robust normal error structure for the proportions at length in the catch and surveys. For each survey, the log-likelihood for the total catch is given by:

$$\ell_{survey}^i = -\sum_1^n \ln \sigma^i - \frac{1}{2}\log 2\pi - \sum_t \frac{(\ln \widetilde{I}_t^i - \ln I_t^i)^2}{2(\sigma^i)^2},$$

where *n* is the number of observations in the series, σ^i is the standard deviation of a normal distribution prior to exponentiation and $\widetilde{I}^i$ is the observed survey index value in year *t*. We used a constant value of 0.3 for all σ^i in this analysis.

For a given gear and sex category, the robust normal log-likelihood for proportions at length in the catch is:

$$\ell_{length-comp.}^{g,s} = 0.5 \sum_{t=1}^{Y} \sum_{l=1}^{A} \log(2\pi(\varsigma_{t,l}^{s,g} + 0.1/A_l)) + \sum_{t-1}^{nyears} A_l \log(\tau_t^{s,g})$$

$$- \sum_{t=1}^{Y} \sum_{l=1}^{A} \log\left[\exp\left\{ \frac{-\left(\widetilde{P}_{l,t}^{s,g} - P_{l,t}^{s,g}\right)^2}{2\left(\varsigma_{t,l}^{s,g} + 0.1/A_l\right)\tau_t^{s,g}} \right\} + 0.01 \right]\quad,$$

where Y is the number ofwith observed proportions at length, A is the number of length categories, $\tau_t^{s,g}$ is the sample size and $\varsigma_{t,l}^{s,g}$ is the variance (Fournier et al. 1990). Sample sizes were arbitrarily set at 1,000 for all years so that the catch-at-length data for all years was weighted equally, and the variance used was that of the predicted proportions (Fournier et al. 1990):

$$\varsigma_{t,l}^{s,g} = P_{t,l}^{s,g}(1 - P_{t,l}^{s,g}).$$

We used a length-frequency distribution of the sexes combined for some years (see the Data section) with appropriate modifications to the above equations.

Two penalty functions are used to constrain the model during estimation. Because the catch-at-age is subtracted from the numbers-at-age, a small penalty is added to the objective function to keep the numbers-at-age positive. A second penalty function is used to constrain the exploitation rate to be less than 50%.

The final objective function is then:

$$O.F.V. = -\left(\sum_i \ell^i + \sum_{g,s} \ell_{catch-comp.}^{g,s} + \sum_{g,s} \ell_{survey-comp.}^{i,s} + penalties \right)$$

We programmed this model using AD Model Builder (Fournier 1996). AD Model builder uses the C++ auto-differentiation library for rapid fitting of complex non-linear models, has Bayesian and profile likelihood capabilities, and is designed specifically for fitting these types of models.

The production model and reference points

We modelled the population dynamics using two equations: a spawner-recruit relationship that expresses recruitment as a density dependent function of spawner abundance, and the replacement line, the slope of which is the inverse of the rate at which recruits produce replacement spawners. Here, an implicit assumption is made that all density-dependent processes occur between spawning and recruitment. The production model also includes a third component: a yield per recruit relationship. Recent Canadian landings are highest in the directed longline/handline fishery. We therefore used the selectivity curves for this fishery when estimating reference points. All results are therefore specific to that fishery. Results would vary if other selectivity curves were assumed.

The SR model was discussed in the previous section. We modelled the rate at which recruits produce spawners (the inverse of the slope of the replacement line) by calculating the number of

spawners per recruit (SPR_F) as a function of fishing mortality (Shepherd 1982, Mace and Sissenwine 1993, Mace 1994):

$$SPR_F = 0.5 \sum_1^{a_{max}} \left[m_a e^{-\sum_1^{a-1}(M_{F,a-1}+F^g_{F,a-1})} \right] ,$$

where $F^g_{F,a}$ is the age and gear specific fishing mortality rate for females. Again, these calculations are specific to the selectivity assumed in the calculation.

The yield per recruit for a given F (YPR_F) is found similarly:

$$YPR_F = \sum_s \sum_1^{a_{max}} e^{-\left(0.5M_{s,a}+\sum_1^{a-1}(M_{s,a-1}+F^g_{s,a-1})\right)} \left(1 - F^g_{s,a}\right) w_{s,a} .$$

For a given value of F, the spawning biomass produced by the number of recruits in year t is $SSN = SPR_F \cdot R_t$. Equilibrium spawning biomasses and recruitment levels (denoted with asterisks) were found by solving this equation for R_t, and substituting the result into the spawner-recruit model (Quinn and Deriso 1999):

$$\frac{SSN*}{SPR_F} = \frac{\alpha SSN*}{1+\dfrac{\alpha SSN*}{R_{asy}}} .$$

The equilibrium spawning biomass ($SSB*$) is then:

$$SSN* = \frac{(\alpha SPR_F - 1)R_{asy}}{\alpha} ,$$

and the equilibrium number of recruits ($R*$) is found by substituting the $SSN*$ in the spawner-recruit model:

$$R* = \frac{\alpha SSN*}{1+\dfrac{\alpha SSN*}{R_{asy}}} .$$

The equilibrium catch ($C*$) is $R*$ multiplied by the yield per recruit for the given value of F:

$$C* = R* \cdot YPR_F .$$

Reference points from the spawning biomass per recruit and yield per recruit analyses were found using a grid search across a set of F's {0 to 4.0; increment of 0.0025}. We calculated YPR_F and SPR_F for each value of F, and reference points were then estimated by selected the fishing mortality rate corresponding to the appropriate reference point criterion. The $SPR_{x\%}$ reference points were found by selecting the fishing mortality rate where the SPR_F was x% that of $SPR_{F=0}$.

We estimated five reference points from the production model. The equilibium spawning biomass in the absence of fishing, SSN_{eq}, was estimated directly from the production model. A spawning biomass of 20% SSN_{eq} is sometimes used as a minimum threshold population size (Beddington and Cooke 1983, Goodyear 1993). $SSN_{20\%}$ was calculated as 20% the equilibrium female spawner abundance in the absence of fishing:

$$SSN_{20\%} = 0.2 \frac{(\alpha SPR_{F=0} - 1)R_{asy}}{\alpha}$$

The grid searches were used to find the fishing mortality rate that produces maximum sustainable yield (F_{msy}), the corresponding spawner biomass that produces maximum sustainable yield (SSN_{msy}) and the fishing mortality rate that drives the population to extinction (F_{col}). We estimated F_{msy} by calculating C^* for each value of F, and selecting the value where C^* was maximized. SSB_{msy} was the value of S^* corresponding to this fishing mortality rate. The equilibrium fishing mortality rate at which the population goes extinct, F_{col}, is determined by the slope of the SR relationship at the origin α, and is the value of F where $1/SPR_{F=0} = \alpha$.

Population Modelling: Data

Data used in the model are shown in Figures A1.3 to A1.13. The survey data series (Figure A1.3), show different trends. The cod4VW RV survey, Georges RV, and sentinel 4VsW longline survey show declining trends in the index value. The summer RV survey is split into two indices to reflect a gear change in 1982. Taken together, these surveys show an increasing trend, whereas if treated separately, they indicate a high but stable population in recent years. The total landings (Figure A1.3) were primarily foreign from the mid-1960's to the late 1970's whereas the bulk of the recent landings are domestic. Most of the recent landings are in the directed longline/handline and gillnet fisheries (Figure A1.4).

Length-frequency data for the commercial fisheries that were used in the model are: the 4X longline/handline fishery from 1997 to 2006 (Figure A1.5), the 4W gillnet fishery from 2003 to 2006 (Figure A1.6) and the 4X gillnet fishery (Figure A1.7). Trends are not obvious in these data although the data are variable from year-to-year and a marked outlier is present in the 4X gillnet data for males.

Six length frequency data series were used from the surveys (Figures A1.8 to A1.13). The summer survey proportions-at-length (Figure A1.8) show decreasing proportions of smaller dogfish from the mid-1990's onwards, although some recent surveys have captured proportionally higher numbers of smaller dogfish. The 4VsW sentinel longline survey (Figure A1.9) and the 4VW cod survey (Figure A1.10) have highly variable proportions-at-length. The Georges RV survey (Figure A1.12) also shows a shift to greater proportions of larger dogfish with some exceptions since 2000.

Population Modeling: Results and Discussion

We took a stepwise approach to building this population model. We first included only the commercial data and summer RV survey data, and then added the other data discussed above. More data could be added to the model, although addressing some of the issues identified herein should be a first step prior to expanding the model (see discussion).

When examining the model results, the reader should be aware of some of the model behaviours. The first is that, in its present form, the model has a tendency to converge at local minima. Although the summer RV survey index suggests an increasing population size, the summer proportions-at-length and some other survey data are indicative of a declining population size. One solution to this issue is for the model to drift to very high constant population size estimates (hundreds of billions) and to assume all trends are noise. In these runs exploitation rate estimates are extremely low, and if estimated in the model, the estimate of α tends to a low value so that the population size does not change much from 1960 to present. This problem was more common when all data were included. A second behaviour is that in nearly all formulations that were evaluated (most of which are not presented), if R_{asy} is estimated within the model, the estimate is equal to the upper bound, even at high values for α. In the runs presented, R_{asy} is fixed arbitrarily at 50 billion age-1 recruits. As a result, very little density dependence occurs within the model, and for this reason fishery reference points such as B_0, F_{msy}, B_{msy} have little meaning. They are not presented in the results for this reason. When convergence occurs at more realistic abundance levels (and at a lower OFV), the estimates of α exceed the maximum fecundity of dogfish by a factor of about three.

In an attempt to avoid the above issues, we fit models with α set at constant values ranging form 1.25 to 4. Given an average litter size of 6 pups every 2 years, an alpha of 1.25 would correspond to a survival to age-1 of roughly 40% and, assuming the survival rates and maturity schedule herein, corresponds to a lifetime reproductive rate of 1.04. A value of 4 slightly exceeds the average annual fecundity (but not that expected from larger females) and corresponds to a lifetime reproductive rate of 3.34. These scenarios are intended to bracket what might be plausible reproductive rates for dogfish.

Six model runs are presented in this paper to illustrate the above issues: three models fit only to the summer RV and commercial proportions-at-length data with values of α set at 1.25, 2, and 4, and three models fit to all the data with α set at 2 (two runs with different starting vales for N_1) and at 4. Parameter estimates are provided for all six models, but the diagnostic plots are provided only for the model fit to all the data with α set at 2 and a low starting value for N_1. For the reasons above, as well as some of the residual issues discussed below, none of the results presented should be interpreted as being a good approximation of the status of dogfish.

Model parameter estimates for the summer RV survey only fits (Models 1 to 3; α = 1.25, 2 and 4 respectively) are provided in Table A1.2. Parameter estimates for the model runs fitted to all the data: two with α =2 (two runs with different starting vales for N_1) and one with α =4 are provided in Table A1.3. In Model 4, the starting value for N_1= 70 million fish, and in Model 5 it is set at 1.7 million fish, and the models converge at different values with different trajectories. Model 6 has α =4.

Both abundance estimates (Tables A1.4 and A1.5) and abundance trends (Figure A1.14) differ markedly among models. Models 1 and 5 show a declining trend in spawner abundance, models 2 and 4 show no trend, whereas 3 and 6 show a strongly increasing trend. This pattern is mostly explained by the assumed productivity in each run.

Selectivity parameters are mostly similar among the models (Table A1.2 and Table A1.3), and indicate a relatively narrow selectivity curve for all gear except the new summer survey and spring survey for females (Model 5 example in Figure A1.15). These selectivity patterns are likely too narrow to be real, although dogfish at times do segregate by age which is a possible explanation for the pattern. Fits to the survey data (Model 5 example in Figure A1.16) do vary

among models, but the jump in catchability in the summer survey associated with the gear change, as well as the lack of fit to the sharp declines in the cod4vsw and Georges RV surveys, are characteristic of all model fits. This sharp decline is more likely representative of a change in distribution rather than a change in overall abundance.

The spawner-recruit relationship for Model 5 (Figure A1.17), indicative of little to no density dependence in the processes determining abundance, was similar in all 6 models. If this pattern holds true in subsequent analyses, the implication for fisheries management is that the MSY reference points, which are based on the concept of a compensatory density dependent response to decreased abundance, would not have meaning for this population, at least over the range of abundances observed here.

Numbers-at-age (Model 5 example in Figure A1.18) indicate an issue with the fit for some models: the estimated abundance in the starting year is unrealistically low and influences abundance during those first years. Residual plots for the proportions-at-length (Figures A1.19) show some issues with model fit. Particularly with the summer RV data, the residual pattern is skewed with respect to age, and also shows a pattern through time, with larger residuals in the earlier and later years.

While the output from this model must be treated with caution, the 6 scenarios presented here all place spawner abundance in 2006 in the range of 5 to 35 million. If the models with α =4 are not included (say if the productivity was deemed unreasonably high), then the higher estimates are about 20 million. The commercial length frequency data suggests that the mode of the selectivity curves for the fisheries are typically near or above the age of 50% maturity. If true, dogfish are afforded the opportunity to reproduce prior to being removed by the fishery.

The following modifications to the model in its next iteration are suggested as ways to improve the model:

> 1. Compile the commercial catch and RV data on the same spatial scale so that spatial structuring within the population and movement between areas can be examined more readily.
>
> 2. Although the model is a two sex model, some parameters are common between the two sexes. Modelling the two sexes completely separately may improve model performance particularly if the spatial distribution differs between sexes. Separate q's may improve the selectivity curves.
>
> 3. The variability in the proportions-at-length in some of the data series may be contributing to the unrealistic selectivity curves presented herein. In this version of the model, sample size is assumed constant. Using the actual sample sizes might improve the fits, particularly if the more extreme observations are the result of small samples.
>
> 4. The assumption in the present model that the standard deviation of length-at-age is constant is likely unrealistic and a topic for further research.
