## Assessment of Cod in Division 4X in 2008 <br> Évaluation de la morue dans la division 4X en 2008

D. S. Clark and J. Emberley<br>Department of Fisheries and Oceans<br>Biological Station<br>531 Brandy Cove Road<br>St. Andrews, New Brunswick<br>Canada E5B 2L9

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

La présente série documente les fondements scientifiques des évaluations des ressources et des écosystèmes aquatiques du Canada. Elle traite des problèmes courants selon les échéanciers dictés. Les documents qu'elle contient ne doivent pas être considérés comme des énoncés définitifs sur les sujets traités, mais plutôt comme des rapports d'étape sur les études en cours.

Les documents de recherche sont publiés dans la langue officielle utilisée dans le manuscrit

Clark, D.S., and J. Emberley. 2010. Assessment of Cod in Division 4X in 2008. DFO Can. Sci.
Advis. Sec. Res. Doc. 2009/018. vi +101 p.

#### Abstract

A population model was used to provide estimates of abundance, fishing mortality and natural mortality for 4 X cod. Mortality for causes other than reported landings, including natural mortality, for cod of ages 4 and older increased in 1996 and is currently 0.7. The high mortality greatly restricts productivity. Spawning stock biomass (SSB) at the beginning of 2008 is $9,000 \mathrm{t}$; this is the lowest level in the time-series, which started in 1948.

## RÉSUMÉ

Un modèle de population a servi à produire les estimations de l'abondance, de la mortalité par pêche et de la mortalité naturelle de la morue de la division 4X. La mortalité autre que celle qui est associée aux débarquements déclarés, y compris la mortalité naturelle, des morues de 4 ans et plus a augmenté en 1996 et est actuellement de 0,7 (46 \%). Cette mortalité élevée réduit grandement la productivité. La biomasse du stock reproducteur (BSR) au début de 2008 se chiffrait à 9000 t ; cela représente le plus bas niveau de la série chronologique, commencée en 1948.

## COD STOCK STRUCTURE IN NAFO DIVISION 4X

Cod ranges from Georges Bank to northern Labrador in the Canadian Atlantic. There are several concentrations of cod within this range, including those on the Southern Scotian Shelf and Bay of Fundy in Northwest Atlantic Fisheries Organization (NAFO) Divisions 4X and 5Y (Figure 1). Cod in 4 X and the Canadian portion of 5 Y (jointly referred to as 4 X cod) have been managed as a unit since 1985, with a single quota for this area.

Cod in 4X are relatively fast growing. They begin to recruit to the fishery at age 2 and the majority begin spawning by age 3 . Growth is faster and weight is higher for a given length in the Bay of Fundy/Gulf of Maine region (Figure 2a; Figure 2b). The average length at age 5 is about 70 cm on the western Scotian Shelf (4Xmno and Browns Bank in 4Xp; referred to as 4X East) and 80 cm in the Gulf of Maine/Bay of Fundy (4Xqrs5Y and deep water of 4Xp; referred to as 4X West). Similarly, condition (Fulton's K; weight/length ${ }^{3}$ ) is generally higher for cod in the Gulf of Maine and Bay of Fundy.

Spawning is distributed broadly through the area, both geographically and seasonally. Spawning occurs in the fall (October-December) along the coast of Nova Scotia. This spawning has been described most thoroughly for Halifax Harbour and around Sambro Head to St. Margarets Bay (McKenzie 1940). Fish aggregating in the deeper water around Sambro Head were the target of a seasonal gill net fishery, which landed roughly 1,000 t of cod annually, and for a period in the 1980s, were also targeted by large draggers in the winter fishery. This fishery began to decline in the early 1980s, and has now all but disappeared. Fish in spawning state have been caught in this area in recent years, and juvenile cod $(3-5 \mathrm{~cm})$ were captured with a beach seine in Halifax Harbour in spring of 1999 and 2000. Fishermen also continue to catch ripe fish in the Shelburne area in the fall.

Spawning occurs in the spring, primarily on Browns Bank, but also in other areas. Ripe fish were caught in spring Research Vessel (RV) surveys conducted in the early 1980s in the Bay of Fundy and around Browns Bank. Fishermen have identified the waters off Digby Neck and Grand Manan as areas where they encounter spawning fish in the spring (Benham and Trippel 1998).

Egg and larval studies support these observations, showing eggs and larvae distributed along the coast of Nova Scotia and into the Bay of Fundy in fall, and on Browns Bank and in the Bay of Fundy in spring (Neilson and Perley 1996). The presence of both spring and fall spawners results in a bimodal length frequency for cod at age 1 in the RV and Individual Transferable Quota (ITQ) surveys (Clark and Paul 1999).

The degree to which fish spawning in different areas in 4 X mix during the year is not clear. Tagging studies from the 1940s to 1960s generally showed that fish tagged in inshore areas show little dispersal from the tagging area, and those tagged in the Bay of Fundy tended to be returned from inside the bay (Halliday 1971; McKenzie 1956; Templeman 1962). A major tagging project in the 1980s showed that cod tagged on Browns Bank in spring, however, disperse widely through the 4X area, although the majority of tags were recaptured in 4Xp and further west (Campana and Simon 1985; Hunt et al. 1999). Similarly, some fish tagged on Georges Bank were recaptured in 4 X . The proportion of fish tagged on Georges Bank that move into 4X has generally been considered small (Templeman 1962); however, analyses of tagging conducted in the 1990s concluded there was a high level of movement into 4 X from Georges Bank (Hunt et al. 1999).

Given the conflicting results of past studies, and concern amongst some fishermen that there were separate spawning components in the Bay of Fundy that were being overfished (Clark et al. 1998), new tagging was undertaken starting in 2001. The work was planned as a joint project involving the Department of Fisheries and Oceans (DFO), the Scotia-Fundy Mobile Gear Fisherman's Association and the Centre for Community Based Management at St. Francis Xavier University, and received strong support from fixed gear fishermen's associations in Southwest (SW) Nova Scotia. In 2001 and 2002, much of the tagging was conducted during trips onboard 20 commercial fishing vessels, and release sites were widespread in 4X and 5Z (Figure 3). The majority of cod were released in the Bay of Fundy, off Digby, Nova Scotia, and the Wolves Islands of New Brunswick, or on the banks of the Scotian Shelf east of Browns Bank. Several trips were made on and around Browns Bank, but relatively few fish were tagged in this area. Most releases on the Scotian Shelf were from hook and line, while those in the Bay of Fundy were primarily from otter trawler. Approximately 14,000 cod were tagged and released.

Additional tagging of cod caught incidentally in lobster pots was conducted by commercial fishermen from 2003-2004. This tagging was primarily off SW Nova Scotia, with some releases also in the Bay of Fundy. Over 6000 tags were released by the 60 fishermen who took part in this initiative.

Tagging continued from May of 2003 to 2005 as part of the North-East Regional Cod Tagging Program, which included tag releases from south of Maryland across Georges Bank and throughout the Gulf of Maine into the Bay of Fundy (Figure 4). The tagging in Canadian waters as part of this study took part almost exclusively in the Bay of Fundy, with small numbers also released south of Browns Bank. Unfortunately, there was no tagging conducted as part of this study in Canadian waters on the northeast peak of Georges Bank. Over 115,000 cod were tagged in this program, with roughly 6,000 of them released during DFO tagging trips.

The general results relevant to the 4X management area are summarized below.
Cod released in the Bay of Fundy in 2001-2002 were generally recaptured west of Browns Bank in the Gulf of Maine and Bay of Fundy, with some returns on Georges Bank and in the Western Gulf of Maine (Figure 5). Cod tagged east of Browns Bank were predominantly recaptured on the Scotian Shelf, with few recaptured west of Browns Bank. This is consistent with the length-at-age data which suggest cod on the shelf are distinct from those in the Bay of Fundy.

Tagging on Browns Bank was conducted during spawning season in February-March of 1984 and 1985. Fish were tagged in two locations on Browns Bank, and over 1300 tags were returned in total. There are some intriguing differences in the pattern of returns between the two release sites. Roughly 10\% of returns were from Georges Bank, but almost all of these came from one of the two release locations. However, tagged cod were recovered broadly in both eastern and western 4 X from both release sites (Figure 6). Few cod were recaptured from tagging on and around Browns Bank in the recent tagging projects, but they also showed movement both into the Gulf of Maine, where many of the cod tagged in the Bay of Fundy were recaptured, as well as farther north and east onto the Scotian Shelf (Figure 7).

Juvenile cod tagged in coastal areas off SW Nova Scotia were recaptured primarily in 4Xpq and $5 Z$, with the proportion returned from Georges Bank increasing with duration after release (Figure 8).

Cod released in winter in 5Zm (2003 and 2004) all remained on Georges Bank (Figure 9). Cod released in winter in 5Zj dispersed more, with many recaptured in 4 X , primarily in the Bay of

Fundy and Georges Basin (Figure 10). These results are similar to those from tagging on Georges Bank in 1994 (Hunt et al. 1999).

While cod tagged in the Bay of Fundy (4Xrs) and those tagged in eastern 4X (4Xno) exhibit little mixing, cod tagged near the boundary between the Gulf of Maine/Bay of Fundy and the Scotian Shelf (4Xp) are captured in both 4Xpqrs and 4Xmnop.

Roughly $25 \%$ of cod released in 5Zj are recaptured in $4 X$. Mixing from 5Zm to $4 X$ is much lower. Reciprocal movement from 4 X is also observed. Despite the apparent mixing, cod from spawning grounds in 5Zj, Browns Bank and Bay of Fundy can be resolved using microsatellite DNA (Ruzzante et al. 1998). A review of cod tagging results at the 5Zjm cod framework meeting (Worcester 2009; Wang et al. 2009) concluded that, despite the observed mixing, cod in 5Zjm and 4 X could be managed and assessed separately.

While there are clearly separate spawning components in the $4 X$ management area, some of which display very little mixing, separating landings into two regions in $4 X$ for assessment may not be feasible. It is clear, however, that there is not broad mixing of cod throughout the management area, which means that a concentration of fishing effort could lead to overexploitation of some components of the resource while leaving others unharmed. Management of the fishery is recommended be conducted in a fashion which aims to avoid over-exploitation in any part of the stock area.

## BRIEF HISTORY OF FISHERY AND ASSESSMENT

Prior to 1963, the cod fishery in 4 X (including the Canadian portion of Division 5Y; Figure 1) was primarily an inshore fishery. The majority of fishing was done by Canadians, hand lining and long lining from small vessels (Table 1). Between 1957 and 1962, 82-87\% of landings were 'inshore', with the remainder split between Canadian and U.S. vessels fishing Browns and LaHave banks (Halliday 1971). Landings showed a slow decline between 1948 and 1958 from 20,000 to 12,000 (Figure 11). This decline was attributed primarily to decreases in effort, as fishing was directed more for haddock, but also to declining abundance (Beverton and Hodder 1962). Foreign and Canadian otter trawlers (OT) began fishing for cod on Browns and LaHave banks in 1962. Due to the increased exploitation on the offshore banks, almost exclusively by OT, landings increased rapidly after 1962, to a maximum of about 35,500t in 1968.

In 1970, landings dropped by 10,000t. This reduction came almost entirely from Canadian OT landings, while landings by longline (LL) and handline (HL) were largely unaffected. There was no quota for cod in 4X at this time; however, due to the mixed species nature of the groundfish fishery in this area, management measures implemented to regulate fishing on one species inevitably influenced others. The large reduction in cod landings in 1970 has been linked to reductions in fishing effort due to the institution of quotas for haddock and the closure of Browns Bank to fishing for March and April, both of which occurred in 1970.

The 4X area was recognized as including a number of separate cod spawning stocks whose distributional boundaries were unclear, thus, it was felt to be inappropriate to assess it as a unit stock. Assessments were conducted for the offshore (primarily Browns and LaHave banks), which was thought to be a discrete stock, and Total Allowable Catch (TAC) was first established for this area in 1975. These TACs, however, are thought to have had limited impact on landings due to misreporting to the inshore area, where no TAC was in place (Gagne et al. 1983).

Landings throughout much of the 1970s remained in the region of 20-24,000t, increasing to $31,000 \mathrm{t}$ by 1980. As a result of this rapid increase in landings to near historically high levels, a TAC was imposed for 4X cod for the first time in 1982 (Figure 11). The TAC was set at 30,000t (a level selected to prevent landings from exceeding the maximum landings observed in the early 1980s), and held at this level for four years. It had little influence on the landings as a whole, which declined from 32,000t to 21,000t between 1982 and 1985. Aside from the <65ft draggers, no quota group met its allocation from 1983 to 1985 (Campana and Simon 1986).

The treatment of cod in 4 X and 5 Yb as a single stock for assessment purposes commenced in 1985. This step was taken partly in response to changes in fishing practices, and partly because mixing between inshore and offshore stocks appeared to be more extensive than had previously been thought. It was not considered possible to separate landings reliably between inshore and offshore areas (this was not a requirement for logbook records), and the increasing range of much of the fleet made the apportioning of landings to inshore or offshore on the basis of tonnage class unreliable. Furthermore, the results from tagging of cod on Browns Bank in spring suggested there may be mixing between inshore and offshore stocks, as well as among inshore spawning groups. It was felt that an assessment that grouped all of 4 X would be acceptable due to the mixing occurring among spawning groups and the mixed nature of the fishery (Campana and Simon 1986).

With the imposition of more stringent quotas for 4 X cod in 1986, there were suggestions that unreported landings and misreporting by species had become serious problems, particularly in 1987 and 1988 (Campana and Simon 1987; Campana and Hamel 1990). Reported landings since 1989 were considered more accurate due to increased enforcement, and the institution of mandatory weigh-outs in 1990 (Campana and Hamel 1992; Gavaris 1993).

Reported landings remained around 20,000 from 1985-1989, then increased to 28,000 t in 1991. Fishing effort also peaked in 1992, declining rapidly as quota was restricted following 1992. For both otter trawl and longline, effort (days fished) declined by over 50\% between 1992 and 1995 (Gavaris 1996; Clark et al. 1998). Fixed gear effort continued to decline through the 1990s, while for otter trawlers, groundfish directed effort (hours fished for main species cod, haddock or pollock) remained fairly stable through the 1990s but shifted almost entirely to direct for haddock (Clark and Hinze 2003).

Difficulties in predicting age composition of the catch accurately led to experimenting with model formulation, starting with the 1997 assessment. In 1997, an attempt was made to model cod in the Bay of Fundy and Gulf of Maine ( $4 \mathrm{Xqrs5Yb}$ ) separately from cod on the western Scotian Shelf (4Xmnop). The results were quite similar to those from modelling it as a single stock, and suggested that recruitment patterns were very similar in the two areas. These results may, however, have been confounded by the degree of mixing of cod between these areas.

The 1998 and 1999 assessments provided multiple potential model formulations, without resolving which was most plausible. These included models that incorporated a change in survey catchability or an increase in natural mortality. Cohorts were being depleted more quickly than could be explained with these parameters held constant. All models confirmed that the population was low, and, in 1999, the quota was set at 6,000t for a three year period to promote rebuilding.

In 2000, a single model formulation was provided in the assessment. This model included the "around the corner" formulation, in which the oldest age is explicitly estimated for several years prior to the terminal year. The model results indicated that fishing mortality was strongly domed,
with a very low partial recruitment at older ages. The model was used again in the 2002 assessment and displayed a strong retrospective pattern.

In 2003, the Virtual Population Analysis (VPA) was rejected. Assessments for this stock since 2003 have been based on a summary of fishery and survey data with no formal model results reviewed. These assessments concluded that the stock remained at a very low level and that removals should be as low as practicable to promote rebuilding.

Effort has continued to decline, with the handline fleet, which accounted for up to $20 \%$ of the landings as recently as 1996, almost disappearing from the fishery.

## Reliability of Landings

As with all other stocks, there is some uncertainty regarding the accuracy of landings data, particularly before the 1990s. Both fishermen and plant owners have indicated that some landings went unreported in the past, and the extent of this is unclear. With the imposition of more stringent quotas for 4 X cod in 1986, there were suggestions that unreported landings and misreporting by species had become serious problems, particularly in 1987 and 1988 (Campana and Simon 1987; Campana and Hamel 1990). Reported landings since 1989 were considered more accurate due to increased enforcement and the institution of mandatory weigh-outs in 1990 (Campana and Hamel 1992; Gavaris 1993). Anecdotal reports of substantial unreported landings in some communities were noted in 2000 and 2001, when cod quota was restrictive to the mixed fishery. While it was not possible to estimate how much cod was caught and not reported, it was still thought to be considerably less than the reported landings (Clark et al. 2002). With cod landings not reaching the quota in recent years, there would seem to be no incentive to discard cod, and landings are considered reliable.

## DESCRIPTION OF THE FISHERY

Landings declined through the 1990s and these reductions were a reflection of the TAC, which declined from 26,000 in 1992 to 7,000 t in 1999. The TAC was set at 6,000 t for three years, starting in 2000, to promote an increase in biomass. This was not successful; biomass continued to decline, and the TAC was further reduced to 5000t in 2006. Landings have remained near 4,000 and below the TAC since 2005 (Figure 11).

For the 2008 fishing year, 4,064t of the 5,000t quota was landed, slightly higher than in 2005 2007. With the low quotas, many participants in the fishery are reserving cod as a bycatch in other directed fisheries. In 2008, the hook and line fishery accounted for $51 \%$ of the landings from 4 X , the gill net fishery for $8 \%$, and the dragger fleet for $41 \%$ (Table 2). The quota is allocated amongst gear sectors according to historical shares of the landings, with $60 \%$ of the cod quota allocated to the fixed gear sectors, and $40 \%$ to mobile gear.

The precision of geographic location recorded for landings has improved gradually over time. Latitude and longitude have been recorded for otter trawl trips since 1991 and for fixed gear since 1998. In the early 1990s, dragger landings were broadly distributed from Roseway Basin in 4Xo around into the Bay of Fundy (Figure 12). Through the 1990s, the proportion of landings coming from 4 Xqrs increased (Figure 13; Table 3), primarily due to redirection of dragger and gillnet effort (Clark et al. 2000). From 2002 to 2004, much of the dragger fleet directed their effort to the Bay of Fundy to target a good yearclass of haddock concentrated in this area. The proportion of the cod catch coming from this area peaked in 2004 and has declined sharply since then. Since 2004, fishers have reported poor catches in the Bay of Fundy for cod,
haddock and pollock. Effort has again shifted, with an increasing concentration in Georges and Crowell basins in 4Xp. The proportion of landings taken in 4Xp in 2008 is among the highest observed in the time series (Figure 13).

The groundfish fishery in 4 X is prosecuted year round. Landings generally peak in June and July; however, in recent years, landings have been distributed more evenly throughout the year, peaking in the fall (Table 4). The change in the end of the quota year to March 30 has led to an increase in landings early in the year, as fishers attempt to catch any remaining quota.

Cod are captured as part of a multi-species fishery in $4 X$. For some sectors of the fishery, cod is an important part of the catch, while for others it comprises a small part of the overall multispecies landings. Observer coverage is very low in the 4X groundfish fishery (Table 5), and it is not sufficient for any detailed analysis of bycatch in the fishery. The longline fishery catches a mix of cod, haddock, halibut, white hake and cusk (Figure 14), with geographic variability in which species is dominant in the catch. The gillnet fishery catches a mix of cod, pollock and white hake (Figure 15). The otter trawl fishery lands a mix of haddock, pollock, cod, flounder and redfish (Figure 16). As a result, the distribution of fishing effort is impacted by the distribution of several species and by the relative level of quota for each of these species. Fishermen are attempting to maximize the financial return from a fishing trip while depleting the quota for each species simultaneously, rather than selecting areas based on abundance of any single species.

While there may be periodic issues with the accuracy of some landings data for 4 X cod, during the period used for calibrating the assessment (1983-2008) it seems unlikely that these issues are of sufficient magnitude to render the modelling unreliable.

While fixed gear catch was widely distributed in $4 X$ in the past (Figure 17), landings in 2008 are much more restricted to offshore areas in 4Xnop (Figure 18). Fishing in coastal areas and the Bay of Fundy with fixed gear has almost completely disappeared. Otter trawl catches were broadly distributed in 1991 (the first year with precise locations) but concentrated in Roseway Basin and the mouth of the Bay of Fundy (Figure 12). Catches by otter trawlers remain broadly distributed (Figure 19); however, catches are low in areas that had provided good catches in the past, and more of the cod are coming from areas of deep water. While cod continue to be caught in most areas of 4 X either by fixed or mobile gear, the area where good catches were taken in 2008 was restricted to waters around Browns Bank.

In recent years, the cod quota has not been met by any quota sector, while most groups have landed their pollock quota and, in 2007, their haddock quota as well (Table 6). Shortfalls in landings of cod by small draggers reflect their success in targeting haddock in the winter fishery. The large dragger fleet often leave some quota uncaught, and may have held some cod in reserve for bycatch in the pollock fishery.

In 2008, most fixed gear groups reported improved fishing off SW Nova Scotia. Despite this, 464t of the 2907t fixed gear <45' quota went uncaught. Almost half of the fixed gear shortfall was quota held by SW New Brunswick quota group. Their fishery was poor in 2008, and they were unwilling to have their uncaught quota taken from another area. The remaining 200t of cod quota left by the fixed gear fleet was split amongst a number of groups that did not land their full quota for any species. This may be a result of some quota groups leaving too much quota for the end of the year. Furthermore, many large longliners are fishing with individual quotas; some individuals will have landed all their cod and others all their haddock, resulting in some of each species being left in the water.

Effort by the otter trawl and the tonnage class (TC) 2 and 3 longline and gillnet fleets declined after the early 1990s, (Clark et al. 1998). The number of fishing trips made by TC1 fixed gear vessels also declined by about 50\% between 1992 and 1996; however, detailed information on the effort (days fished) is only available for smaller TC1 vessels since 1996

The number of vessels actively engaged in the fishery has dropped since 1996 for all gear types (Table 7a), with handliners almost disappearing from the fishery. The number of vessels fishing declined again for 2008 and was the lowest in the series for each gear type Effort for all fixed gear vessels declined in 2008, with gillnet effort down almost 50\% since 2005 (Table 7b).

## CATCH- AND WEIGHT-AT-AGE

## Fishery Samples

The 2007 catch-at-age was based on 33 samples that included otoliths, and 68 additional length frequency samples (Table 8a). Some cells were combined in the construction of length frequencies due to a lack of data. In the first half of 2008, 12 samples which include otoliths, and an additional 29 length frequency samples are available (Tables 9a).

Samples were aggregated by area, quarter and gear type. Aggregation by area was done to account for growth differences between the Bay of Fundy (4Xqrs5Yb) and SW Scotian Shelf (4Xmno). Variability in growth rates are also found within 4 Xp , with cod caught in the deep water of $4 \times p$ growing faster than on Browns Bank and the rest of the Scotian Shelf. In accordance with this, $4 X p$ is split, with catches from deep water grouped with the Bay of Fundy ( $4 X$ West) and from shallower water grouped with the rest of the Scotian Shelf (4X East). The depth of separation was set at 90 fathoms.

The seasonal length-weight parameters used in deriving catch numbers at age (Table 8b and 9b) were those from Campana and Hamel (1992). These parameters were calculated as seasonal averages over the years for which seasonal survey information were available, and have been used since 1985 when seasonal surveys in 4X were discontinued.

## Landings

Landings reported from 4Xu (unspecified area) were apportioned to 4X West and 4X East for each statistical district according to known area landings by gear type and tonnage class for that statistical district and quarter. Landings reported from 5Y from 1983 to 1986 for each statistical district were divided between 4 X East and 4 X West according to the same protocol. Misreporting to 5 Y from 4 X was identified as a problem in these years in past 4 X cod assessments (Campana and Simon 1987; Campana and Simon 1988).

Fishery length frequencies from 2007 peaked at 49cm in 4X East (Figure 20a) and at 55cm in the 4X West (Figure 20b). Cod caught by gillnet were larger, but all other gear-types had similar length ranges. Modal length is slightly lower in 2008 for 4X East (Figure 21a) and slightly higher in 4X West (Figure 21b).

## Catch-at-Age

The 2003 yearclass has been dominant in the fishery in 2007 and 2008, and the 2004 yearclass has made little contribution (Table 10; Figure 22). The catch-at-age for 2008 is only available to July 1. Later in 2008, small cod, likely age 2, dominated the catch. The contribution of cod over
age 6 to the landings has been very low in the last decade, and remains low in 2007 and 2008.
Weights at age for commercial landings from both 4X East and 4X West in 2008 were generally lower than average, except for younger ages (Table 11). Given the very low numbers in the catch above age 6 , these weights-at-age may not be reliable.

## ABUNDANCE INDICES

Annual RV stratified random surveys have been conducted in NAFO Division 4X during the summer since 1970. Coverage begins at 50 fm off the south shore of Nova Scotia, and 15 fm in the Bay of Fundy, and extends out to 200 fathoms along the shelf edge. An area north of Browns Bank, while of suitable depth, is untrawlable bottom, and is excluded from coverage for this reason (Figure 23). Cod are generally abundant in the Bay of Fundy and on the Scotian Shelf banks.

From 1970 to 1981, surveys were conducted with the RV A. T. Cameron, a side trawler, using a Yankee 36 bottom trawl. The gear was changed to a Western IIA bottom trawl in 1982, when the research vessel was replaced with the RV Lady Hammond, a stern trawler. The current research vessel, the RV Alfred Needler, which uses the Western IIA bottom trawl, replaced the RV Lady Hammond in 1983.

A variety of difficulties were experienced in conducting comparative surveys in the early 1980s as part of the change in survey vessels (Koeller and Smith 1983; Fanning 1985). In particular, the speed sensor on the Cameron was not functioning properly. The speed of towing for this vessel was quite variable, and generally higher than $3.5 \mathrm{~nm} / \mathrm{hr}$. The conversion factors calculated for cod have been deemed unreliable (Clark and Brown 1996; Mohn 1999) and, as a result, the indices are only used from 1983 on.

Following a fire on the CCGS Alfred Needler in 2004, the CCGS Teleost was used to conduct the surveys in 2004 and 2007, and the CCGS Wilfred Templeman was used to conduct the survey in 2006. The Templeman is the sister ship to the Needler, and has been assumed to require no conversion in comparison with the Needler. Comparative fishing between the Teleost and Needler has also indicated that no conversion factor is required between these vessels (Clark 2005).

The ITQ survey, which has been conducted by Industry annually since 1996, employs a fixed station design. The coverage includes some coastal areas missed by the RV survey, but there is less coverage of deep water and New Brunswick coastal areas. Three vessels, using a 300 balloon trawl with a 1/2in. codend liner and rockhopper ground gear are involved in the survey. Each vessel completed 60-65 tows, in separate geographic blocks. One of the three vessels was replaced in 2006, but it is assumed that no vessel conversion factor is required. The standard tow is 1 nm . The duration of tow varies according to tidal current; 3 knots is the target towing speed. All sets are made during daylight hours. Much more small cod are caught during this survey than in the RV survey due to the rockhopper ground gear, which provides little avenue for escape below the footrope.

In 1998, 10 stations were added around St. Margarets Bay. The 10 stations added in 1998 account for roughly $1 \%$ of the survey catch each year; thus, $1 \%$ was added to the survey catch for 1996 and 1997 to account for these stations (Clark et al. 2000). The length distribution of fish in these 10 stations peaked around 20 cm each year from 1998-2000, similar to the catch from the inshore stations farther west. In augmenting the length frequencies for 1996 and 1997, the
length frequency for the inshore stations sampled in those years was used as a template, and the total catch at length for the survey was increased by an amount equivalent to $1 \%$ of the surveys catch by weight (Clark et al. 2000).

Indices for this survey are derived using the suite of 184 stations regularly occupied over the time-series (Clark et al. 2002).

## Distribution of Catches and Catch per Tow

In both 2007 and 2008, there were some cod caught in most areas during the RV survey but no large catches (Figures 24 and 25). Catches of cod in the Bay of Fundy in 2008 are particularly small. The total catch for the RV survey (roughly 70 sets) averages around 400 fish, and is as low as 138; in 2008, 157 cod were caught.

Cod were caught in most areas in the ITQ survey in 2008, but, as in the RV survey, very few cod were caught in the Bay of Fundy (Figure 26). Catches on the Scotian Shelf were generally low, except on Roseway Bank, again consistent with the RV survey.

Since the ITQ survey is a fixed station survey, the catch at each station can be compared among years. Catches were below the median at almost all stations in the Bay of Fundy in 2008 (Figure 27). Catches were above median at many sets at the eastern end of the Scotian Shelf in 4 X , but they were below the median for most stations west of Roseway Bank. The proportion of ITQ survey stations where cod were caught, and where catch was above the median for that location, has been fairly stable in 4 X East throughout the 12 year series but declining in 4 X West (Figure 28).

The RV survey biomass index in 4 X East in 2008 is among the lowest in the series, while the ITQ survey biomass index in 4X East show little trend since 1997 and is only slightly below average in 2008 (Figure 29a). The biomass index in 4 X West in 2008 remains low for the ITQ survey, has declined, and is the lowest in the series for the RV survey (Figure 29b). Overall biomass trends for $4 X$ cod are quite consistent for the two surveys (Figure 29c). The 2008 value is the lowest in the RV survey series and second lowest in the ITQ survey series.

## Length Frequencies

Catches at length from the RV survey were below the median in 4 X East for all lengths above 28 cm but above median for smaller sizes (age 0 and 1; Figure 30). Catches at length were very low in 4X West for commercial size cod and were close to median only for lengths below 30cm, consistent with length at age 1 (Figure 30). For the ITQ survey, catch at length was below the median at lengths greater than 34 cm in 4 X West (Figure 31), similar to the RV survey. In 4 X East, catch at length was above the median at lengths $<40 \mathrm{~cm}$ and close to median for larger cod (Figure 31). This differs from the results of the RV survey; however, some of the discrepancy reflects the generally low catch of cod in 4X East since the inception of the ITQ survey.

## Length-at-Age and Condition

Lengths-at-age for 4X cod from the RV survey are stable for both regions (Figure 32). The very low numbers of fish for some ages results in high interannual variability for older ages.

There is no trend in condition for cod in 4 X West (Figure 2b). Condition factor has declined for cod in 4X East and in 2008 is the second lowest observed (Figure 2b).

## Indices at Age

Again in 2008, very few cod over age 5 were caught in the RV survey (Table 12; Figure 33). There was no improvement in age structure for either region. The 2006 yearclass is dominant in both 4X East and 4 X West. Indices are below the median for all ages in both regions except ages 0 and 1 in the east. The combined 4 X indices, as used in the VPA, are very low for all ages (Table 13; Figure 34).

The ITQ survey index in 4 X East is the second highest in the series for age 2 and third highest for age 1, but second lowest for ages 3 and 4 (Table 14; Figure 35). Indices for $4 X$ West are low for all ages except age 1, which is the median for the series. The combined ITQ survey indices for 4 X are above the median for ages 1 and 2, but they are very low for all older ages (Table 15; Figure 36).

## Estimates of Relative Mortality and Total Mortality

The relative fishing mortality (catch biomass/RV survey biomass index), while generally lower for both 4X East and 4X West since 1995 than in the previous decade, appears to be increasing for 4 X East in the last three years (Figure 37). Relative F (fishing mortality) has not declined since a rebuilding strategy was adopted in 2000. Despite low landings, the total mortality estimate from the RV survey remains high in 4 X East and it has been increasing in 4 X West (Figure 38). The continued high Z, while relative F has dropped, suggests there is additional mortality that has not been accounted for in the reported landings.

Total mortality, estimated from RV survey data, shows no trend for young cod in 4X over the time series (Figure 39). If mortality from sources other than reported landings has increased for older cod, it does not appear to have increased on young cod.

Mortality remains high for both regions as estimated from the ITQ survey (Figure 40). This is consistent with the data from the RV survey.

## ESTIMATION OF STOCK PARAMETERS

A series of model formulations were explored for this assessment. Model formulations that had been used in past assessments were presented to illustrate the pathology which led to their rejection and as background for formulations which incorporate changes in assumptions about natural mortality (M) and survey catchability (q). This was consistent with the recommendations of the pre-zonal assessment process (ZAP) assessment meeting.

The adaptive framework (Gavaris 1988) was used to calibrate the sequential population analysis with the survey results in an illustrative base model, using the following data:
$C_{a, t}=$ catch for ages $a=1,2, \ldots, 12$ during the time periods beginning at $t=1983,1984 \ldots$, 2008, 2008.5
$I_{s, a, t}=$ survey abundance index for:
s= RV survey ages $a=2$ to 8 , years $t=1983.5$ to 2008.5
ITQ survey ages $a=2$ to 8 , years $t=1996.5$ to2008.5

The summer survey results were compared to mid-year population abundance. Statistical error in the survey data was assumed to be independent and identically distributed after taking logarithms and the error in the catch at age was assumed negligible. Natural mortality, M, was assumed constant and equal to 0.2 .

A model formulation using In mid-year population abundances in 2008 ( $t=2008.5$ ) as parameters was employed. Define the model parameters:
$\phi_{\mathrm{a}, 2008.5}=\operatorname{In}$ population abundance for ages a $=2,3, \ldots, 12$, (age 1 abundance assumed equal to the geometric mean recruitment 2000-2007), and

$$
\kappa_{\mathrm{sa}}=\text { calibration constants for } \mathrm{RV} \text { and ITQ surveys for ages } a=2,3,4,5,6,7,8 .
$$

ADAPT was used to solve for the parameters by minimizing the objective function

$$
\Sigma\left(\ln \left(I_{\mathrm{s}, \mathrm{a}, \mathrm{t}}\right)-\ln \left(\kappa_{\mathrm{sa}} N_{\mathrm{a}, \mathrm{t}}(\phi)\right)\right)^{2}
$$

where the population abundance $N_{a, t}$, is taken at the corresponding time, $t$, to the survey. Since the sequential population analysis was conducted using half-year catch at age data, the abundance at the mid-year time, $t=y+0.5$, is directly available.

For $t=2008.5$, the population abundances are obtained directly from the parameter estimates,

$$
N_{a, 2008.5}=\exp \left[\phi_{a, 2008.5}\right] .
$$

For all other years, $\mathrm{y}=1983$ to 2008, the population abundance was computed using the virtual population analysis algorithm which incorporates the exponential decay model

$$
N_{\mathrm{a}, \mathrm{t}}=N_{\mathrm{a}+\Delta t, y+\Delta t} \exp \left[\left(F_{\mathrm{a}, t}+M\right) \Delta t\right]
$$

where the fishing mortality is obtained by solving the catch equation using a NewtonRaphson algorithm,

$$
N_{\mathrm{a}, t}=C_{\mathrm{a}, t}\left(F_{\mathrm{a}, t}+M\right) \Delta t / F_{\mathrm{a}, \mathrm{t}} \Delta t\left(1-\exp \left[-\left(F_{\mathrm{a}, t}+M\right) \Delta t\right]\right) .
$$

Statistical properties of estimators were obtained from model conditioned non-parametric bootstrap of the residuals (Efron and Tibshirani 1993) as described in Gavaris and Van Eeckhaute (1998).

A second illustrative formulation was presented, which was identical to the base model but excluded the ITQ survey indices. This formulation was included to show that removal of the ITQ survey indices does not eliminate the strong residual pattern apparent in results of the base model. Residuals switch from primarily negative to predominantly positive around the time the ITQ survey begins (1996).

A model formulation that incorporated a change in survey $q$ was undertaken. The change in $q$ was modeled as a step function beginning in 1994, the year in which residuals switch from negative to positive in the base model. Survey indices for 1994 and later are input as separate series from those before 1994. The assumption made for this model is that landings are reliable
since 1994 and possibly unreliable earlier. It is also assumed that an M of 0.2 and reported landings account for all mortality in all years.

A series of formulations were explored that incorporate a change in natural mortality. ADAPT was used to estimate $M$ in blocks of years. Since there is no indication from survey data that $Z$ has increased on young cod, M was estimated only for ages 4-11. Illustrative VPA results included in the 2006 assessment (Clark and Perley 2006) had estimated $M$ as 0.8. An increase from 0.2 to 0.8 is a large change in a single year. To allow for a phased increase, $M$ was estimated in two time blocks. A gradual increase was simulated by estimating $M$ separately for the periods 1993-2000, and 2001-2008. A sharp increase was simulated by calculating M separately for the periods 1993-1995 and 1996-2008. Based on the results of these models, an additional formulation was considered with M fixed at 0.2 for 1983-1995 and estimated in a single block for 1996-2008.

These model formulations are premised on the assumption that survey catch is representative of abundance with a constant q and a change in M is introduced to account for high recent Z at ages 4+.

Initial investigation of model formulations incorporating changes in M and q showed that the calibration constants ( $\kappa_{\text {sa }}$ ) continued to increase slightly with age for the RV survey, but were consistent across older ages for the ITQ survey. Final formulations stipulated a single calibration constant for ages 5-8, as recommended at the pre-ZAP assessment meeting. In the absence of a reason why catchability should vary among ages that could be expected to be fully recruited to the survey gear, it had been recommended that $q$ for these ages should be linked to reduce the number of parameters estimated.

A final formulation was investigated that included the ITQ survey index at age 1. It was noted during the assessment review that this age-class was caught consistently in the ITQ survey, and that strong and weak cohorts at age 1 seemed consistent with observations in subsequent years. Inclusion of this index would eliminate the need to use geometric mean recruitment for age 1 in the assessment year.

## ASSESSMENT RESULTS

The base model was included for illustrative purposes (Appendix I). The residuals from this model formulation show a strong pattern, switching from almost all negative to almost all positive in about 1994 (Figure 41). This model is not given further consideration.

The timing of the switch from positive to negative residuals in the base model is roughly coincident with the inception of the ITQ survey. The second illustrative model includes only the RV survey indices and has the same strong pattern in residuals (Figure 42). Omitting the ITQ survey indices resulted in no improvement to model fit (Appendix II), and ITQ indices are included in all models given further consideration.

The residuals from the model formulation that includes a change in survey q in 1994 (Appendix III) do not show any strong pattern (Figure 43). Similarly, there is no strong pattern in residuals for a model formulation that estimates M for 1996-2008 (Figure 44; Appendix IV).

There is no improvement in residual pattern or mean squared residual when M is calculated separately for two time periods since 1993. Furthermore, when M is calculated for the period 1993-95, it gives an M of 0.17 (Appendix V ). This is very similar to the assumed M of 0.2 , thus,
a sudden change in M in 1996 seems more consistent with the data. Only the formulation with a single change in M was considered further.

All model formulations examined are effectively in agreement on population status (Figure 45). For all model formulations, current biomass is estimated as the lowest in the series and a fraction of the biomass in 1980.

Trends in $F$, however, differ between ' M change' and other models (Figure 46). From the " M change" models, estimated $F$ declines rapidly after 1992, as fishing effort declined, and remained relatively low after the mid-1990s. For other model formulations F remained very high throughout the 1990s, which seems inconsistent with the trends in fishing effort. The lack of any clear reduction in F with the large reduction in effort argues against those models which do not incorporate a change in M .

Catchability coefficients (q) for 1983-1995 from q-change model shows a slight increase with age after age 5 and all q are less than 1 . Recent $q$ estimated from the $q$-change model increase with age and are $>1$ for most ages and peak at over 2 . This would indicate a several fold increase in the catching efficiency of the net. While in the 1980s, fewer than half the cod in the path of the net were caught, now the net catches more cod than are in the path of the net. This would mean a change in behaviour that led cod to be herded into the path of the net, rather than avoiding the net.

For the base model, the q values estimated are an average of the $q$ values from the two time blocks in the q-change model. In the 1-index model: q values are closer to the 1983-1995 q values because the influence of the recent period is lessened by removal of ITQ survey. The q values derived from the 'estimate M' model are similar to those estimated for 1983-1995, and show only a modest increase above age 5 .

If landings since 1996 are considered reliable, it might be most parsimonious to accept a q-change model. However, concerns with the reliability of reported removals from the groundfish fishery persisted until about 2003. Discards from other fisheries, particularly the lobster fishery, are suspected, but not estimated. It seems unlikely that an M of 0.2 and reported landings from the groundfish fishery account for all the mortality for cod in 4 X .

The very high q estimated for recent years in the "q-change" model seems implausible for cod, again suggesting this formulation is not realistically modelling the population dynamics. In addition, the very high estimates of total mortality $(Z)$ from survey data, while relative $F$ is low, suggests there is a large unaccounted mortality.

The high M estimated from the model could incorporate both natural mortality, and unaccounted fishing mortality. The primary cause of increased natural mortality is likely an increase in seal population, as has been reported for other cod stocks (Swain et al. 2009). Gray seal abundance has increased continuously in recent decades on Sable Island, and much of 4 X is in their foraging range. In addition, gray seal colonies have been established in the 4X/5Y area in recent years. The abundance of harp, harbour and gray seals have all increased in Gulf of Maine (Waring et al. 2007). Furthermore, the fishing industry reports increased levels of nematode parasites in groundfish fillets. As seals are the final host for these parasites, this is consistent with an increased population of seals residing in the area.

Some of the high mortality could also be a result of unreported mortality from the groundfish fishery and other fisheries. Unreported landings or discarding in groundfish fishery was reported as a problem from 1999-2002 (Clark and Hinze 2003), although it is thought to have ceased
since then. There is some discarded bycatch of cod in other fisheries, including scallop, herring, and lobster fisheries. Lobster fishing effort has increased since early 1990s. The scale of bycatch is unknown but will be investigated for the scallop fishery in 2009 and the lobster fishery in 2010. Lobster bycatch has been estimated at about 40t from Halifax to Shelburne (Bundy et al. 2007) and are likely higher off SW Nova Scotia. Cod, however, can be released alive when caught in lobster gear, so mortality from this fishery will be difficult to quantify.

While it is not possible to clearly identify the causes of a high M with the data available, this appears to better fit the available data than does a formulation which assumes that survey catchability has changed.

With acceptance of this basic model structure, minor modifications were made for provision of advice. In accordance with the recommendations of the pre-ZAP assessment meeting, survey catchability for ages $5-8$ were estimated as a single parameter to reduce the number of parameters estimated and eliminate the slight increase in q with age. Also, the ITQ index for age 1 was examined for inclusion in the model. The ITQ survey catches large numbers of age 1 cod, and the index appears to be a good predictor F yearclass strength. There is a relatively large standard error (SE) on age 1, but the q on age 1 has similar SE to other ages (Table 16). Estimates of the 2006 yearclass change little with addition of age 1 index; the age 1 index confirms the estimate which was previously based only on the age 2 index from 2008. The inclusion of this index means that the 2007 cohort can now be estimated, and is slightly higher than 5 million. Including this estimate reduces the importance of assumed recruitment in projections.

## Accepted Model Output

For each cohort, the terminal population abundance estimates from ADAPT were adjusted for bias and used to construct the history of the stock status (Table 17). Beginning of year weights-at-age were back-calculated from RV survey weights-at-age, and used to calculate beginning of year population biomass (Table 18).

Population numbers are estimated to be well below average for all ages (Table 17). Recruitment above 20 million was common in the 1980s; since the 1992 yearclass, no recruitment has approached this level. Recruitment for the 2006 and 2007 yearclasses are below average but about twice the abundance of the very low 2003 and 2004 yearclasses. While estimates of catch-at-age are less precise and likely underestimated in some years prior to 1980, for illustrative purposes, the results of an assessment that included landings starting in 1948 have been included for years before 1980. Spawning population numbers in 2008 are the lowest estimated in the 60 year time-series (Figure 47).

A fishing mortality ( $F$ ) of 0.2 was adopted as the target for this stock during the 1980s. Fishing mortality has been above this level since 1980, and it was 0.34 in the first half of 2008 (Table 20; Figure 48).

There has been a general decline in biomass throughout the period assessed (Table 18; Figure 49). The relatively strong 1985, 1987 and 1992 yearclasses resulted in only short-term improvements in biomass. Spawning stock biomass (SSB) at the beginning of 2008 is 9,000 t; this is the lowest level in the time-series, which started in 1948.

There is no consistent retrospective trend for this assessment (Figure 50). Following the high 2002 survey index, there is some pattern of decline in following biomass estimates, but the four most recent estimates are in close agreement. Similarly, there is no consistent retrospective
pattern in fishing mortality estimates. Successive estimates of F are variable but without a clear trend, and they were anomalously high, with large positive residuals at several ages. This led to large retrospective increases in the estimate of $F$ in the following years, but successive estimates of $F$ have both increased and decreased as the past four years of data were added (Figure 50).

## PROGNOSIS

A SSB limit reference point (LRP) of 25,000t has been adopted because, below this value, the likelihood of poor recruitment increases (Figure 51). Projections for this resource indicate, that at removals of 1,450 t in 2009 (management target of $F=0.2$ ), there is a $>95 \%$ probability of at least $10 \%$ growth in SSB; however, SSB is unlikely to reach the LRP of 25,000 t in 2010 even with no harvest (Figure 52).

Given the very high estimate for M , biomass increase for this resource appears to be entirely dependent on recruitment. With improved recruitment for the 2006 and 2007 yearclasses, the $3+$ biomass (fishable biomass) is expected to increase above 2008 levels by 2010, if fishing mortality in 2009 is moderate. While a continuation of improved recruitment may lead to some additional biomass increase, some decline in M will be needed before the stock biomass can increase substantially.

Although point estimates of biomass and fishing mortality rate for alternative projected yields are provided, these numbers should not be treated as precise values. The risk plots are provided to give a general sense of the associated uncertainties and to assist in assessing the consequences of alternative choices. Further, these uncertainties are dependent on the set of assumptions, data, and model used in the analyses. Though these assumptions were deemed most suitable, there may be other plausible assumptions. The risk evaluation indicates that fairly significant changes in yield are required to influence the probability of not exceeding $10 \%$ growth in 4+ biomass (Figure 52). This reflects the reliance on recruitment, which is not estimated precisely, for growth.

Biomass has remained low since 2000 when the quota was reduced to 6,000 t to promote rebuilding. There is no indication of a decline in total mortality or relative fishing mortality since 2000. Natural mortality is estimated to have increased to 0.7 and this greatly restricts productivity. Landings of about 3,900 t in recent years have contributed to a continuing decline in abundance, and biomass is projected to decline further from 2008 to 2009. Survey recruitment estimates for the 2006 and 2007 yearclasses are improved over the preceding two yearclasses, and should result in an increase in stock biomass in the short-term.

A yield of 1,450t in 2009 would be consistent with the target exploitation rate of 16.5\% (Table 19). At this yield, there is a high probability of $10 \%$ growth in SSB (>95\%) between 2009 and 2010; however, this will only return the SSB to about the same level as in 2008. A reduction in the removal of cod from all fisheries to the lowest possible levels would be a strategy compliant with the principles of the precautionary approach. This would imply substantial reductions in TAC below current catch levels, and additional measures to reduce cod catch in the mixedspecies groundfish fisheries and cod by-catch in other fisheries.

Cod in 4X are harvested as part of a mixed species groundfish fishery. With current fishing practices and species catch ratios, achieving rebuilding objectives for cod may constrain the harvesting of other groundfish. An imbalance in quotas creates potential for discarding and may
require improved monitoring. Modifications to fishing gear and practices, with enhanced monitoring, may mitigate these concerns.

## ACKNOWLEDGMENTS

We would like to thank those members of the fishing industry who assisted us with sampling of commercial landings and took the time to meet with us and discuss the state of the fishery. The continued careful attention of Laura Brown to age reading for 4 X cod is greatly appreciated.

Table 5. Proportion of NAFO Division $4 X$ cod landings caught during trips with Observer coverage in the $4 X$ groundfish fishery.

| Year | Otter trawl |  | Longline |  |
| :---: | :---: | :---: | :---: | :---: |
|  | Tonnage | Proportion | Tonnage | Proportion |
| 2001 observed | 45.4 | 380\% | 11.1 | 0.74\% |
| 2001 landed | 1188 | 3.80\% | 1500 | 0.74\% |
| 2002 observed | 0.266 | 0.01\% | 6.3 | 0.30\% |
| 2002 landed | 1777 |  | 1867 |  |
| 2003 observed | 20.2 | 0.79\% | 6.9 | 0.82\% |
| 2003 landed | 2540 | 0.79\% | 842 | 0.82\% |
| 2004 observed | 88.3 | 3.60\% | 12.3 | 0.99\% |
| 2004 landed | 2453 | 3.60\% | 1243 | 0.99\% |
| 2005 observed | 30.4 | 1.52\% | 8.9 | 0.72\% |
| 2005 landed | 1990 | 1.52\% | 1233 | 0.72\% |
| 2006 observed | 33 | 2.05\% | 6.2 | 0.36\% |
| landed | 1609 | 2.05\% | 1735 | 0.36\% |
| 2007 observed | 31.3 | 195\% | 2.0 | 0.11\% |
| 2007 landed | 1607 | 1.95\% | 1865 | 0.11\% |
| 2008 observed | 21.1 | 1.24\% | 15.7 | 0.007\% |
| 2008 landed | 1699 |  | 2107 |  |

Table 6. Proportion of groundfish quotas landed in the NAFO Division $4 X$ fishery by gear sector.

| 2005 Quota Report | cod | haddock | pollock |
| :--- | :---: | :---: | :---: |
| FIXED < 45' | $66 \%$ | $42 \%$ | $87 \%$ |
| MOBILE <65' (ITQ) | $80 \%$ | $77 \%$ | $97 \%$ |
| VESSELS >100' | $81 \%$ | $80 \%$ | $102 \%$ |
| Aboriginal Fishery | $68 \%$ | $64 \%$ | $88 \%$ |
|  |  |  |  |
| 2006 Quota Report | cod | haddock | pollock |
| FIXED < 45' | $74 \%$ | $63 \%$ | $82 \%$ |
| MOBILE <65' (ITQ) | $82 \%$ | $72 \%$ | $93 \%$ |
| VESSELS >100' | $51 \%$ | $74 \%$ | $100 \%$ |
| Aboriginal Fishery | $83 \%$ | $68 \%$ | $88 \%$ |
|  |  |  |  |
| 2007 Quota Report | cod | haddock | pollock |
| FIXED < 45' | $78 \%$ | $73 \%$ | $98 \%$ |
| MOBILE <65' (ITQ) | $80 \%$ | $100 \%$ | $97 \%$ |
| VESSELS >100' | $95 \%$ | $108 \%$ | $99 \%$ |
| Aboriginal Fishery | $83 \%$ | $111 \%$ | $90 \%$ |

Table 7a. Number of fishing vessels reporting landings of cod, haddock, pollock or white hake in NAFO Division $4 X$ annually.

| Year | Otter trawl | Gill net | Longline | Handline |
| :---: | :---: | :---: | :---: | :---: |

## Appendix IV. Calculated M for Ages 4+

Population abundance (number in thousands) for cod in NAFO Division 4 X from a virtual population analysis using the bootstrap bias adjusted population abundance.
