Assessment of the Bay of Fundy sea urchin fishery, Lobster Fishing Area 36

Évaluation de la pêche à l'oursin de la Baie de Fundy, zones de pêche du homard 36

David Robichaud

Department of Fisheries and Oceans Population Ecology Section, Maritimes Region Biological Station 531 Brandy Cove Road St. Andrews, New Brunswick E5B 2L9

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research documents are produced in the official language in which they are provided to the Secretariat.

La présente série documente les fondements scientifiques des évaluations des ressources et des écosystèmes aquatiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit envoyé au Secrétariat.

Robichaud, D. 2010. Assessment of the Bay of Fundy sea urchin fishery, Lobster Fishing Area 36. DFO Can. Sci. Advis. Sec. Res. Doc. 2010/002. vi + 60 p.

ABSTRACT

The green sea urchin (Strongylocentrotus droebachiensis) commercial fishery was initiated along the coast of southwestern New Brunswick, in the Bay of Fundy, in 1989. The sea urchin fishery was separated into 2 management areas. These 2 areas were assigned the same boundaries as Lobster Fishing Areas (LFAs) 36 and 38. In LFA 36, the existing sea urchin fishery is based on a total allowable catch (TAC) system. The sea urchins are harvested mainly by diving and to a lesser extent by dragging. Presently, there are 14 diver based licence operators and only 4 licensed dragging operators. It is currently managed using a minimum legal size limit of 51 mm test diameter (TD) and by a fishing season. A TAC of 900 t was established in 1996 and it has been in place since. In this assessment, fishing effort, landings trends and catch rates were evaluated using logbook information. In addition, sea urchin size structure, densities and biomass were re-evaluated using diver based survey information. The traditional fishing grounds around Campobello Island, Deer Island, and Letete to Pocologan area were resurveyed in 2002-03 and the results compared with the previous survey results from the 1992-94 surveys. In addition, the expansion area from Maces Bay to Chance Harbour, where no previous surveys had been done, was surveyed in 2002. The TAC and harvesting rates were revised.

Since the establishment of a 900 t TAC in 1996, landings remained below 800 t. However, during the last 4 fishing seasons, urchin landings have exceeded the TAC twice and remained the highest since 1996. There has been a increasing trend in catch per unit effort (CPUE) for both the dive and drag fisheries since 1991-92. The proportion of the catch harvested by divers has fluctuated between 65% (1997-98) and 88% (2003-04). With the exception of Deer Island, where legal size sea urchin densities have decreased, all other areas show no significant differences in densities between the 1992-94 and 2002-03 survey periods. With the exception of immature urchins (< 25 mm TD), the density of urchins was significantly higher in the shallow depth strata (0 - 10 m) during both survey periods. Total biomass has changed little between the 2 survey periods. Estimated fishable biomass appears to have declined, but is not significantly different between the 2 surveys due to a high degree of variability. Based on the established TAC of 900 t, the harvesting rate is estimated to be 7.9%-1.1% higher than the harvesting rate of 6.8% that was approved in 1996. However, the Passamaguoddy Bay area is also fished, but has never been surveyed and, therefore, no biomass estimate for this area is available. For that reason, the 7.9% harvesting rate is an overestimate. A review of the survey design and another survey in the next 2-3 years is recommended.

RÉSUMÉ

La pêche commerciale de l'oursin (Strongylocentrotus droebachiensis) a débuté le long des côtes sud-ouest du Nouveau-Brunswick, dans la baie de Fundy en 1989. Cette pêche d'oursin a été divisée en deux zones de gestion. Ces deux zones possèdent les mêmes délimitations que les Zone de Pêche du Homard (ZPH) 36 et 38. Présentement, dans la ZPH 36, la pêche d'oursin est basée sur un système de Prise Totale Alloué (PTA). Les oursins sont pêchés en grande partie avec des plongeurs mais aussi avec des dragues. Actuellement, il y a 14 opérateurs de plongée et 4 operateurs de dragage. Cette pêcherie est actuellement gérée en utilisant une limite de taille légale minimale de 51 millimètres (diamètre du test (DT)) et par une saison de pêche. Une PTA de 900 t a été établi en 1996 et a demeuré en place depuis. Dans cette évaluation, l'effort de pêche, les tendances des débarguements et le taux des prises ont été évalués en utilisant l'information des journaux de bord. De plus, la structure de taille, la densité et la biomasse des oursins ont été réévalués pour la ZPH 36, en utilisant l'information obtenue par des échantillonnages en plongé sous marine. Les lieux traditionnels de pêche aux alentour de Campobello Island, Deer Island et le long des côtes entre Letete et Pocologan ont été échantillonnés en 2002-03 et les résultats ont été comparés avec les résultats du sondage précédent en 1992-94. De plus, un lieu d'expansion de pêche entre Maces Bay et Chance Harbour, où aucun sondage précédent n'avait été faite a été échantillonné en 2002. Le PTA et les taux de capture ont été passés en revue.

Depuis l'établissement d'une PTA de 900 t en 1996, les débarquements sont restés au-dessous de 800 t. Cependant, pendant les guatre dernières saisons de pêche, les débarguements d'oursins ont excédé le PTA deux fois et sont restés les plus hauts depuis 1996. Depuis 1991-92, il y a eu une constante augmentation dans les prises par unité d'effort pour les plongeurs et les dragueurs. La proportion de la prise débarguée par les plongeurs a fluctué entre 65 % (1997-98) et 88 % (2003-04). À l'exception de Deer Island, où la densité d'oursin de taille légale a diminuée, tous les autres secteurs ne montrent aucune différence significative dans la densité d'oursin entre les périodes de sondages de 1992-94 et de 2002-03. À l'exception des oursins immatures (< 25 millimètres DT) la densité d'oursins était significativement plus haute dans les strates de profondeur peu profondes (0 - 10 m) pendant les deux périodes de sondages. La biomasse totale a changé peu entre les deux périodes de sondages. La biomasse d'oursins de taille commerciale semble avoir baissé, mais n'est pas significativement différent entre les deux sondages en raison d'un haut degré de variabilité. Basé sur un PTA de 900 t, le taux d'exploitation présent a été évalué à 7.9 % - 1.1 % plus haut que le taux d'exploitation de 6.8 % établi en 1996. Cependant, le secteur de Baie de Passamaguoddy est aussi pêché, mais n'a jamais été échantillonné et donc aucune évaluation de biomasse pour ce secteur n'est disponible. Pour cette raison le taux d'exploitation de 7.9 % est un surestimés. On recommande une revue des méthodes de sondage et un autre sondage dans les prochain 2 à 3 ans.

1. INTRODUCTION

The green sea urchin (*Strongylocentrotus droebachiensis*) fishery along the coast of southwestern New Brunswick, in the Bay of Fundy, operated at a small scale in the 1950s, 1960s, and the early 1980s. The commercial industry did not actually develop until 1989. The sea urchin fishery in southwestern New Brunswick was separated into 2 management areas. These 2 areas were assigned the same boundaries as Lobster Fishing Areas (LFAs) 36 and 38 (Figure 1). In LFA 36, the existing sea urchin fishery is base on a total allowable catch (TAC) system. The urchins are harvested mainly by diving and, to a lesser extent, by dragging. It is currently managed using a minimum legal size limit of 51 mm test diameter (TD) and by a fishing season. Fisheries based in both LFAs are also eligible to fish in a small adjoining area, LFA 37. The majority of the catch is taken from shallow water coastal areas less than 10 m.

Management and sea urchin fishers were concern about the lack of up to date information on the status of the sea urchin stock. In order to address this lack of information, diver-based sea urchin surveys were initiated during the summer of 2002 and 2003. The objective was to survey the expansion area from Maces Bay to Chance Harbour, where no previous survey had been done, and to resurvey the traditional fishing grounds around Campobello Island, Deer Island, and the area along the coast between Letete and Pocologan (Figures 2, 3, 4, and 5).

This report has the following objectives:

- Evaluate the status of the sea urchin stock in LFA 36 and the impact of the fishery.
- Compare the more recent information with the previous surveys results from the 1992-94 surveys.
- Revise the overall legal biomass estimates and review the total allowable catch.

1.1 BIOLOGY

The green sea urchin, *Strongylocentrotus droebachiensis*, is an echinoderm that is distributed in the Atlantic Ocean from New Jersey to the Arctic, extending south to Britain. It is also distributed in the Pacific Ocean from Washington to Alaska. The animals are omnivorous in nature, although they feed primarily on seaweeds. Sea urchins are most plentiful in shallow waters less than 10 m deep, although they may be found down to 1,200 m. Urchins can be found on virtually any type of substrate, but they generally prefer harder surfaces. The animals have separate sexes, mature at approximately 25 mm test diameter (TD), and spawn in late winter/early spring. The planktonic larvae settle in 8 to 12 weeks. Growth can be quite variable, and is dependent on food supply and environmental conditions. The time estimated to reach commercial size (51 mm TD) may take from 3 to 15 years. Currently there are no estimates of natural mortality available. There is no evidence of mortality due to the infectious disease caused by *Paramoeba invadens* in the Bay of Fundy, as has been experienced in the past along the Atlantic coast of Nova Scotia.

1.2 RECENT MANAGEMENT ISSUES

The sea urchin fishery exploitation rate is currently based on a percentage of fishable biomass (6.8%, implemented in 1996) that was estimated using survey data from 1992-94 (DFO 1996). The last peer-reviewed advice on biomass for LFA 36 was completed in 2000 (DFO 2000). Updated peer-reviewed advice on the fishable biomass is required, including results of resource surveys from 2002 and 2003.

2. THE FISHERY

The LFA 36 sea urchin fishery is currently managed by Fisheries and Oceans Canada (DFO). A Conservation and Harvesting Plan (CHP) was developed in consultation with all the license holders in the fishery. At the present time, all participants must have a personal fisher's registration, and the fishery is subject to owner operator policies. The CHP includes; a minimum size limit (TD of 51 mm or 2.0 in.); sea urchins to be sorted and culled on the fishing grounds as soon as possible, with the culled animals returned to the sea immediately upon being culled and in a manner that causes the least harm; harvesting between sunrise and sunset; mandatory submission of logbooks; and dockside monitoring of 50% of all landings (trips). The season extends from October 1 to May 15. At the inception of the commercial LFA 36 sea urchin fishery in the early 1990s, this fishery was limited entry and the number of licenses by gear type was split evenly. The conversion of a drag license to a dive license is permanent, which is a management measure to gradually move the fishery toward an all-dive fishery. As of 2008-09, there were 14 diver based license operator and only 4 licensed dragging operators. The conversion of a drag license is permanent.

The diver-based fishing consists of a maximum of 4 divers in the water and 2 skiffs with a maximum length of 7.3 m (24 ft) each. The skiffs may be used within 457 m (1,500 ft) of the mother boat to tend the divers.

Dragging operations are required to use urchin drags with a maximum opening width of 3 m (10 ft). In addition, dragging operations are subject to mobile gear restrictions that limit access to inshore areas off LFA 36 until the second Tuesday in January, and again starting April 1 until the end of the season to avoid gear conflicts with other fleets and specially designated non-fishing areas.

The fleet operates competitively under a TAC of 900 t. These management measures are reviewed on an annual basis with members of the sea urchin industry.

2.1 LOGBOOKS, LANDINGS, AND CATCH RATES

Landing trends in LFA 36 are analyzed using logbook information. Logbook data are used to calculate effort trends and catch per unit of effort (CPUE) indices for individuals, groups, and locations. Catch rate and effort trends based on the analysis of logbook information is presented as the average kilogram of sea urchin landed per fishing trip (kg/trip) and the total number of fishing trips during each fishing season.

Log information on number of tows, average duration of each tow, or average dive time per diver is only available since 2003. All fishing trips with landings less than 200 kg were not included in the analysis. These trips were considered incomplete due to boat breakdown or bad weather condition. The CPUE information used for the fishing seasons between 1991-92 and 1996-97 comes from the DFO 2000 Stock Status Report (DFO 2000). For that data series, separate urchin landings from drag and dive licences are not available.

During fall 2008, a new type of logbook was introduced, that reported the location of fishing by previously defined fishing areas (Appendix 1). The fishing areas were determined based on biological and fishing characteristics that were previously determined during diver-based surveys and fisheries information from the urchin fishers. However, data from the new logbook were not yet available in time to be analyzed for this report.

3. DIVER BASED SEA URCHIN SURVEYS

3.1 INTRODUCTION

In LFA 36, a seasonal TAC of 900 t was established in 1996 based on biomass estimates from diver based surveys that were done between 1992, 1993, and 1994 in Campobello Island, Deer Island, and Letete to Pocologan fishing areas (Figures 2, 3, and 4). The TAC was set on an estimated total biomass of legal size urchins of 13,245 t (6.8%). Since 1992-94, the sea urchin fishery expanded further along the New Brunswick coast into Maces Bay, and up to the Chance Harbour area (Figure 5).

More recently, urchin surveys were initiated during the summer of 2002 and 2003 and included the newer area of Mace Bay. These initiatives were made possible through Joint Project Agreements (JPA) between the license holder groups, Sea Urchins of New Brunswick Inc., the St. Mary's First Nation, and Fisheries and Oceans Canada.

3.2 MATERIALS AND METHODS

3.2.1. Survey Methods

The 2002-03 survey methods were based on similar diver transect methods used during the 1992-94 surveys (Robinson and MacIntyre 1993, 1995). Although fewer transects were sampled overall, they were located in the exact same positions as in the 1992-94 survey. Only data from locations resurveyed in 2002-03 were compared with the corresponding locations surveyed in 1992-94.

Prior to the start of the 2002-03 sea urchin dive surveys, preliminary information on the distribution of commercially important beds of sea urchin was gathered from urchin logbooks and from confidential interviews with individual fishers. This information was used to define fishing locations of relative importance to be included in the survey.

Three major fishing areas were defined, based on the 1992-94 survey. The Campobello Island area, which included all the fishing locations around Campobello Island (Figure 2), the Deer Island area, which included all the fishing locations around Deer Island, and the surrounding Islands (Figure 3), and the Letete area, which included the coastal fishing locations between Letete and Pocologan (Figure 4). The dive transects that were completed during July, August, and September of 2002-03, were located at the exact same positions as in the 3 fishing areas that were surveyed in 1992, 1993, and 1994 (Figures 2, 3, and 4). The locations that were resurveyed were chosen mainly because of their high importance to the fishery. However, several locations were chosen due to their proximity to home port of the available survey vessels.

A fourth fishing area, called the Maces Bay area that was not part of the fishing grounds during the 1992-93 survey was surveyed in 2002. Maces Bay includes the coastal fishing locations between Maces Bay and Chance Harbour (Table 3; Figure 5). The locations of the additional transects in Maces Bay were determined based on same survey methods used during the 1992-94 surveys (Robinson and MacIntyre 1993, 1995).

The coastline in the new Maces Bay fishing area was divided into fishing locations. Each location was prioritize as high, medium, or low importance based on fisher information, The coastline within each location was then divided every 250 m intervals, and each potential

transect was assigned a number. The position of each transect was selected so that they began at MLW and extended perpendicular to shore. In areas where water depth under 10 m extended longer distances from MLW, additional transects were placed further out at 250 m distance from MLW. Transects were then randomly selected within each location. The number of dive transect within each location was determined based on the size of fishable bottom area within each location and weighted by an importance factor of high: medium: low, (3:2:1). For example, a high importance location was assigned 3 times as many dive transects as a low importance location of the same size.

The transects were laid out with a collapsible 2-meter bar holding 150 m of 3/16" nylon rope wound on a rotating spool. The line was marked with twine markers every meter and with numbered tags every 10 m. At the end of each transect, one of the divers would collapse the bar and rewind the transect line on the rotating spool with the help of an attached handle.

Most transect began at MLW and continued perpendicular to shore up to a maximum distance of 150 m. GPS coordinates were recorded at the beginning of each transect along with a compass heading. Two divers swam side-by-side, jointly holding a 2 m long, foldable bar and counted the urchins as they passed under the bar 1 m on each side of the transect line. At every 10 m interval along the transect line, the divers recorded the numbers of urchins and noted their relative size, depth, and bottom type. Mycrophyte composition and other commercially important benthic species were recorded.

After the completion of each dive transect, a maximum of 4 size frequency samples of 100 urchins each were collected at intervals based on size characteristics previously observed along the transect, and the depth of each sample was recorded. The 4 samples were then brought up to the vessel, and the TD were measured to the nearest millimetre. Approximately 30 urchins of commercial size (> 50 mm TD) were broken open and the roe was graded into 6 categories according to the following description:

1. Grade A light: The roe is a bright yellow color and has a very smooth, firm texture. The roe is 2.5 to 3 cm long and is divided into 2 clear distinct halves by a small vein running down the middle.

2. Grade A dark: The roe is a tangerine orange color and has a smooth, firm texture. The roe is 2.5 to 3 cm long and divided into 2 clear distinct halves by a small vein running down the middle.

3. Grade B light: The roe is a paler yellow color and has a smooth firm texture but softer than Grade A. The roe is 2.5 to 3 cm long and the 2 halves are less distinguishable.

4. Grade B dark: The roe is a paler orange color and has a smooth firm texture but softer than Grade A. The roe is 2.5 to 3 cm long and the 2 halves are less distinguishable.

5. Grade C: The roe is a dark yellow or orange color and has soft rough texture. The roe is 2 cm long and the 2 halves can still be differentiated.

6. Poor quality roe: The roe is red, brown, greyish brown or very dark in color and can be variable sizes. The roe has a very soft texture and has a rough or granular appearance with occasional whitish patches.

Roes rated into the first 4 categories are considered acceptable for market.

3.2.2. Ageing and Growth

A useful tool in assessing the status of a population is by determining the age structure of this population. Robinson and MacIntyre (1997) have demonstrated that populations of sea urchins throughout the southwestern New Brunswick area differ in their size and age distributions, and in some areas could be up to 25 years old. Their results showed a great deal of variation in the age at a particular size, suggesting the animals were limited in their growth potential, probably through lack of food. For example, a 20 mm sea urchin could be between 2 and 10 years old, while a 50 mm sea urchin could range from 4 to almost 25 years.

Robinson and MacIntyre (1997) noted that older urchin do not grow as quickly as younger ones of the same size and that urchins may be older than previously thought. The ageing is based on the number of rings found in the coronal test plates and the rotulas (components of the Aristotle's lantern). The ageing processing methods followed was the same as described by Robinson and MacIntyre (1997). Each ring is assumed to be the equivalent of a year of growth based on similar assumptions as for tree rings or otholytes rings in fishes.

During 2002-03, after completion of each transects the Aristotle's lantern of approximately a dozen sea urchins of various test diameters of legal size urchins (\geq 51 mm TD) were collected for ageing and growth. The lanterns were then brought to the lab and frozen until they could be processed later. The ageing data collected during 2002-03, were compared to previous data collected at similar location during the early 1990s.

3.2.3. Biomass Calculation

The urchin biomass was calculated for each location based on the urchin's size, density, and the relationship between the test diameter and wet weight. Within each location, the total bottom area was estimated for the section between the MLW and the 10 m stratum and the section between the 10 and 20 m stratum. Within each location, the density of urchins in number per meter square was calculated separately for the 2 depth strata, and then the total number and biomass of urchin were summed up for each location. Within each location, the dive transects data were pooled. The size-weight equation (Robinson and MacIntyre 1993, 1995) used in the conversion of the size frequency data is:

Weight (g) = $0.0009947 \times \text{Test Diameter (mm)}^{2.77}$.

As in the previous surveys, the total number of urchin and the biomass was estimated for each location. Urchin densities, in number of urchins per square meters (Number of urchins/m²), based on size groupings, locations, and depth strata were compared between survey periods using ANOVA analysis. In the analysis of variance, only the averages of all the mean densities from each location within each fishing area were compared between survey periods and depth strata.

4. RESULTS AND DISCUSSION

4.1. THE FISHERY

4.1.1. Landings

For the first 6 years, since the inception of this commercial fishery in 1989-90, landings increased dramatically until 1994-95 (Table 1; Figure 6). A TAC of 900 t was established in 1996 and it has been in place for the subsequent 12 years. For the following 7 fishing seasons, landings remained below 800 t and declined to lows of 617 and 619 t during the 1999-00 and 2000-01 seasons. Subsequently, during the 2004-05 fishing season, landings peeked at 1,068 t followed 3 years later by the second highest landing (1,028 t) during the 2007-08 season (Table 1; Figure 6). Landings exceeded the TAC in 1996-97, 2004-05, and 2007-08. During the years when the fleet TAC was exceeded, final landing statistics were summarized only later after the end of the season.

The proportion of the catch in LFA 36 harvested by divers has fluctuated between 65% (1997-98) to 88% (2003-04) and is currently at the long-term average of approximately 77% (Table 1).

4.1.2. Catch Rates

There has been an increasing trend over time in CPUE for both the dive and drag fisheries since 1991-92 (Figure 7). This could be due to improved fishing practices and experience, changing market conditions, or changes in abundance.

In the dive fishery, since the 1991-92 fishing season, the seasonal CPUE per dive trip increased from 519 kg/trip to a peak of 912 kg/trip during 1995-96. Over the next 7 seasons (between 1997-98 and 2003-04), the seasonal catch rate fluctuated between 595 and 739 kg/trip. The catch rate peaked again at 911 kg/trip during the 2004-05 fishing season and since then remained at higher level above 827 kg/trip (Table 1; Figure 7).

For the dive fishery, the number of fishing trips showed an increasing trend from 1999 to 2005, but has been variable in recent years (Table 1). The total number of dive trips per season varied between 661 and 979. The highest numbers of fishing trips were recorded during 2004-05 (979 trips) and during 2007-08 (909 trips).

For the drag fishery since the 1991-92 fishing season, the seasonal CPUE has fluctuated from a low of 593 kg/trip during 1994-95 to a peak of 1,016 kg/trip during 2004-05 (Table 1; Figure 7). Since the 2004-05 fishing season, the CPUE has remained relatively stable at over 900 kg/trip. For drag licences, the number of trips has declined from 325 during the 1996-97 fishing year to 88 during 2003-04 and has been increasing since.

The average weekly catch rates fluctuated throughout each fishing season (Figures 8 and 9). However, there was no evident trend in the weekly catch rate within each fishing season for both the diving and dragging operations.

The largest difference between draggers and divers is the number of days they can fish. The dragging industry has seasonal restrictions on dragging. However, even though there is only 4 drag licence compared to 14 dive licences, during the 2007-08 season, the seasonal average number of trips per dive licences (65 trips) and drag licences (67 trips) were similar. Divers are limited to calmer periods of weather and locations.

CPUE has elements of population abundance, but is influenced by discarding due to product quality and market prices. Therefore, the CPUE series must be interpreted with caution, and cannot be used exclusively as an indicator of population abundance.

4.2 DIVER BASED SURVEYS

During July, August, and September of 2002, 31 commercial vessel days were volunteered and 83 dive transects were completed. Of these, 50 dive transects were completed along the New Brunswick coastline in the Maces Bay area, where no previous survey had been done (Figure 5). Another 11 dive transects were completed around Deer Island, and the remaining 22 dive transects were done around Campobello Island at the same locations as during the 1992-93 urchin survey (Figures 2 and 3; Tables 2 and 3).

During July, August, and September of 2003, 23 commercial vessel days were volunteered and 65 dive transects were completed. Of these, 36 dive transects were completed along the coast between Letete Passage and Pocologan, and 29 dive transects were completed around Deer Island at the same locations as during the 1993-94 urchin survey (Figures 3 and 4; Table 2).

In summary, 98 dive transects were completed during July, August, and September of 2002-03, in the 3 fishing areas that were surveyed in 1992-94 (Figures 2, 3, and 4; Table 2) and an additional 50 transects were completed in the expansion area of Maces Bay (Figure 5; Table 3). Due to budget constraint and time limitation, approximately half of the 200 dive transects previously surveyed in 1992-94 were resurveyed in 2002-03. Only data from locations resurveyed in 2002-03 were compared with the corresponding locations surveyed in 1992-94.

4.3. CAMPOBELLO ISLAND SURVEY (1992 VERSUS 2002)

During 2002, around Campobello Island, 9 locations (1, 2, 3, 4, 5, 7, 14, 15, and 16) were resurveyed out of 16 locations that were previously surveyed in 1992, (Figure 2; Table 2). The 9 locations represented approximately 65% of the overall fishable bottom area surveyed in 1992. Of these 9 locations revisited in 2002, 3 locations (1, 2, and 5) were only partially (50%) resurveyed. However, for comparison between 1992 and 2002, all 9 locations were included in the analysis. The total fishable bottom area of the 9 locations was 9.4 km², of which 5.4 km² were within the 0 to 10 m depth strata and 4.0 km² were between 11 and 20 m (Tables 4A to 10).

4.3.1. Size Structure

The proportion of legal size urchins (\geq 51 mm TD) was generally lower in both depth strata during 2002 in comparison to 1992 (Figure 10; Table 4A). The proportions of fishable urchins showed in Table 4A are weighted by the bottom area (m²) of each location and those in Figure 10 are not. Therefore, the estimated percentages of fishable urchins in Table 4A are lower and provided a more realistic picture of the overall proportion of legal size urchins for each location and fishing area.

During 1992 and 2002, the size distribution of sea urchins varied among locations and between the shallow (0 to 10 m) and deeper strata (11 to 20 m), (Figure 10; Table 4A). During the 1992 and 2002 surveys, the overall percentage of legal size sea urchins (\geq 51 mm TD) was higher (17% and 13%, respectively) in shallow water in comparison to deeper water (2% and 7%, respectively). The proportion of legal size sea urchins in the 0 to 10 m depth strata was higher

(17%) in 1992 than in 2002 (13%). This is in contrast to the proportion of legal size sea urchins in deeper water (10 to 20 m), which was lower (2%) in 1992 than in 2002 (7%), (Figure 10; Table 4A).

There was no mode to distinguish age classes. However, the proportion of sub-legal size sea urchins (25 to 50 mm TD) was higher (76%) in 2002 than in 1992 (65%) in the 0 to 10 m depth strata, and was lower during 2002 (52%) in deeper water compared to 1992 (56%), (Table 4A). The proportion of immature sea urchins (< 25 mm TD) was lower in 2002 (12%) compared to 1992 (18%) in shallow water, and was similar for both survey periods (41% and 42%) at depths of > 10 m. The proportion of immature sea urchins was much larger in the deeper strata (>10 m) during both survey periods.

4.3.2. Density

Off Campobello Island, in 1992 and 2002, the density of sea urchin (all size combined) was 14.7 and 26.0 urchins/m², respectively, in the 0 to 10 m depth strata, and 15.6 and 10.2 urchins/m², respectively, in the 11 to 20 m depth strata (Table 4A). However, due to the high variability in sea urchin densities between locations, there was no significant difference in the overall sea urchin densities between the 2 survey periods and between depth strata (Tables 4B and 4C). During 2002, the density of sea urchins (all size combined) within each location was always higher in the 0 to 10 m depth strata.

During both survey periods, the highest densities of sea urchins (all size combined) were located off the northern end of Campobello Island at locations 1, 2, 15, and 16, and southern end at locations 4 and 5 (Figure 2; Tables 4A to 10). The overall densities for these same 6 locations, in the 0 to 10 m depth stratum, ranged between 17 and 40 urchins/m² (average 27 urchins/m²) during 1992, and ranged between 23 and 83 urchins/m² (average 46 urchins/m²) during 2002. The most notable increase in sea urchin density occurred in adjacent locations 1 and 15. In location 1, in the 0 to 10 m stratum, the density of sea urchins increased from 40 urchins/m² during 1992 to 71 urchins/m² in 2002, and in location 15 the density increased from 25 to 83 urchins/m². Low densities, which ranged between 0 and 1 urchin/m² during 1992 and 0 and 3 urchins/m² in 2002, were found at locations 3 and 14 (Figure 2 and Tables 4A).

The density of legal size sea urchins (\geq 51 mm TD) was significantly higher in the shallow depth (0 – 10 m) strata in comparison to the deeper stratum (> 10 m) (Table 4C). During 1992 and 2002 surveys, the overall density of legal size sea urchins (\geq 51 mm TD) was 2.5 and 3.2 urchins/m², respectively, in shallow water in comparison to 0.3 and 0.7 urchin/m² respectively, in deeper water (Table 4A). However, due to the high variability in the density of sea urchins between locations there was no significant difference in the overall legal size urchin densities between the 1992 and 2002 survey periods (Table 4B). The highest increases in legal size sea urchins occurred in locations 2, 5, 15, and 16 (Figure 2; Table 4A).

There were no significant differences in the overall densities of sub-legal size sea urchins (25 to 50 mm TD) between the 1992 and 2002 survey periods and between depth strata (Tables 4B and 4C). In the 0 to 10 m depth stratum the density of sub-legal size sea urchins was 19.9 urchins/m² in 2002 compared to 9.5 urchins/m² in 1992 (Table 4A). In deeper water > 10 m the density of sub-legal size sea urchins was 5.3 urchins/m² in 2002 compared to 8.8 urchins/m² in 1992.

There were no significant differences in the overall densities of immature sea urchins (< 25 mm TD) between the 2 survey periods and between depth strata (Tables 4B and 4C). The only

exception was during the 1992 survey when the density of immature sea urchin was significantly higher in the deeper depth stratum. The density of immature sea urchins in the 0 to 10 m depth stratum was 3.0 urchins/m² in 2002 compared to 2.6 urchins/m² in 1992 and in deeper water > 10 m was 4.2 urchins/m² in 2002 compared to 6.6 urchins/m² in 1992 (Table 4A).

4.3.3. Biomass

During 2002, the overall fishable biomass for the Campobello Island fishing area, was estimated at 1,240 t, compared to 1,014 t in 1992 (Tables 5 to 10; Appendixes 2 to 5). This represented an increase of approximately 22% since 1992. This increase in legal biomass occurred in both the 0 to 10 m depth stratum and in the 11 to 20 m depth stratum. The legal size biomass in the shallow water (0 - 10 m) increased by 13%; from 938 t during 1992 to 1,063 t during 2002. In the deeper water (11 to 20 m), the legal size biomass increased by 133%; from 76 t in 1992 to 177 t in 2002 (Tables 5 to 10). Most of the legal size biomass increase occurred in the northern part of Campobello Island (locations 1, 2, 15, and 16) and in location 5 on the southern end (Figure 2).

4.4. DEER ISLAND SURVEY (1992-93 VERSUS 2002-03)

During the 2002-03 survey, only 9 locations (18, 19, 20, 24, 25, 29, 30, 31, 32) out of the 18 locations that were previously surveyed around Deer Island in 1992-93, were resurveyed (Figure 3; Table 2). These 9 locations included most of the eastern part of Deer Island and several smaller adjacent islands on the eastern side of Deer Island and represented 50% of the overall fishable bottom areas surveyed in 1992-93 (Figure 3). The total fishable bottom area of the 9 locations was 10.7 km², of which 6.7 km² were within the 0 to 10 m depth strata and 4.0 km² were within the 11 to 20 m depth strata (Tables 5 to 10).

4.4.1. Size Structure

Around Deer Island and the surrounding islands, the size distribution of sea urchins varied among locations and between the shallow (0 to 10 m) and deeper depth strata (11 to 20 m) (Figure 10; Table 4A). The proportions of fishable sea urchins showed in Table 4A are weighted by the bottom area (m²) represented in each location and those in Figure 10 are not. Therefore, as previously mentioned, the estimated percentages of fishable sea urchins in Table 4A are lower, and provided a more realistic picture of the overall proportion of legal size sea urchins for each location and fishing area.

During the 1992-93 and 2002-03 survey periods, the overall percentage of legal size sea urchins (\geq 51 mm TD) was higher (13% and 8%, respectively) in the shallow stratum (0 to 10 m) in comparison to the deeper stratum (7% and 6%, respectively) (Table 4A). The percentage of legal size sea urchins was lower during 2002-03 (7%) compared to 1992-93 (12%) (Tables 7 and 10).

There was no mode to distinguish age classes. However, the proportion of sub-legal size sea urchins (25 to 50 mm TD) was higher in 2002-03 than in 1992-93 in the 0 to 10 m depth stratum (76% compared to 65%) and similar in the deeper stratum (52% compared to 56%), (Figure 10; Table 4A). The proportion of immature sea urchins (< 25 mm TD) was lower in 2002-03 (12%) compared to 1992-93 (18%) in the shallow stratum and was similar in the deeper stratum (>10 m) (41% compared to 42%). The proportion of immature sea urchins was much larger in the deeper stratum (>10 m) during both survey periods.

4.4.2. Density

Off Deer Island, due to the high variability in sea urchin densities (all size combined) between locations, there was no significant difference in the overall sea urchin densities between the 1992-93 and 2002-03 survey periods (Figure 3; Tables 4A and 4B). The overall density of sea urchins was 34.7 urchins/m² in 1992-93 and 24.9 urchins/m² during 2002-03. The overall densities at each location ranged between 29 and 55 urchins/m² during 1992-93, and between 6 and 39 urchins/m² during 2002-03.

The density of sea urchins (all size combined) was significantly higher in the 0 to 10 m depth stratum during the 1992-93 and 2002-03 survey periods (Table 4C). The overall density of sea urchins in the 0 to 10 m depth stratum during 1992-93 was 42.0 urchins/m² and 32.2 urchins/m² during 2002-03. In the 10 to 20 m depth stratum, the overall density of sea urchins was 22.5 urchins/m² during 1992-93 and 12.6 urchins/m² during 2002-03 (Table 4A).

The density of legal size sea urchins (\geq 51 mm TD) was significantly lower during 2002-03 than in 1992-93 in the 0 to 10 m depth stratum (2.4 urchins/m² compared to 5.5 urchins/m²) and when both depth strata were combined (1.8 urchins/m² compared to 4.0 urchins/m²) (Tables 4A and 4B). Although the overall density of legal size sea urchins in the deeper water was also lower in 2002-03 (0.7 urchin/m²) than in 1992-94 (1.5 urchins/m²) there was no significant difference in density of sea urchins between the 2 survey periods. The highest decreases in the density of legal size sea urchins occurred in locations 18, 19, 24, 29, 30, 31 and 32 (Figure 3; Table 4). The density of legal size sea urchins (\geq 51 mm TD) was significantly higher in the shallow depth strata during both survey periods (Table 4C)

The density of sub-legal size sea urchins (25 to 50 mm TD) was not significantly different between the 2 survey periods, both in the 0 to 10 m depth stratum (23.8 urchins/m² in 2002 compared to 26.2 urchins/m² in 1992-93) and in the deeper stratum (7.0 urchins/m² in 2002 compared to 10.2 urchins/m² in 1992-93), (Table 4A and 4B). However, the density of sub-legal size sea urchins was significantly higher in the shallow depth stratum during both survey periods (Table 4C).

The density of immature sea urchins (< 25 mm TD) was not significantly different between 2002 $(6.0 \text{ urchins/m}^2)$ and 1992 $(10.2 \text{ urchins/m}^2)$ in the 0 to 10 m depth stratum, but was significantly lower in deeper water > 10 m and when all depths were combined during 2002 (4.5 and 5.5 urchins/m², respectively) in comparison to 1992-93 (10.8 and 10.4 urchins/m², respectively), (Tables 4A and 4B). During 1992-93 and 2002, the density of immature sea urchins was not significantly different between the shallow and deeper stratum (10.2 and 10.8 urchins/m², respectively) during 1992-93 and during 2002 (6.0 and 4.5 urchins/m², respectively), (Tables 4A and 4C).

4.4.3. Biomass

During 1992-93, the overall fishable biomass off Deer Island was estimated at 2,965 t, compared to 1,200 t in 2002-03 (Tables 5 to 10; Appendixes 6 to 9). This represents a decrease of approximately 60% since 1992-93. This decrease in fishable biomass occurred both in the 0 to 10 m depth range and in the 11 to 20 m depth stratum. The fishable biomass, in the shallow water (0 - 10 m) decreased by 60%; from 2,538 t during 1992-93 to 1020 t during 2002. In the deeper water (11 to 20 m), the fishable biomass decreased by 58%; from 427 t in 1992-93 to 179 t in 2002 (Tables 5 to 10; Appendixes 6 to 9).

4.5. LETETE TO POCOLOGAN SURVEY (1993-94 VERSUS 2003)

During the 2003 survey, only 10 locations were surveyed (35, 36, 37 38, 43, 45, 46, 48, 53, 54) out of the 20 locations that were previously surveyed along the coastline between Letete and Pocologan in 1993-94 (Figure 4; Table 2). Locations 35, 36, 37, 38, 43, 45, 46, and 48 were located on the west end of this coastal area in the Letete and Letang area and locations 53 and 54 were located at the east end near Pocologan (Figure 4). These 10 locations represented approximately 54% of the overall fishable bottom area surveyed in 1993-94. The total fishable bottom area of the 10 locations was 16.8 square kilometres (km²), of which 11.2 km² were within the 0 to 10 m depth stratum and 5.7 km² were between 11 and 20 m (Tables 5 to 10).

4.5.1. Size Structure

The proportions of fishable sea urchins showed in Table 4A are weighted by the bottom area (m^2) represented in each location and those in Figure 11 are not. Therefore, as previously mentioned the estimated percentages of fishable sea urchins in Table 4A are lower and more representative of the overall proportion of legal size sea urchins than those showed in Figure 11. The proportion of legal size sea urchins in both depth strata was 12% and 6% during 2003 and 15% and 8% during 1993-94 (Table 4A). Similarly to Campobello and Deer islands, the overall percentage of legal size urchins (\geq 51 mm TD) was higher (15% in 1993-94 compared to 12 % in 2002-03) in shallow water in comparison to deeper water (8% and 6%, respectively) (Figure 11; Table 4A).

As in the other areas, there was no mode to distinguish age classes. However, the proportion of sub-legal size sea urchins (25 to 50 mm TD) was higher in 2003 than in 1993-94 in the 0 to 10 m depth strata (64% compared to 55%) and lower in deeper water (35% compared to 56%), (Table 4A). The proportion of immature sea urchins (< 25 mm TD) was lower in 2003 (24%) compared to 1993-94 (30%) in shallow water and was higher during 2003 in the deeper stratum (>10 m) (59% compared to 35%). The proportion of immature sea urchins was higher in the shallow stratum (0 to10 m) during 1993-94 (35% compared to 30%) and lower in the shallow water during 2003 (24% compared to 59%).

4.5.2. Density

Along the coastal area of Letete to Pocologan, due to the high variability in sea urchin densities between locations, there was no significant difference in the overall sea urchin densities (all sizes combined) between the 2 survey periods and in both depth strata (Figure 4; Tables 4A and 4B). The overall density of sea urchins (all sizes combined), varied between 26.5 and 16.6 urchins/m² in the 1993-94 survey compared to 27.8 and 8.5 urchins/m² during the 2003 survey period, in the shallow and deep strata, respectively. During both surveys, the highest densities occurred at location 35 and the lowest at locations 37 and 54. Although the densities of sea urchins were generally higher in the shallow depth strata during both survey periods (Table 4C).

Due to the high variability in sea urchin densities between locations there was no significant difference in the densities of legal size sea urchins (\geq 51 mm TD) between the 2 survey periods in both depth strata (Tables 4A and 4B). During the 1993-94 and 2003 surveys, the overall density of legal size sea urchins was 4.0 and 3.3 urchins/m², respectively, in shallow water in comparison to 1.4 and 0.5 urchins/m², respectively, in deeper water (Table 4A). The highest decreases in legal size sea urchins occurred in locations 35 and 36, near Letete (9.3 and

4.8 urchins/m² in 1993-94 compared to 2.4 and 1.1 urchins/m², respectively, during 2003), (Figure 4; Table 4). In contrast, there was a notable increase in the density of legal size sea urchin in location 54 near Pocologan (0.2 urchins/m² in 1993-94 compared to 2.6 urchins/m² in 2003). The densities of legal size sea urchins were significantly higher in the shallow depth stratum during both survey periods (Table 4C).

There was no significant difference in the densities of sub-legal size sea urchins (25 to 50 mm TD) between the 1993-94 and 2003 survey periods in both depth strata (Tables 4A and 4B). The overall density of sub-legal size sea urchins in the 0 to 10 m depth stratum during 2003 was 17.9 urchins/m² compared to 14.5 urchins/m² in 1993-94, and in deeper water was 3.0 urchins/m² during 2003 compared to 9.3 urchins/m² in 1993-94. The density of sub-legal size sea urchins was significantly higher in the shallow depth stratum during 2002-03, but was not significantly different between depth strata during the 1993-94 survey period (Table 4C).

The density of immature sea urchins (< 25 mm TD) was not significantly different between the 1993-94 and 2003 survey periods in both depth strata (Tables 4A and 4B). The density of immature sea urchins in the 0 to 10 m depth stratum was 8.0 urchins/m² during 1993-94 compared to 6.6 urchins/m² in 2003. In the deeper water > 10 m, the density of immature urchins was 5.9 urchins/m² during 1993-94 compared to 5.0 urchins/m² in 2003. The density of immature sea urchins was not significantly different between depth strata during both survey periods (Table 4C).

4.5.3. Biomass

The overall fishable biomass for the Letete fishing area was estimated at 2,631 t during 2003 compared to 3,721 t in 1993-94 (Figure 4; Tables 5 to 10). This represented a decrease of approximately 29% since 1993-94. This decrease in legal biomass also occurred in the 0 to 10 m depth range and in the 11 to 20 m depth stratum. The legal biomass in the shallow water (0 - 10 m) decreased by 23% or from 3,128 t during 1993-94 to 2,412 t during 2003. In the deeper water (11 to 20 m) the legal biomass decreased by 63% or from 593 t in 1993-94 to 218 t in 2003 (Tables 5 to 10; Appendixes 10 to 13).

4.6. MACES BAY SURVEY (2002)

The Maces Bay area was surveyed for the first time during August and September 2002 (Figure 5). Eleven new locations (55 to 65) were surveyed (Table 3). The total fishable bottom area was estimated at 16.4 km². Most of the fishable bottom (13.3 km²) was located on shallow bottom of less than 10 m (Figure 5; Table 3).

4.6.1. Size Structure

The proportions of fishable sea urchins showed in Table 4A are weighted by the bottom area (m^2) represented in each location and those in Figures 11 are not. Therefore, as previously mentioned, the estimated percentages of fishable sea urchins in Table 4A are lower and more representative of the overall proportion of legal size urchins than those showed in Figure 11. The overall percentage of legal size sea urchins ($\geq 51 \text{ mm TD}$) was lower (22%) in the 0 to 10 m depth stratum in comparison to deeper water > 10 m (28%), (Figure 11; Table 4A). The proportion of sub-legal size sea urchins (25 to 50 mm TD) was 58% in the 0 to 10 m depth strata compared to 49% in deeper water. The proportion of immature sea urchins (< 25 mm TD) was 20% in shallow water and 23% in deeper water.

4.6.2. Density

In the Maces Bay coastal area, the overall density of sea urchins (all sizes combined) was 10.3 urchins/m^2 (Figure 5; Table 4A). The highest densities of sea urchins occurred at locations 59 (25 urchins/m²) and 60 (27 urchins/m²). In all the other locations, the densities of sea urchins were less than 13 urchins/m². Although the overall sea urchin density was higher in the shallow depth stratum (0 to 10 m) (12.1 urchins/m² compared to 2.8 urchins/m² in the 11 to 20 m depth strata), the density of sea urchins was not significantly different between depth strata (Tables 4A and 4C).

Even though the overall density of legal size sea urchins (\geq 51 mm TD) was more than 3 times higher (2.7 urchins/m²) in the shallow depth stratum (0 to 10 m) compared to the deeper bottom area > 10 m (0.8 urchin/m²), there was no significant difference in the density of legal size sea urchins between depth strata (Tables 4A and 4C). The density of sub-legal and immature sea urchins was not significantly different between depth strata (Table 4C). The density of sub-legal size sea urchins was 7.0 urchins/m² in shallow water and 1.4 urchins/m² in the deeper stratum. The density of immature sea urchins (< 25 mm TD) was 2.4 urchins/m² in the shallow stratum and 0.6 urchin/m² in deeper water > 10 m (Table 4A).

4.6.3. Biomass

The estimated legal biomass for the Maces Bay area was 2,706 t (Table 11; Appendixes 14 and 15). The estimated legal biomass was mostly located in the shallow depth stratum (2,510 t in the 0 - 10 m stratum compared to 196 t in the deeper water).

4.7. OVERALL BIOMASS ESTIMATE

During 2002-03, the fishable biomass was re-evaluated using the corresponding resurvey locations as in the 1992-94 survey (Tables 12 and 13). Consequently, the revised estimate of the fishable biomass for the 1992-94 survey was 7,700 t. In comparison, for the corresponding locations in the 2002-03 survey the biomass was estimated at 5,071 t a decreased of 34%.

During the 2002-03 survey, an additional sea urchin fishing area between Maces Bay and Chance Harbour was surveyed. An additional 2,706 t of legal size urchins was estimated for this relatively new fishing area, which was not included in 1996 when the original TAC was established (Table 13). Therefore, the total legal biomass for all the fishing areas surveyed during 2002-03, including Maces Bay, was estimated at 7,777 t.

Assuming a decline of 34% of the overall legal biomass of 13,245 t that was estimated for all the fishing areas surveyed during 1992-94, the revised fishable biomass was estimated to have decline to 8,742 t (Robinson and MacIntyre 1993, 1995; DFO 1996, 2000) (Table 12). By adding the 2,706 t of fishable biomass from the Maces Bay area, a total fishable biomass of 11,448 t was estimated. Based on the established TAC of 900 t, the harvesting rate was estimated to be 7.9% - 1.1% higher than the harvesting rate of 6.8% that was approved in 1996.

5. ROE QUALITY

Sea urchin roe quality expressed as proportion of marketable roe prior to the opening of the fishery provides an indication of quality later in the year and may be important in the management of the fishery. At this time, data on roe quality from the July to September period is only available from surveys.

The 2002-03 survey provided new information on the stage of gonads development. In order to compare this data with roe quality data previously collected during the 1992-93 surveys, only data that came from the same locations and season were used in the analysis. Data from July, August, and September 1992-93 and 2002-03 were compared in the analysis (Figures 12 and 13).

Based on survey data, roe quality had improved during 2002-03 in comparison to 1992-93, which is consistent with anecdotal information from the fishery. However, no data are available for the intervening years. During the July-September 1992-93 survey periods, few Grade A and B roe were found in comparison to the 2002-03 period (Figure 12). Off Campobello Island, the proportion of marketable roe had increased from 48% in 1992-93 to 66% in 2002-03 (Figure 13). Off Dear Island and Letete, the proportion of marketable urchins increased from 61% and 47%, respectively, in 1992-93 to 75% for both areas in 2002-03. In the Maces Bay area, the proportion of marketable urchins was 67% (Figures 12 and 13).

During 1992-93 the proportion of marketable sea urchins was much higher in the shallow depth stratum (0 -10 m) off Campobello and Deer islands (51% and 66% in shallow depth compared to 17% and 33% in deeper depth) (Figures 12 and 13) Off Letete, the proportion of marketable urchins was similar between depth strata (46% and 49%). During 2002-03, the proportions of marketable urchins were also higher in the shallow depth strata (ranged between 67% and 78%). However, the proportion of marketable urchins in the deeper strata had increased substantially since 1992-93 and ranged between 58% and 71% (Figure 13).

6. AGE STRUCTURE

Robinson and MacIntyre (1997) have demonstrated that growth rings in the test of the green sea urchin can easily be revealed and that the lines appear to have an annual periodicity. They also showed that the wild populations of sea urchins throughout the southwestern New Brunswick area differ in their size and age distributions and, in some areas, could be up to 25 years old. Their results showed a great deal of variation in the age at a particular size, suggesting the animals were limited in their growth potential, probably through lack of food. For example, a 20 mm sea urchin could be between 2 and 10 years old, while a 50 mm sea urchin could range from 4 to almost 25 years (Robinson and MacIntyre 1997).

Urchin size is a poor indicator of age. This explains why the size-frequency distributions may not be particularly helpful in separating year-classes. While some locations have very poor growth, there are others that seem to have fast growing sea urchins. Some of the difference between the sites may be due to fishing activity reducing the densities of larger sea urchins. Their results suggest that if sufficient food is available, then the sea urchins are capable of responding to the increased resources (Robinson and MacIntyre 1997). However, size age data collected during 2002 in areas that have been heavily fished for at least a decade shows similar variability in age at size (Figure 14). In these areas, we can assume that food is not a limiting factor for growth since a large proportion of legal size urchins are removed every year, giving the smaller urchins more space and food to grow. The variability in the age at size increases proportionally with larger size urchin suggesting that maybe there could be a problem with the ageing technique used in the ageing of older urchins. A sample where only large urchins were aged, taken in the Deer Island fishing area, showed negative growth (Figure 14). However, in all areas sampled there are large animals that are younger than some of the smaller animals in the sample. Thus, the Deer Island sample results could just be a sampling issue or could reflect a recent change in the environment/habitat/food supply that resulted in faster growth and younger animals overtaking the older animals there before the change.

7. CONCLUSIONS AND ADVICE

There has been an increasing trend over time in CPUE for both the dive and drag fisheries since 1991-92 (Figure 7). Catch rates based on both sea urchin dragger and diver logbooks have been the highest during the last 4 fishing seasons since 1996. However, CPUE has elements of population abundance, but is influenced by discarding due to product quality, yield, and market prices. Therefore, the CPUE series must be interpreted with caution, and cannot be used exclusively as an indicator of population abundance. Implementation of the new logbook format will facilitate collection and analysis of effort and harvesting rate data allowing the fishery to be more closely monitored on a timelier basis.

With the exception of Deer Island, where legal size sea urchin (\geq 51 mm TD) densities have significantly decreased during 2002-03, all other areas show no significant differences in densities for each size grouping between the 2 survey periods. The density of legal size and sub-legal size urchins was significantly higher in the shallow strata (< 10 m) during both survey periods and within each fishing area compared to the deeper strata (10 – 20 m). Survey designs biases may have been introduced because survey transect locations were not re-randomized for the most recent surveys (Waddell et al. 2003). Only 2 surveys are available, and are 10 years apart, and do not provide a time series to interpret biological characteristics.

Total biomass has changed little between the 2 survey periods. However, the estimated fishable biomass appears to have declined. Based on the established TAC of 900 t, the harvesting rate is estimated to be 7.9% - 1.1% higher than the harvesting rate of 6.8% that was approved in 1996 (Robinson and MacIntyre 1993, 1995; DFO 1996; 2000). However, the Passamaquoddy Bay area is also fished but has never been surveyed; thus, no biomass estimate for this area is available. Therefore, the 7.9% harvesting rate is an overestimate.

The 2002-03 survey can be used as a benchmark for the LFA 36 sea urchin fishery. Even if we assume that the harvesting rate has been low, the overall legal biomass has nevertheless decreased over the last 10 years. For species that move little, there is a risk of serial depletion of the stock. This occurs when the highest densities are fished first. Some of the lower density areas may not have been harvested because they were uneconomical to fish. Therefore, it is possible that economic densities are more depleted than the total density. A cautionary approach should be taken and a low harvesting rate should be maintained to ensure the long-term sustainability of this sea urchin fishery.

The LFA 36 sea urchin fishery is mainly harvested by divers. Consequently any impact from dragging operation is greatly reduced. Although important quantities of sub-legal size sea urchins are harvested by divers and subsequently sorted and discarded on board the vessel, very little by-catch is harvested by divers and divers cause minimal disturbance on the bottom.

Fishery impacts on the ecosystem with respect to by-catch of non-urchin species and potential impact of urchin fishing on the habitat requires an approach to collect and process new information. There is a lack of information on indirect mortality due to interaction with drags and divers. Drag impacts on the benthos and the survival of culled and undersized urchins from the drag fishery is also unknown. Natural mortality is unknown. At present, there is no at-sea observer coverage, which limits quantification of by-catch amounts by the dragger fleet and the ability to evaluate ecosystem impacts of the fishery by both divers and draggers.

The diver based surveys are critical to the assessment of this resource and another survey including all fishing areas in LFA 36 is recommended in the next 2 to 3 years. Prior, to any new survey a review of the survey design is recommended.

9. TABLES

Table 1. Lobster Fishing Area (LFA) 36 historical sea urchin landings and total allowable catch (TAC) in metric tons (t), the percentage of the season total landings for each fishery type, the catch rates in kilogram per trip (kg/trip) and effort in number of trips per season for dive and drag licenses by fishing season from 1989-90 to 2007-08. Missing data from earlier years are indicated as blank and the weight in kilograms came from available log information and was used for determining catch rate (kg/trip) and trip number.

Table 4B. ANOVA analysis comparing the mean urchin densities (urchins/ m^2) between the 1992-94 and 2002-03 survey periods, for each fishing area, depth stratum, and size category. The cases, where the mean density is significantly different at p < .05, are indicated with an *.

Table 4C. ANOVA analysis comparing the mean urchin densities (urchins/ m^2) between the shallow depth stratum (< 10 m) and the deep stratum (10 – 20 m), for each fishing area, size category, and survey period. The cases, where the mean density is significantly different at p < .05 are indicated with an *.

10. FIGURES

Figure 1. Bay of Fundy/Gulf of Maine map showing Lobster Fishing Areas (LFAs) 35, 36, 37, and, 38, and adjacent LFA 34.

Figure 2. Map showing the locations (shaded area) and the position of each transect sampled (•) around Campobello Island during 2002.

Figure 3. Map showing the locations (shaded area) and the positions of each transect sampled (•) around Deer Island during 2002-03.

Figure 4. Map showing the locations (shaded area) and the positions of each transect sampled (•) in the Letete to Pocologan area during 2003.

Figure 5. Map showing the locations (shaded area) and the position of each transect sampled (•) in the Maces Bay area (from Maces Bay to Chance Harbour) during 2002.

Figure 6. Lobster Fishing Area (LFA) 36 historical landings and total allowable catch (TAC) in metric tons (t).

Figure 7. The average catch in kilograms per fishing trip and the number of trips per season for the LFA 36 diving fishery (top) and drag fishery (bottom) from the 1991-92 to 2007-08 fishing seasons.

Figure 8. Weekly landings and catch rate (kg/trip) for the urchin dive fishery in Lobster Fishing Area (LFA) 36 during each fishing season between 1996-97 and 2007-08.

Figure 8. Continued.

Figure 9. Weekly landings and catch rate (kg/trip) for the urchin drag fishery in Lobster Fishing Area (LFA) 36 during each fishing season between 1996-97 and 2007-08.

Figure 9. Continued.

Figure 10. Size frequency distribution of the total number of sea urchins sampled off Campobello (top) and Deer Island (bottom) in 1992 and 2002 for the 0 to 10 m depth stratum (left) and the 11 to 20 m depth stratum (right).

Figure 11. Size frequency distribution of the total number of sea urchins sampled Letete to Pocologan (top) and Maces Bay to Chance Harbour (bottom) in 1992-94 and 2002-03 for the 0 to 10 m depth stratum (left) and the 11 to 20 m depth stratum (right).

Figure 12. Roe quality by Grade categories as a percentage of the total number (N) of legal size urchins tested during each survey periods (1993-94 and 2002-03) for each survey area and depth stratum. Only roe quality that falls within Grade A and B is considered marketable. Grade A being the best quality roe and Grade C and D the worst or non commercial roe.

Figure 13. Proportion of marketable roe for each survey periods (1993-94 and 2002-03) and for each depth stratum and all depth combined within each survey period.

Figure 14. Test diameter versus age for the Maces Bay area (locations 59, 60, 61, and 62) and Campobello (locations 2 and 16) during 2002.

11. APPENDICES

Appendix 1. Map showing the location of fishing areas as recorded by fishers in the new area based urchin logbook which was introduced during fall 2008.

Appendix 2. Calculation of mean, minimum, and maximum number of sea urchins for each location in the 0 to 10 m depth stratum (A), the 11 to 20 m depth stratum (B), and combined depth stratum (C), for the Campobello Island fishing area based on the 1992 survey data.
