## **Foreword**

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

## ABSTRACT

The status of the marine species caught in the Saguenay Fjord recreational fishery was assessed annually from 1995 to 2010 and every two years from 2012 to 2018. This assessment is based on various indicators from a monitoring program for the winter recreational fishery (also known as ice fishing) (1995–2018), a Fisheries and Oceans Canada (DFO) research survey (2000–2018) and a recent individual logbook initiative (2015–2018). This report presents the data and methods used to derive the indicators from the monitoring program for the winter recreational groundfish fishery in the Saguenay Fjord. Estimates of the number of fish per unit of effort (NUE) for more than 20 years of recreational fishery sampling (1996–2018) are presented for the following species: redfish (*Sebastes spp.*), Atlantic cod (*Gadus morhua*), Greenland cod (*Gadus ogac*) and Greenland halibut (*Reinhardtius hippoglossoides*). In addition, biological parameters of the sampled populations are indicated.

Groundfish catches in the Saguenay winter recreational fishery are composed on average of 88% redfish, 10% cod (Atlantic and Greenland cod) and 2% Greenland halibut for the 1996–2018 time series. For the Saguenay as a whole, the redfish index of abundance decreased from 1996 to 2006 and remains low since with values clearly below those at the beginning of the series. Indices of abundance for Atlantic cod, Greenland cod, and Greenland halibut are at low level. However, since 2013 there has been an increase in NUE for the Atlantic cod and Greenland halibut with values above their respective series average.

Studies published in the late 2000s (Sévigny et al. 2009, Sirois et al. 2009) suggest that groundfish populations in the Saguenay appear to be sink populations whose recruitment depends on the arrival of juveniles from the St. Lawrence Estuary (Bui et al. 2012). Although groundfish reproduction does occur in the Saguenay, larval survival of these species would be compromised by conditions in the warm, brackish surface water layer, preventing a significant local contribution to recruitment, particularly for redfish and cod (Sirois et al. 2009). Strong cohorts of redfish (*Sebastes mentella*) (2011, 2012 and 2013) were noted in the Estuary, and their abundance was at the highest level seen in the last 30 years (Bourdages et al. 2019). The presence of these new cohorts in the Saguenay Fjord has been observed since 2013, namely in the stomach contents of large redfish, during a major stranding at Saint-Fulgence in December 2014, in the smelt fishery and during research surveys (Gauthier et al. 2019). The recent high-abundance cohorts are beginning to recruit to the recreational fishery, but the fish are small in size. These redfish had a modal size of 16 cm in 2017 and of 20 cm in 2018 and made up nearly 10% of redfish catches. The medium-term outlook is encouraging for the winter recreational redfish fishery in the Saguenay Fjord.

---

## INTRODUCTION

The winter recreational groundfish fishery in the Saguenay Fjord, or ice fishing, is unique in Quebec because of its size and the variety of fish species caught. The groundfish species caught in that region are periodically assessed to determine whether changes in the status of the resource might warrant adjustments to the conservation approach. The last regional peer review of this fishery was performed on November 21, 2018, at the Maurice Lamontagne Institute in Mont-Joli. The main indicators used for that review come from the sampling of the winter recreational fishery, individual logbooks and a DFO scientific survey (Gauthier and Marquis 2017, Gauthier et al. 2019, DFO 2019).

This report includes an update of the indicator data from the recreational fishery sampling in 2017 and 2018. The methodology and data from 1996 to 2016 have already been presented in Gauthier and Marquis 2017. Information from the new logbook initiative introduced in 2015 is also provided. For the conclusions on the status of groundfish populations in the Saguenay, please consult the most recent Science Advisory Report (DFO 2019).

## DESCRIPTION OF THE FISHERY

The winter recreational fishery extends throughout the entire upper watershed of the Saguenay Fjord, between Saint-Fulgence and Petit-Saguenay (Figure 1a). The main fishing villages are associated with the municipalities of L'Anse-Saint-Jean, Rivière-Éternité, Saint-Félix-d'Otis, Sainte-Rose-du-Nord, Saint-Fulgence and the La Baie borough (City of Saguenay). Until 2012, the La Baie borough included the L'Anse-à-Benjamin, Grande-Baie and Les Battures fishing villages. The latter village has been closed since 2013 as a result of a recurring problem of inadequate ice cover.

Fishing villages generally have two areas where cabins are set up: a “pelagic fish” area near the shore where mainly smelt (*Osmerus mordax*) is caught, and a “groundfish” area farther out on the ice where the species discussed in this report are caught.

Winter recreational fishing in the Saguenay is still very popular. In the 2017 and 2018 fishing seasons, an average of 1,376 cabins were set up on the pack ice between Saint-Fulgence and L'Anse-Saint-Jean (Guy Girard, Promotion Saguenay, pers. comm., Appendix 1). This represents a decrease of nearly 100 cabins compared to the average for the 1998–2016 period (Figure 1b). Annually, close to 200 cabins are set up on the sites located in the Saguenay–St. Lawrence Marine Park (SSLMP). More than 80% of the cabins set up on the Saguenay Fjord are concentrated in the La Baie sites. The “groundfish” areas account for 60% of all fishing cabins.

The regulatory length of the fishing season has varied over time, and the opening and closing dates are shown in Table 1. Following the decline in resource abundance, the fishing season was shortened in 2005 and again in 2011 from an average of 59 days between 2005 and 2009 to 43–45 days between 2011 and 2016. The season was 50 days in 2017 and 2018. Weather conditions regularly result in the actual fishing season being reduced because of late ice cover formation and/or early thaws.

No licence is required for this fishery, and only line fishing methods are permitted, i.e. tip-ups, rollers and rods. There are no limits on the number of lines and hooks, but fishing gear may not be left unattended for more than 72 hours after it has been set up. The [regulations](#) include the mandatory release of crustaceans, mollusks, Atlantic halibut (*Hippoglossus hippoglossus*), spotted wolffish (*Anarhichas minor*), Atlantic wolffish (*Anarhichas lupus*), northern wolffish (*Anarhichas denticulatus*), sharks and skates. It is also prohibited to sell, trade or waste fish.

---

Two main types of gear are used in this fishery: a fishing rod and a roller. The roller consists of a line mounted on a pulley. Rollers have become very popular in recent years and have largely replaced tip-ups. They are generally set up on the pack ice outside the cabins, while rods are used primarily inside the cabins.

There are three main approaches to ice fishing. The first is characteristic of fishers who watch their gear closely. When the fish takes the hook, the fisher removes the line, unhooks the fish, and baits and sets the line again. The second approach involves social activities. The gear is baited and lowered into the water, but the fishers do not watch the gear as attentively. As a result, a fish that takes the bait can be hooked to the line for a number of hours before being pulled out. This means there is virtually no chance that another fish will be caught with the gear during this time. Lastly, the third approach involves baiting and lowering the gear in the evening, for example, and pulling it out at the beginning or end of the next day. This approach is more common for tip-ups and rollers.

## **MONITORING PROGRAM FOR THE WINTER RECREATIONAL GROUNDFISH FISHERY IN THE SAGUENAY FJORD**

The winter recreational groundfish fishery in the Saguenay Fjord took off in the early 1980s. It has been the subject of monitoring coordinated by DFO since 1995 (Lambert and Bérubé 2002, Gauthier 2018). This monitoring is carried out in collaboration with the Société des établissements de plein air du Québec (Sépaq) and Parks Canada (PC), which are co-managers of the SSLMP, as well as Promotion Saguenay and fishers' associations.

This monitoring has three components. Component 1, *catch per unit of effort*, is conducted by samplers and consists of describing fishing activities by surveying recreational fishers. Component 2, carried out by index fishers, involves collecting biological data on the various species caught, including size and weight. Component 3 was added in 2015 and consists of logbooks completed by recreational fishers recruited from the main fishing sites. This component is also intended for fishers who practise their activities outside fishing villages and who are not covered by Component 1 of the monitoring.

### **MONITORING PROGRAM – COMPONENT 1 – CATCH PER UNIT OF EFFORT**

The sampling for this component is carried out by PC for the Sainte-Rose-du-Nord and Saint-Fulgence sites; Sépaq for the L'Anse-Saint-Jean, Rivière-Éternité and Saint-Félix-d'Otis sites; and Promotion Saguenay for the L'Anse-à-Benjamin, Les Battures and Grande-Baie sites. Each of these partners hires one or more samplers to visit and collect data for their respective sites in accordance with the protocol developed by DFO and enter the data after the fishing season. The data are then forwarded to DFO for processing.

The annual sampling plan for Component 1 is 20 visits per fishing site, with a maximum of 15 fishers surveyed per visit. Data are gathered on catches (species, number), fishing effort (number of lines, hooks and fishing hours) and number of active fishers at the time of the visit. The main objective is to identify trends in catches per unit of effort (CPUE). Table 2 presents the number of visits per site and per year in the groundfish area, as well as the average number of fishers surveyed per visit. The visits to each site are conducted on weekdays and weekends throughout the fishing season (Figure 2). The use of echosounders has been noted since 2010 but was not considered in the analyses. Echosounders were used by 50% of fishers surveyed between 2010 and 2018. A copy of the form used to collect data for Component 1 – *catch per unit of effort* is provided in Appendix 2.

---

For the analyses, invalid or incomplete data were removed, as were data collected outside the groundfish area. Only data obtained since 1996 were used. Data with a fishing time greater than 12 hours are not used in calculating catches per unit of effort. However, these data are retained for estimating total catches.

Table 3 shows the number of catches reported in Component 1 for each species studied. From 1996 to 2018, 45,471 catches of *Sebastes spp.*, 1,317 cod spp., 3,134 Atlantic cod, 2,987 Greenland cod and 658 Greenland halibut were reported to samplers. Prior to 2001, no distinction was made between Atlantic cod and Greenland cod, which is why analyses for the different cod species began in 2001.

### Catch per unit of effort

The catch per unit of effort (CPUE) or catch rate of a species is considered to be proportional to its abundance. The CPUE is the number of individuals of a species caught per unit of effort. The sample unit considered is a fisher's activity between the start of the day and the time they meet with the sampler. Effort is defined as the total number of hooks used (number of hooks per line multiplied by the number of lines) multiplied by the number of fishing hours. Between 1996 and 2018, fishers used an average of 2.2 lines with an average of 2.9 hooks per line (Table 4). The average number of lines used per fisher has decreased over time. From 1996 to 2006, it was three lines, which fell to less than two between 2007 and 2018. This decrease could be explained by the introduction of sonar in this fishery and the phasing out of the use of rollers and tip-ups. The average number of hooks per line is more consistent. In addition, for a given fisher, an average of 4.8 hours elapsed between the start of fishing activity and the meeting with the sampler.

Three factors that can have an impact on fishing success are noted. These are the year, the fishing site and the day of the week. The site represents the eight different cabin villages, i.e.: Sainte-Rose-du-Nord, Saint-Félix-d'Otis, Rivière-Éternité, L'Anse-Saint-Jean, Saint-Fulgence, Grande-Baie, L'Anse-à-Benjamin and Les Battures. The winter fishery clientele is assumed to be different depending on the day of the week. Weekday fishers are considered to have a more attentive fishing approach, while weekend fishers have a more social approach. Fishing success is considered to be greater on weekdays than on weekends. Thus, the last factor describes when the activity is performed.

Standardizing the data makes it possible to account for the part of the variability of the CPUE that is attributable to these various factors. This makes it possible to focus the analysis on annual trends in the catch rate and, consequently, on changes in the population status. To determine an appropriate method for achieving this standardization, three models were explored (Desgagnés et al. 2011). The generalized linear model (GLM) with a negative binomial distribution was used for these analyses.

CPUEs by species and by year were estimated for the entire Saguenay and for two subsets, i.e. sites within the SSLMP (L'Anse-Saint-Jean, Rivière-Éternité, Saint-Félix-d'Otis and Sainte-Rose-du-Nord) and those within the Baie des Ha! Ha! (L'Anse-à-Benjamin, Grande-Baie and Les Battures) (Figures 3 to 6). It is hypothesized that the CPUE is a good indicator of stock status. Figures 3 to 6 also show the effect of factors such as the site and day of the week on estimated catch rates. The correspondence is multiplicative in base e (base of natural logarithms), so an effect of 1 does not change the estimated CPUE, and each increase in the effect of one unit multiplies the estimated CPUE by e (i.e. about 2.7183) (Desgagnés et al. 2011).

For redfish throughout the Saguenay, recreational catch rates show a continuous downward trend from 1996 to 2004, with stabilization at a low level and below the series average since

---

2004 (Figure 3). Similar analyses conducted at the sites located within the SSLMP boundaries show a comparable trend, but the downward trend there is more marked. However, the situation is different if only the three Baie des Ha! Ha! sites are analyzed. The CPUE does not show a clear downward trend and is rather stable.

For Atlantic cod throughout the Saguenay, recreational catch rates are low (Figure 4). The CPUE index showed a decline between 2000 and 2007 and rebounded in 2008, followed by a decrease until 2013. Since then, it has been on the rise, and the 2018 value is above average and comparable to the numbers at the start of the series. The CPUE for the Rivière-Éternité, Sainte-Rose-du-Nord and Saint-Fulgence sites show a positive effect on the index, while the day of the week (weekday/weekend) appears to have little influence. The general trend is similar for the SSLMP sites. Catch rates for the Baie des Ha! Ha! sites show annual fluctuations without a clear trend.

For Greenland cod, recreational catch rates are generally low (Figure 5). The CPUE index showed a decrease between 2000 and 2007 throughout the Saguenay. Since 2008, the CPUE has been at a low level compared to the start of the series. The Rivière-Éternité site stands out for its high effect on the catch rate, while the timing of the fishery appears to have little influence. The decrease in the CPUE is more pronounced when only the SSLMP sites are taken into account, but the trends are similar. At the start of the series, the CPUE is significantly higher in the SSLMP than in the Baie des Ha! Ha! sites.

Greenland halibut are seldom caught in the Saguenay recreational fishery, which makes using the CPUE for this fishery as an abundance index very speculative (Figure 6 and Table 3). Since 1996, 650 Greenland halibut have been inventoried, an average of about 30 fish per year. The L'Anse-Saint-Jean and Saint-Fulgence sites stand out for their positive effect on the CPUE. Since 2010, an increase in the CPUE has been noted throughout the Saguenay and at the SSLMP sites. The 2018 value is the highest of the series.

### Total effort deployed by fishing season

The overall annual frequentation (number of fisher-days) is calculated as follows:

$$AF = \sum_{i=1}^{nSites} \sum_{j=1}^{sfs} nDay_{i,j} \times \overline{nFD}_{i,j}$$

Where  $nSites$  is the number of sites considered,  $sfs$  is the number of day categories (in this case, two: weekdays and weekends),  $nDay_{i,j}$  is the number of fishing days at site  $i$  and in the day category  $j$  (Table 1), and  $\overline{nFD}_{i,j}$  is the average number of fishers present at site  $i$  on a given day in category  $j$  (Appendix 3).

The opening and closing dates of the fishery do not appear to be a good indicator of season length, since inadequate ice cover can prevent the establishment of fishing villages and significantly reduce the frequentation. We also have no data on the thickness of the ice cover or the dates cabins were set up on the pack ice, which could have been used as an indicator of the actual length of the fishing season. The number of days in a season is approximated by considering the number of days between the first and last sampler visit (Figure 2). The season length is assumed to be the same for all sites.

The average number of fishermen-days is calculated based on the frequentation estimated by the sampler at each visit to a site (Figure 7, Appendix 3). A significant number of fishers are inside the cabins, complicating the work of the samplers. Moreover, this estimate is largely influenced by the annual sampling frequency of fishing activities. Thus, in 2006, the significant drop in total estimated effort is largely attributable to the lack of sampling at the

---

L'Anse-à-Benjamin site (Table 2, Figure 7, and Appendix 3), which had only one week day visit. No data were available for weekend days. The L'Anse-à-Benjamin site accounts on average for 20% of the total annual fishing effort. No assessment was conducted of the accuracy and variability of these estimates. The average number of fishermen-days and the results of the calculations using this value should therefore be used with caution.

The frequentation average for 1996–2018 is approximately 27,000 fishermen-days (Figure 8). Variations in frequentation reflect, among other things, adverse weather conditions in some years, a shortened fishing season and the adoption of more stringent municipal bylaws to ensure safety on the ice. Fishing effort, estimated in number of fishermen-days, has decreased and is below the series average since 2016 at the La Baie sites and increased in the SSLMP, more specifically in the village of L'Anse-Saint-Jean. In 2017–2018, the estimate of the number of fishermen-days for the entire Saguenay region is below the series average.

### Total annual catch

For a given year, the total catch ( $TC$ ) is calculated as follows:

$$TC = \sum_{i=1}^{nSites} \sum_{j=1}^{sfs} nDay_{ij} \times \overline{nFD_{ij}} \times \frac{totCatch_{ij}}{nFSur_{ij}}$$

Where  $totCatch_{ij}$  is the sum of catches reported at site  $i$  on the day category  $j$ , and  $nFSur_{i,j}$  is the total number of fishers surveyed at site  $i$  and on the day category  $j$ .

During the winter recreational fishery in 2017 and 2018, redfish, Atlantic cod, Greenland cod and Greenland halibut (turbot) accounted for 76%, 14%, 2% and 8% of groundfish catches, respectively (Figure 9a). The total annual catch of each of these species is shown in Figure 9b.

Annual variations in the total catch of the species are. The total catch for each species has decreased since the start of the series. Catches of Redfish and Greenland cod come mainly from the villages of La Baie, while catches of Atlantic cod and Greenland halibut are generally higher in villages located in the PMMSL.

The information presented in this document on the number of fishermen-days and on the total annual catch by species is different from that presented in the previous documents (Desgagnés et al. 2011, Gauthier and Marquis 2017). This difference stems from an error which consisted of an inversion between the total number of weekdays (Number of weekdays) and the total number of weekend days per fishing season (Number of weekdays) (Table 1). In the previous documents, the average number of fishermen active on weekends were multiplied by the total number of weekdays for a given season and vice versa. Thus the attendance of the weekend, much larger than that of the week, had been multiplied by the total number of weekdays, a number greater than the total number of weekend days. This resulted in erroneous and larger estimates of the number of fishermen-days and the total annual catch.

Figure 10 presents the percentage of fishers surveyed based on the total number of fish they had caught when they met with the sampler. Catch categories range from 0 to 16 fish.

Category 16 includes events where the number of fish caught is equal to or greater than 16. The daily catch limit was 25 until 2002, 15 in 2003 and 5 since 2004. Since 2004, fishing success has been low, and in more than 90% of activities, fishers do not catch their daily limit of five groundfish. In 2018, nearly 60% of the recreational fishers surveyed had not caught any fish at the time of their meeting with the sampler, which occurred an average of four hours after the start of their fishing activity.

---

## **MONITORING PROGRAM – COMPONENT 2 – BIOLOGICAL DATA**

Between two and six fishers are recruited annually from each of the fishing villages to collect biological data on the various species of fish caught. These individuals are identified as index fishers. Component 1 samplers also participate in this collection. Table 5 presents the number of fish measured and weighed by species. The frequency of data collection for Component 2 is dependent on the availability of the index fishers. A copy of the form used to collect data from 1996 to 2018 is provided in Appendix 4.

### **Size frequencies**

Descriptive total length statistics from biological data collected in Component 2 of the monitoring program are presented in Table 6 for redfish, cod and Greenland halibut. Size frequency distributions for Greenland halibut, Atlantic cod and Greenland cod show a wide range of sizes, indicating that multiple cohorts are present in the fishery (Figure 11).

The situation is different for redfish. The slow and steady increase in the median size of redfish in the fishery since 1996 suggested that there had been no significant influx of recruits to the fishery and that it had been directed by a small number of cohorts. However, since 2016, more redfish under 23 cm have been caught, accounting for nearly 10% of catches in 2018. The total modal length of these fish was 20 cm in 2018 (Figure 12). These redfish come from the entry into the Saguenay of fish from the 2011, 2012 and 2013 cohorts, of which the abundance in the Estuary and Gulf of St. Lawrence is on a scale never seen in 30 years (Bourdages et al. 2019).

Descriptive total length statistics for fish species occasionally sampled in the winter recreational fishery are presented in Table 7 for Atlantic halibut (*Hippoglossus hippoglossus*), lycodes spp., white hake (*Urophycis tenuis*), flounder spp., skate spp. and Arctic cod (*Boreogadus saida*).

The relationship between total mass and total length is calculated for the four main species (Table 8 and Figure 13). The 2017 and 2018 values are compared to the adjusted curve for the data set. These adjustments are obtained by a non-linear regression that corresponds to an allometric relationship between the mass and length of the individuals analyzed:

$$y = ax^b$$

where  $y$  is the total mass (g) for a fish of total length  $x$  (cm),  $a$  represents the coefficient of the fish body shape, and  $b$  is the allometric coefficient.

### **Condition index**

The Fulton condition index ( $K$ ) of fish is calculated according to the following formula:

$$K = 100 \times \frac{W}{L^3}$$

where  $W$  is the total mass (g) and  $L$  is the total length (cm). Annual data by species are presented in Table 9.

---

## **MONITORING PROGRAM – COMPONENT 3 – LOGBOOKS**

In 2015, a new logbook initiative was implemented to collect additional data on fishing activities. Logbooks are distributed to recreational fishers who fish with lines on a regular basis. These fishers carry out their activities both inside and outside the fishing villages.

One of the main advantages of these logbooks is that fishers provide their effort and catches for all of their fishing activity. By comparison, in the Component 1 monitoring conducted by the samplers since 1995, fishers are surveyed when they meet with the sampler and have not

---

necessarily completed their fishing day; they may be at the start, in the middle or at the end. Nevertheless, Component 1 monitoring provides information that is not available through logbooks, including an estimate of the total number of fishers on the ice at the time the data are collected. These two sources of information are therefore complementary. In addition, logbooks provide information on the more sport-oriented fishers who practise their activities outside fishing villages.

The logbook data are presented in Appendix 5. Appendix 6 provides information on the number of logbooks completed annually, the number of activities recorded in the logbooks, whether or not recreational fishers use sonar and the number of activities for each fishing site. Since 2015, the number of logbooks completed has varied between 18 and 24. Some of these logbooks and some fishing activities were removed from the analyses for a variety of reasons, including incomplete information. For the 2015–2018 period, between 12 and 18 logbooks were retained, representing between 229 and 333 fishing activities. On average, an activity lasts 6 hours, and each fisher uses an average of 1.7 lines with 2.6 hooks for an average total effort of 26 hook-hour (Figure 14).

### **Fishing success of logbook participants**

The fishing success of participants is increasing, and the percentage of activities where fishers caught their daily limit of five groundfish increased from 12% to close to 30% between 2016 and 2018 (Figure 15).

The total annual number of fish caught by species in Component 3 is presented in Figure 16.

### **Catch per unit of effort of logbook participants**

Logbook data indicate that recreational catch rates for the four groundfish species remained stable between 2015 and 2018 (Figure 17).

Sonar was used in 78% of fishing activities. When catch rates are calculated separately for activities with and without sonar, the catch per unit of effort (CPUE) for redfish are higher when sonar is used (Figure 18). During the peer review (DFO 2019), the recreational fishers in attendance indicated that these results were consistent with their experience of this fishery, as redfish are caught when the fish are moving through the water column and are detectable on sonar. For the other species, cod and Greenland halibut, catches are made near the bottom, where these fish are less detectable on sonar.

## **SAMPLING OF REDFISH IN THE SMELT FISHING AREA**

A valuable source of information on the arrival of new cohorts of redfish in the Saguenay was provided by the recreational smelt fishery monitoring program conducted by the provincial Department of Forests, Wildlife and Parks (Ministère des Forêts, de la Faune et des Parcs [MFFP]). Since 2014, and in greater abundance since 2016, juvenile redfish have been caught in the smelt fishery. Since 2016, while monitoring the recreational smelt fishery, the MFFP has recorded the number of fishers who reported catching small redfish. In 2016, 2017 and 2018, the percentage of surveyed fishers who had caught small redfish in the smelt area increased from 10.5% to 14.7% and then to 17.8%. The number of fishers surveyed was 267, 265 and 383, respectively, for those three years. The average size of these redfish was 7.1 cm in 2014, 8.3 cm in 2016 and 14.0 cm in 2018 (Figure 19).

---

## GENETIC STUDIES ON SAGUENAY REDFISH

Studies published since the mid-2000s suggest that groundfish populations in the Saguenay and, more specifically, redfish (Valentin 2006, Campana et al. 2007, Sévigny et al. 2009, Sirois et al. 2009, Valentin et al. 2014) and cod (Sévigny et al. 2009, Sirois et al. 2009) appear to be sink populations whose recruitment depends on the arrival of juveniles from the St. Lawrence Estuary (Bui et al. 2012). Although groundfish reproduction does occur in the Saguenay, larval survival of these species would be compromised by conditions in the warm, brackish surface water layer, preventing a significant local contribution to recruitment (Sirois et al. 2009).

Since 2014, an abundance of redfish on a scale never seen in 30 years has been observed in the Estuary and Gulf of St. Lawrence (Bourdages et al. 2019). This high abundance is attributable to the large influx of the 2011, 2012 and 2013 cohorts of the redfish species *Sebastodes mentella* (Senay et al. 2019). Juvenile redfish have also been observed in abundance in the Saguenay Fjord since 2014 during DFO research surveys (Gauthier et al. 2017, Gauthier et al. 2019) as well as during the winter recreational smelt and groundfish fisheries.

Two redfish species cohabit in the Gulf of St. Lawrence: the Acadian redfish (*Sebastodes fasciatus*) and the deepwater redfish (*Sebastodes mentella*). Distinguishing between these species is very difficult because of their great similarity. Various meristic, morphometric and genetic tools have been evaluated to differentiate between the two species (Gascon 2003). It was microsatellite genetic markers that made it possible to distinguish the species unequivocally (Roques et al. 1999).

A total of 111 redfish ranging in size from 4.7 to 22.1 cm were harvested in the Saguenay in 2013 (n=12), 2014 (n=71) and 2015 (n=28). These fish were caught during either the winter fishery or a stranding that occurred in Saint-Fulgence in December 2014 (Appendix 7). Based on their size, it can be concluded that the majority of these redfish are from the 2011, 2012 and 2013 cohorts. A tissue sample was taken from each individual for genetic testing using microsatellite markers to determine the species of these new cohorts (Figure 20).

The methods used for DNA extraction, amplification of the 13 loci by PCR,<sup>1</sup> electrophoresis of the amplified DNA fragments and data analysis are described in Valentin et al. 2014. The following modifications were made: electrophoresis was performed using an ABI3130 (Applied Biosystems) sequencer; the LIZ 1200 size standard was used; and GeneMapper v.4.0 software was used for the analyses.

All 111 redfish analyzed were identified as deepwater redfish (*Sebastodes mentella*) (Appendices 8 and 9).

These results are consistent with previous studies that had also shown the dominance of the *Sebastodes mentella* redfish species in the Saguenay (Bourgeois 1993, Valentin 2006, Sévigny et al. 2009, Valentin et al. 2014).

## CONCLUSION

The Saguenay winter recreational fishery is very popular, with an annual average of nearly 1,500 cabins set up on the pack ice. Information from logbooks shows that fishing success increased between 2016 and 2018 from 12% to almost 30% of the activities where fishermen caught their daily limit of 5 groundfish.

---

<sup>1</sup>. DNA polymerase chain reaction.

---

Abundance indices based on the recreational fishery show a significant decline in redfish, by far the main species caught in this fishery. However, the medium-term outlook is encouraging because high abundances of juvenile redfish were identified in the Estuary and Gulf of St. Lawrence between 2013 and 2016 (Bourdages et al. 2019, Senay et al. 2018). These juveniles have also been observed in abundance in the Saguenay (Gauthier and Marquis 2017, Gauthier et al. 2017, Gauthier et al. 2019).

Catch rates for the winter recreational Atlantic cod, Greenland cod and Greenland halibut fisheries are low. However, since 2013, an increase has been noted in the indices for Atlantic cod and Greenland halibut, with values above their series averages. For more information on the status of groundfish populations in the Saguenay, please consult the most recent Science Advisory Report (DFO 2019).

## ACKNOWLEDGEMENTS

The authors would like to thank all the stakeholders involved in monitoring the winter recreational groundfish fishery in the Saguenay Fjord: the partners from Promotion Saguenay; the Société des établissements de plein air du Québec and the Parks Canada Agency, co-managers of the Saguenay–St. Lawrence Marine Park; as well as the samplers and index fishers. Special thanks to Chloé Bonnette, Sarah Duquette, Guy Girard, Laurence Lévesque, Michel Maltais, Anthony Salesse and Mario Vaillancourt. The involvement of Amélie Bérubé from Quebec's MFFP in sampling redfish in the smelt fishery was greatly appreciated. The authors also thank Caroline Senay and Claude Brassard for reviewing this document.

## FIGURES

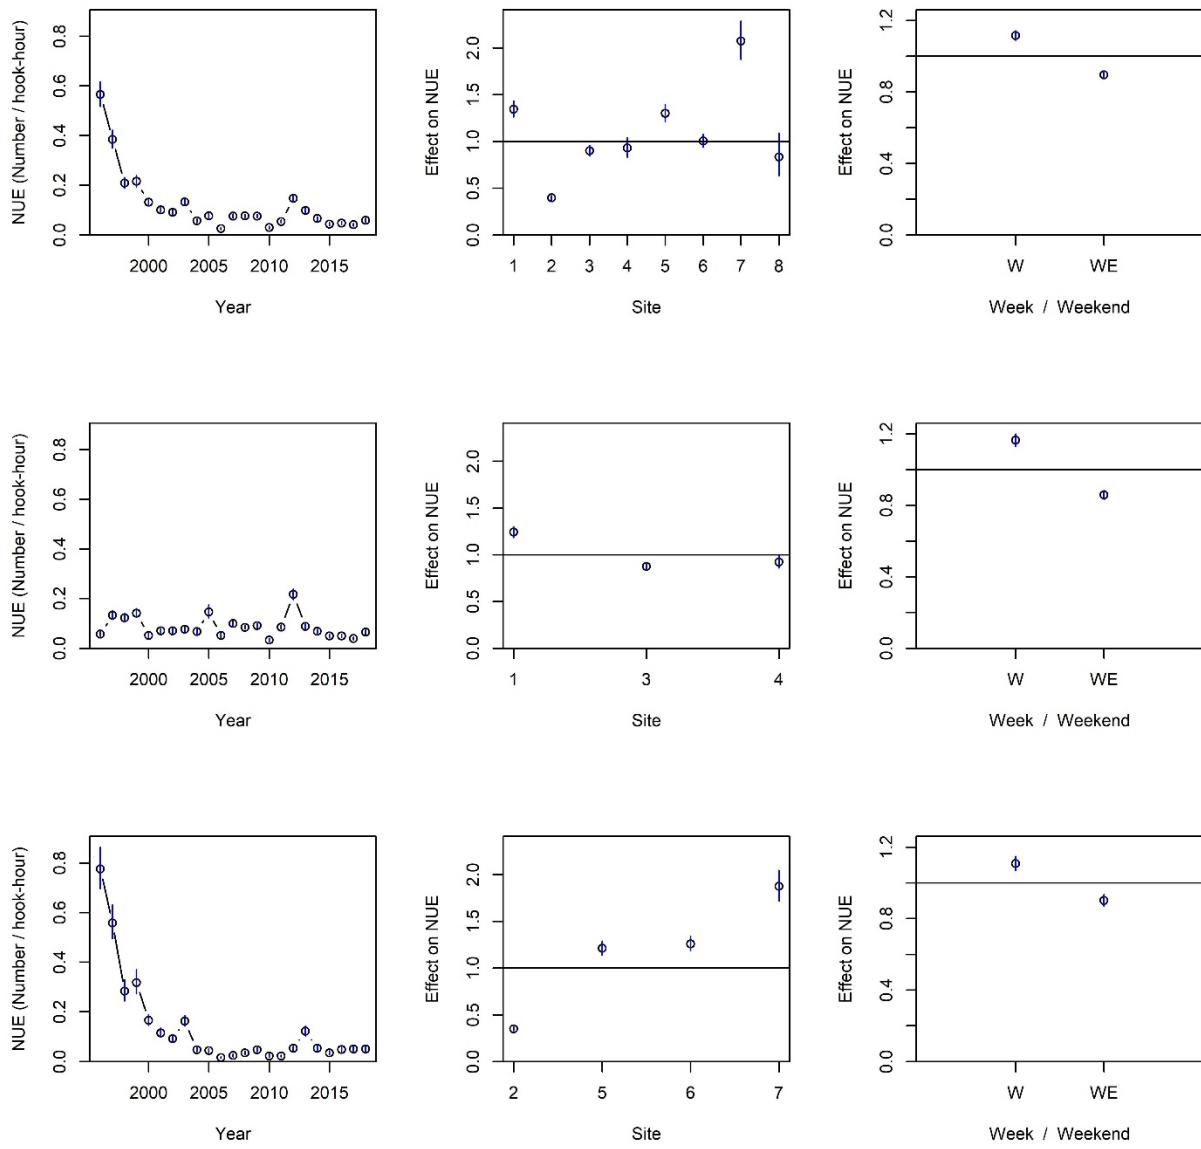

**Figure 1a.** Map of the Saguenay. Fishing villages on the pack ice are established at Saint-Fulgence, L'Anse-à-Benjamin, Grande-Baie, Les Battures, Sainte-Rose-du-Nord, Saint-Félix-d'Otis, Rivière-Éternité and L'Anse-Saint-Jean. The upstream boundary of the Saguenay–St. Lawrence Marine Park is identified on the map.

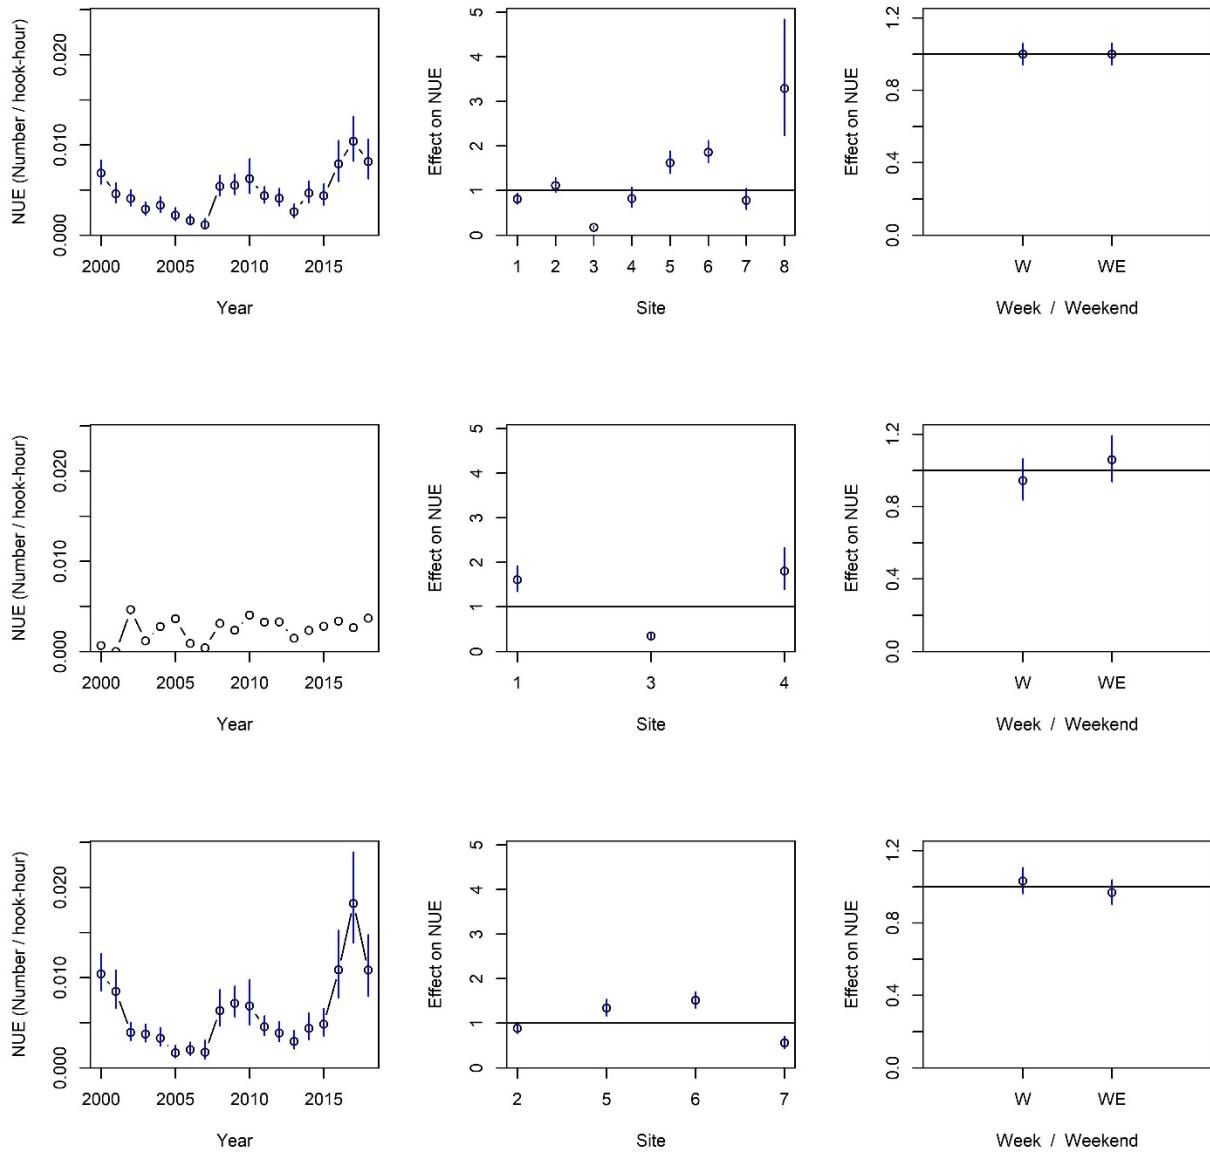

**Figure 1b.** Number of cabins set up on the pack ice from 1998 to 2018 during the winter recreational fishery for the smelt and groundfish areas combined. Information is presented for the entire Saguenay region on the left and for the Saguenay–St. Lawrence Marine Park (SSLMP) sites on the right.

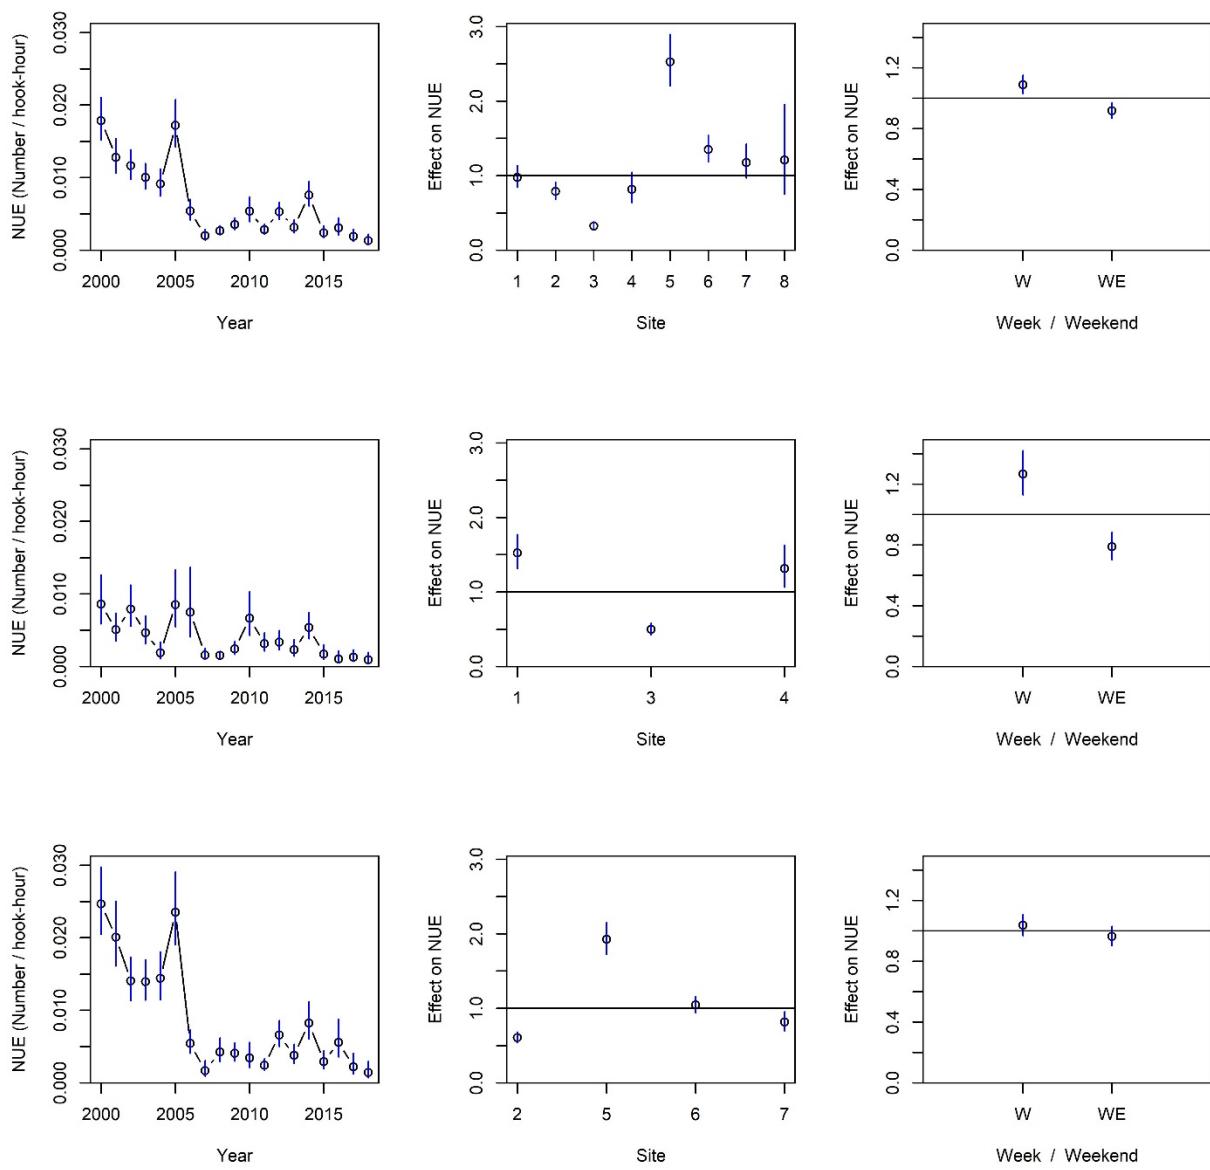

*Figure 2. Annual distribution of sampling activities of the winter recreational fishery in the Saguenay Fjord for Component 1 – catch per unit of effort. The circles represent the opening and closing of the fishery and the + signs represent the sampling days.*

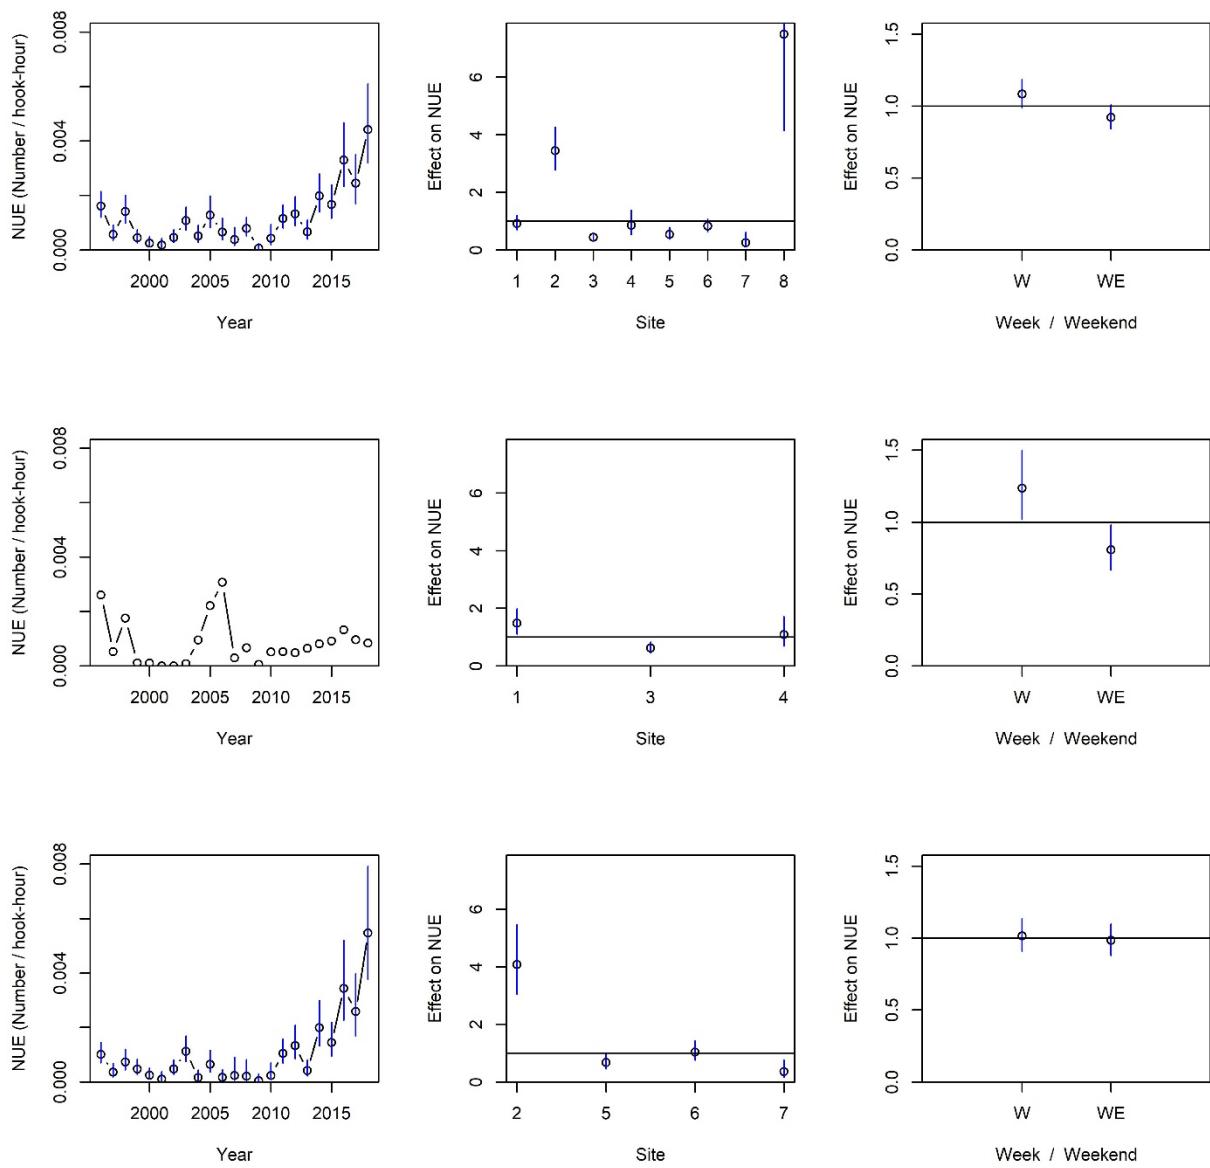

*Figure 3. Annual catch rates (Number per unit of effort (NUE)  $\pm$  95% confidence interval) and the effect on the NUE of the site and time (weekday and weekend) variables for redfish during the winter recreational fishery in the Saguenay Fjord, for the entire Saguenay region (top), for the Baie des Ha! Ha! (middle) and for the SSLMP (bottom). Numbering of the sites: (1) L'Anse-à-Benjamin, (2) L'Anse-Saint-Jean, (3) Grande-Baie, (4) Les Battures, (5) Rivière-Éternité, (6) Sainte-Rose-du-Nord, (7) Saint-Félix-d'Otis and (8) Saint-Fulgence.*

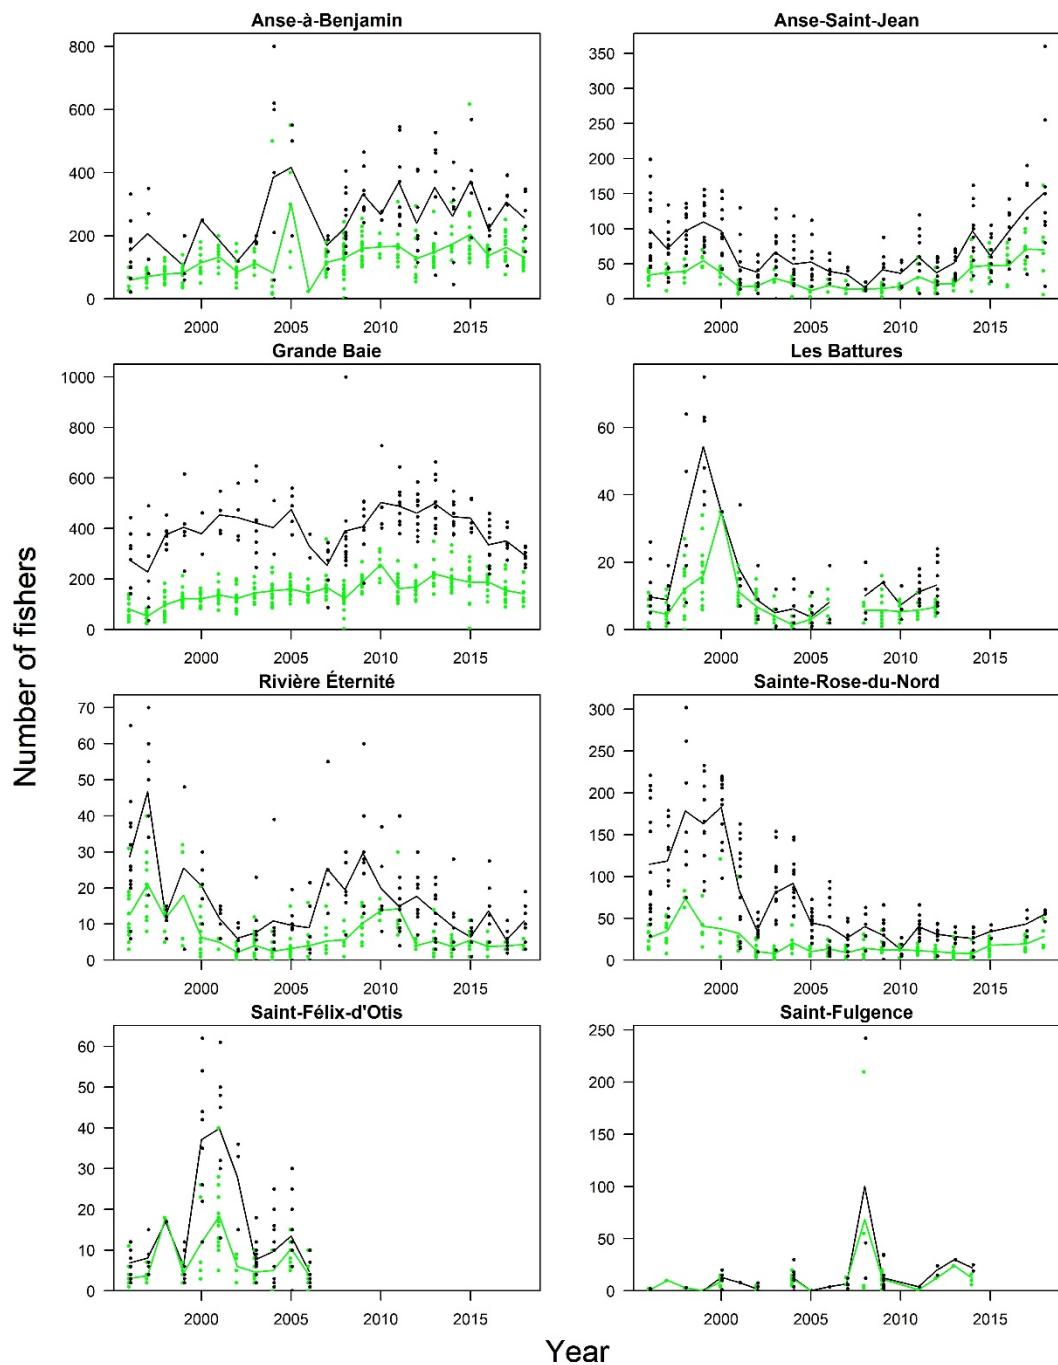

*Figure 4. Annual catch rates (Number per unit of effort (NUE)  $\pm$  95% confidence interval) and the effect on the NUE of the site and time (weekday and weekend) variables for Atlantic cod during the winter recreational fishery in the Saguenay Fjord, for the entire Saguenay region (top), for the Baie des Ha! Ha! (middle) and for the SSLMP (bottom). Numbering of the sites: (1) L'Anse-à-Benjamin, (2) L'Anse-Saint-Jean, (3) Grande-Baie, (4) Les Battures, (5) Rivière-Éternité, (6) Sainte-Rose-du-Nord, (7) Saint-Félix-d'Otis and (8) Saint-Fulgence.*

**Figure 5.** Annual catch rates (Number per unit of effort (NUE)  $\pm$  95% confidence interval) and the effect on the NUE of the site and time (weekday and weekend) variables for Greenland cod during the winter recreational fishery in the Saguenay Fjord, for the entire Saguenay region (top), for the Baie des Ha! Ha! (middle) and for the SSLMP (bottom). Numbering of the sites: (1) L'Anse-à-Benjamin, (2) L'Anse-Saint-Jean, (3) Grande-Baie, (4) Les Battures, (5) Rivière-Éternité, (6) Sainte-Rose-du-Nord, (7) Saint-Félix-d'Otis and (8) Saint-Fulgence.

**Figure 6.** Annual catch rates (Number per unit of effort (NUE)  $\pm$  95% confidence interval) and the effect on the NUE of the site and time (weekday and weekend) variables for Greenland halibut during the winter recreational fishery in the Saguenay Fjord, for the entire Saguenay region (top), for the Baie des Ha! Ha! (middle) and for the SSLMP (bottom). Numbering of the sites: (1) L'Anse-à-Benjamin, (2) L'Anse-Saint-Jean, (3) Grande-Baie, (4) Les Battures, (5) Rivière-Éternité, (6) Sainte-Rose-du-Nord, (7) Saint-Félix-d'Otis and (8) Saint-Fulgence.

*Figure 7. Weekday (green) and weekend (black) fishing site frequentation during the winter recreational groundfish fishery in the Saguenay Fjord. Each dot represents the estimated value of the number of fishers during a visit, and the line connects the annual averages.*

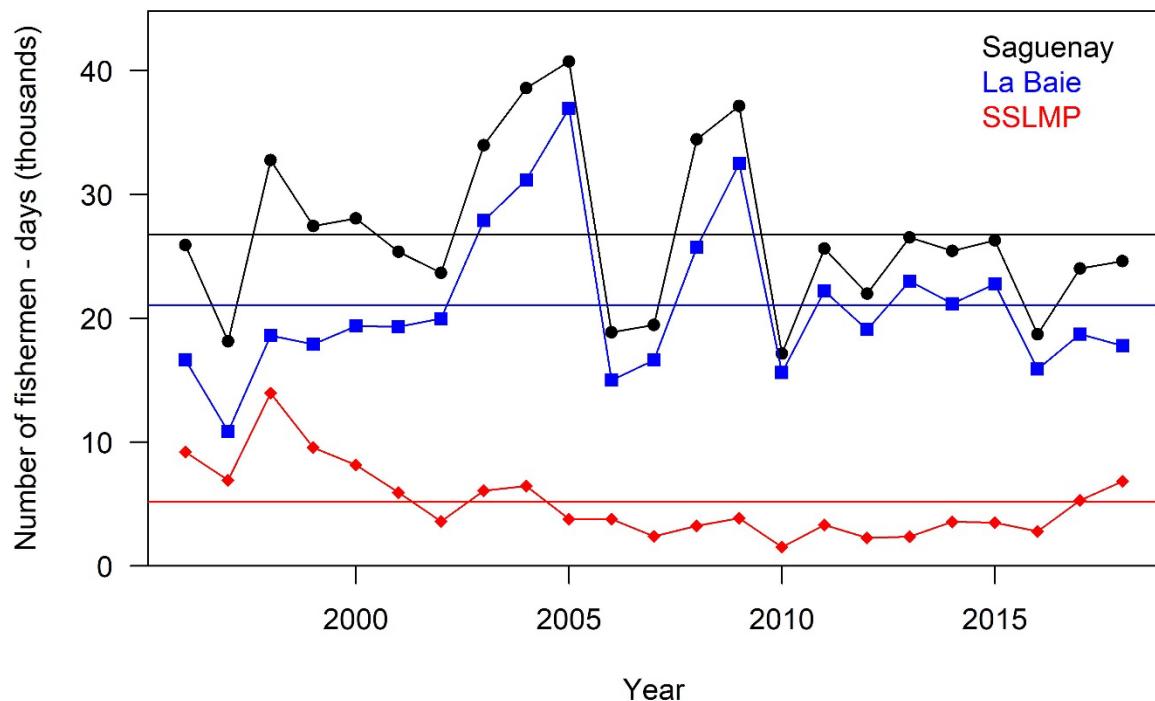

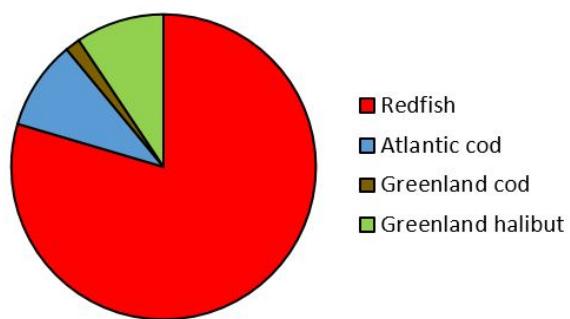

Figure 8. Annual frequmentation of the recreational groundfish fishery for the entire Saguenay region (black circle), the Baie des Ha! Ha! (blue square) and the Saguenay–St. Lawrence Marine Park (red diamond). The horizontal lines represent the average for each series (1996–2018).

A)

B)

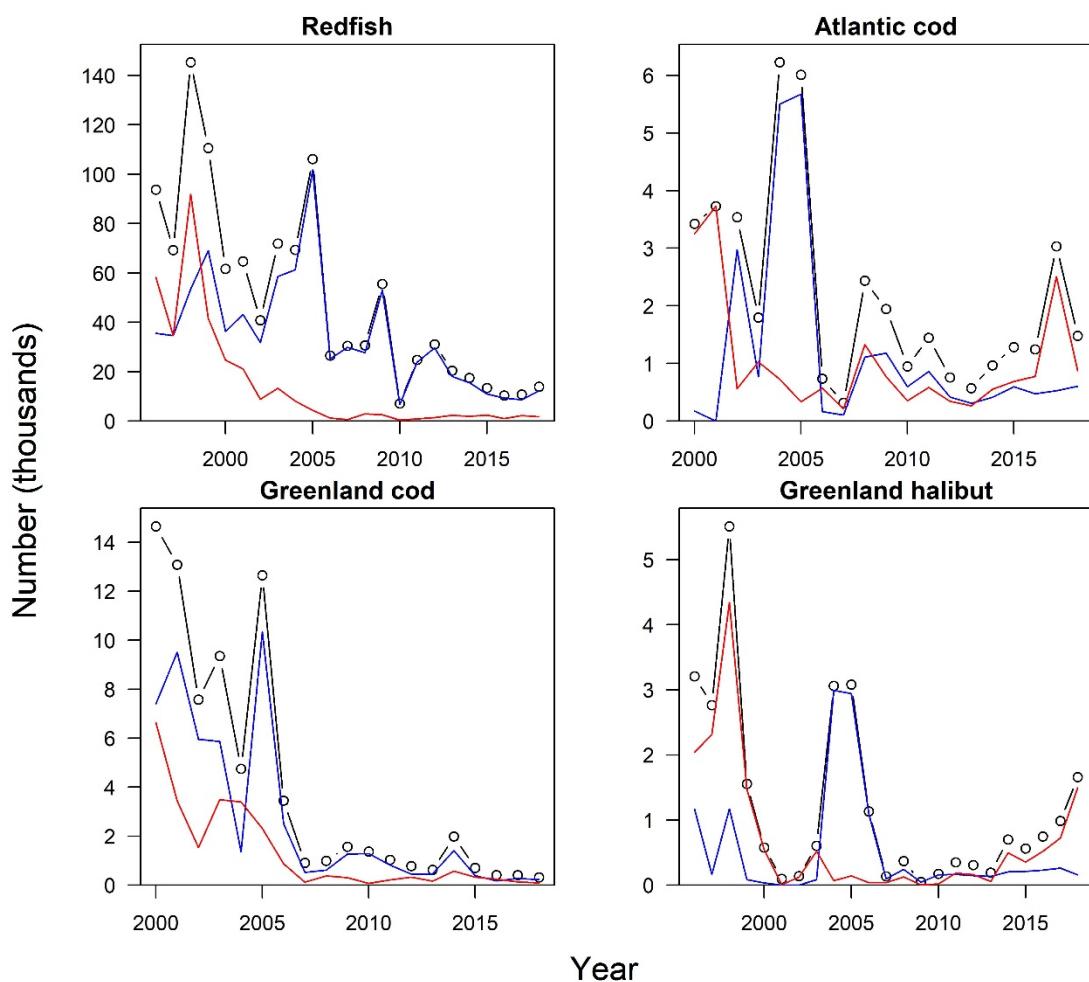

Figure 9. A) Proportion of the four main species in the Saguenay Fjord recreational groundfish fishery out of the total catch estimated in 2018. B) Estimated total catch by species and by year for the entire Saguenay region (black circle), the Baie des Ha! Ha! (blue line) and the SSLMP (red line) during the winter recreational groundfish fishery in the Saguenay Fjord.

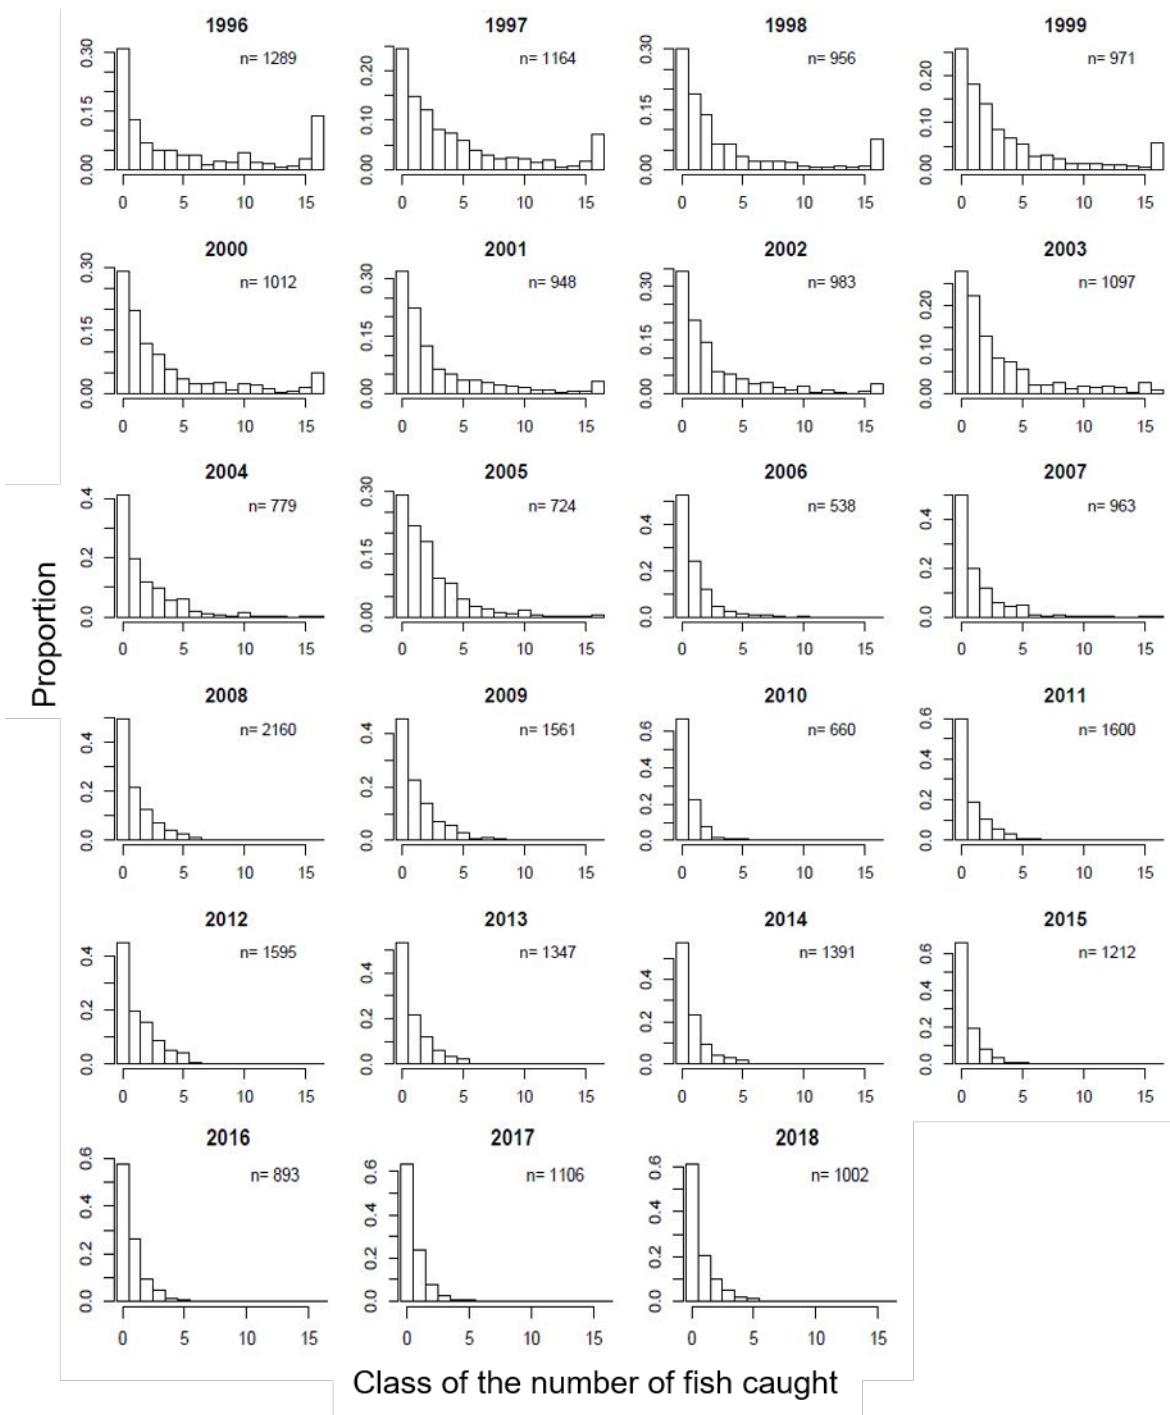

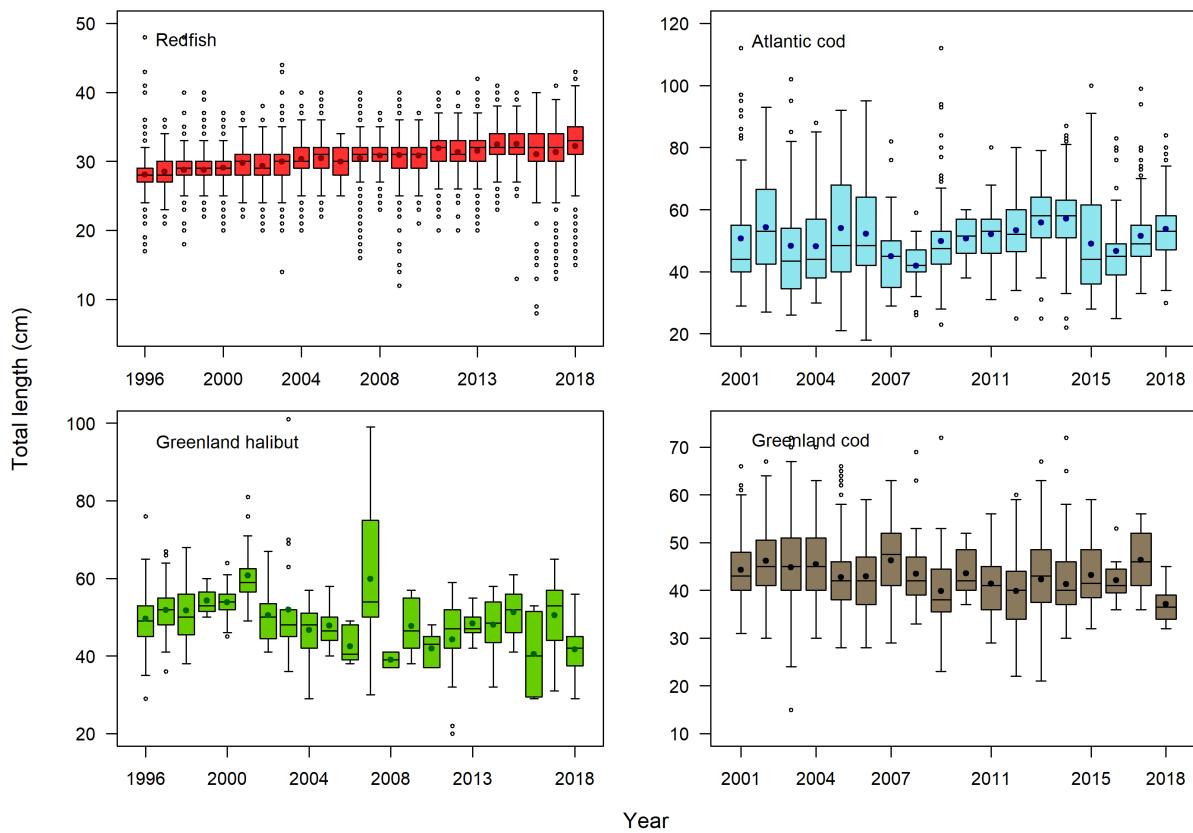

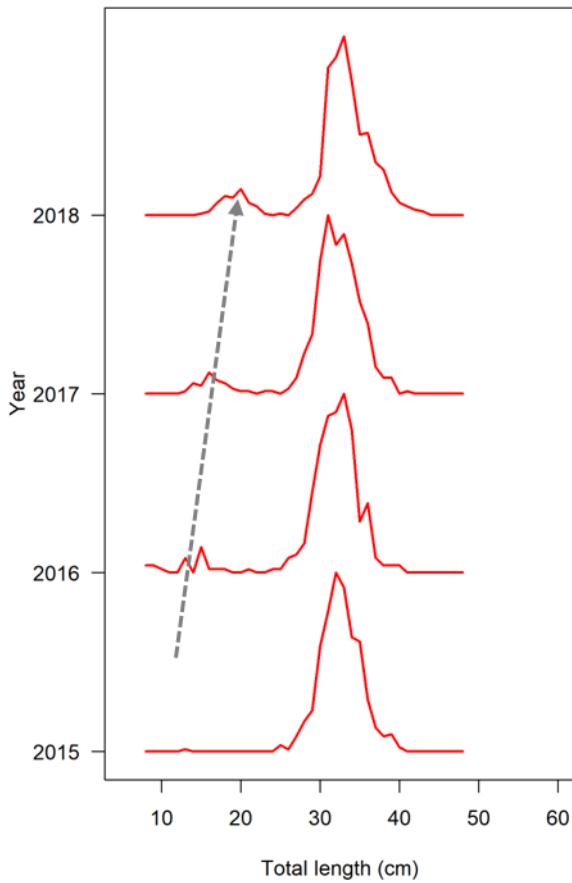

Figure 10. Proportion of fishers surveyed (Component 1) by category of the number of fish caught during the winter recreational groundfish fishery in the Saguenay Fjord.

**Figure 11.** Size frequency distribution (total length) for redfish, Greenland halibut, Atlantic cod and Greenland cod sampled during the winter recreational groundfish fishery in the Saguenay Fjord. Graphic representation in box-and-whisker plots: the line inside the box represents the median and the solid circle is the average. The box ranges from the 25th to the 75th percentile, the whiskers range from the 5th to the 95th percentile and the empty circles represent outliers.

*Figure 12. Size frequency distribution (total length) for redfish sampled from 2015 to 2018 during the winter recreational groundfish fishery in the Saguenay Fjord.*

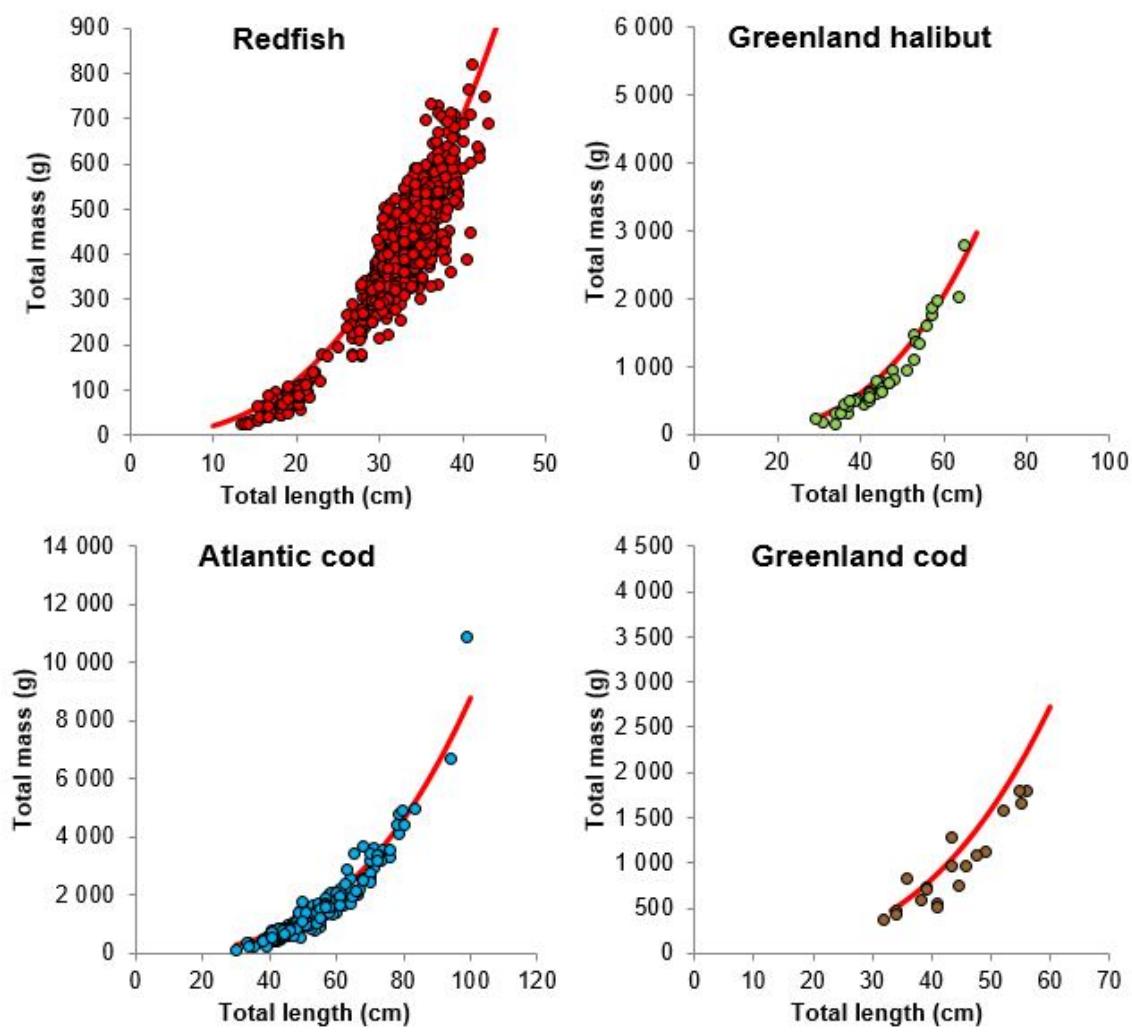

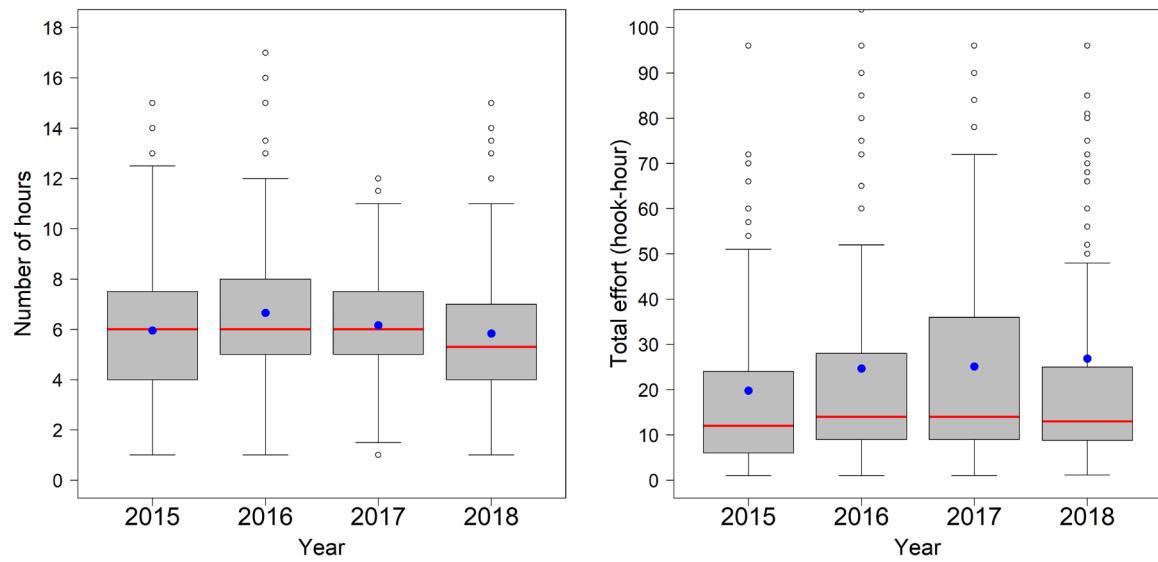

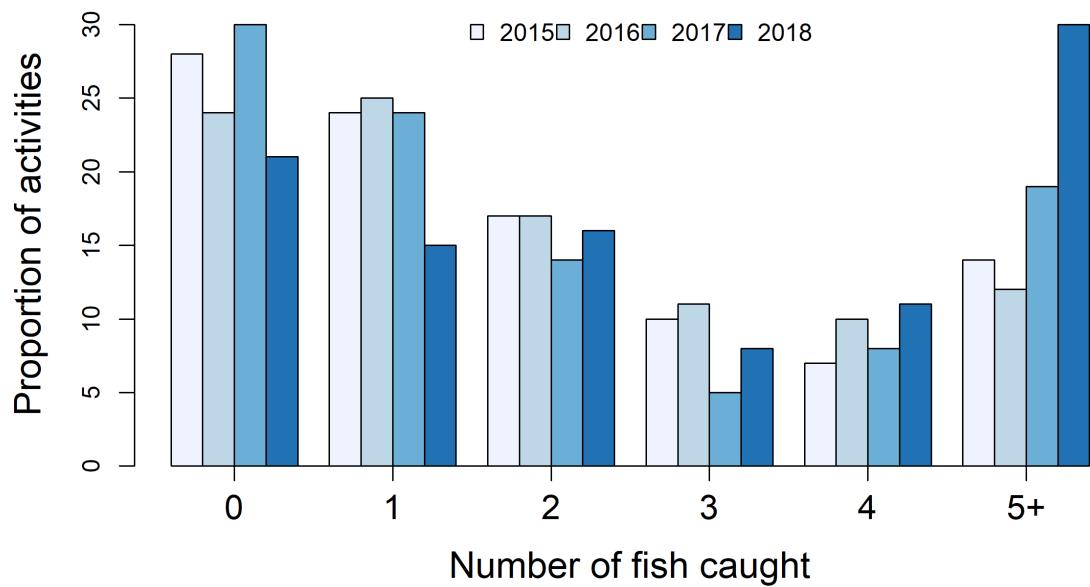

Figure 13. Relationship between total mass (g) and total length (cm) for redfish, Greenland halibut, Atlantic cod and Greenland cod sampled during the winter recreational groundfish fishery. The red line shows the regression for the years 1996–2018, and the dots represent the data for 2017 and 2018.

*Figure 14. Information taken from logbooks from 2015 to 2018. The graph on the left represents the number of fishing hours, and the graph on the right represents the total effort (hook-hours). The information is presented in box-and-whisker plots: the line inside the box represents the median and the solid circle is the average. The box ranges from the 25th to the 75th percentile, the whiskers range from the 5th to the 95th percentile and the empty circles represent outliers.*

*Figure 15. Fishing success, assessed against the daily catch limit of five fish based on information from logbooks. The 5+ category is explained by the fact that catch and release is permitted in this fishery with a retained daily limit of five fish.*

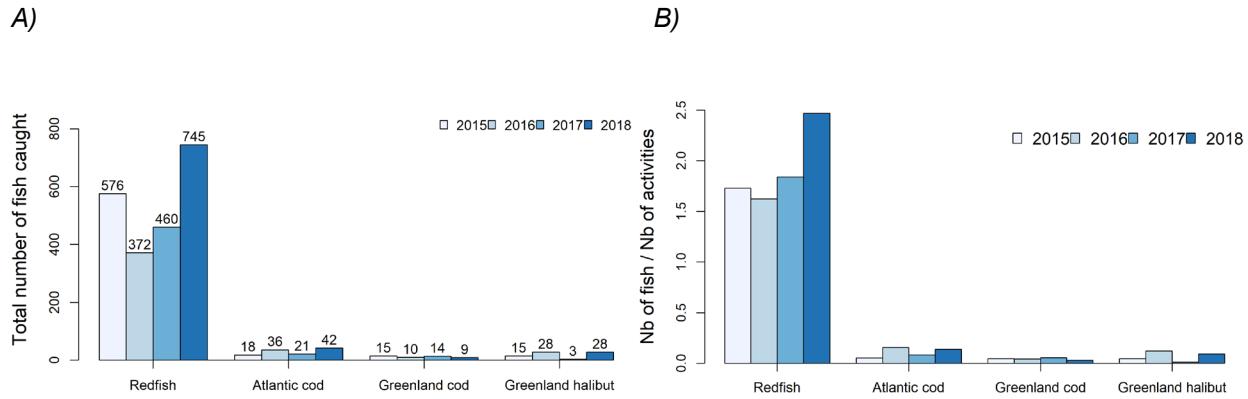

Figure 16. A) Total annual number of fish caught by species for participants in the logbook initiative. B) Number of fish caught by species divided by the number of fishing activities recorded in the logbooks.

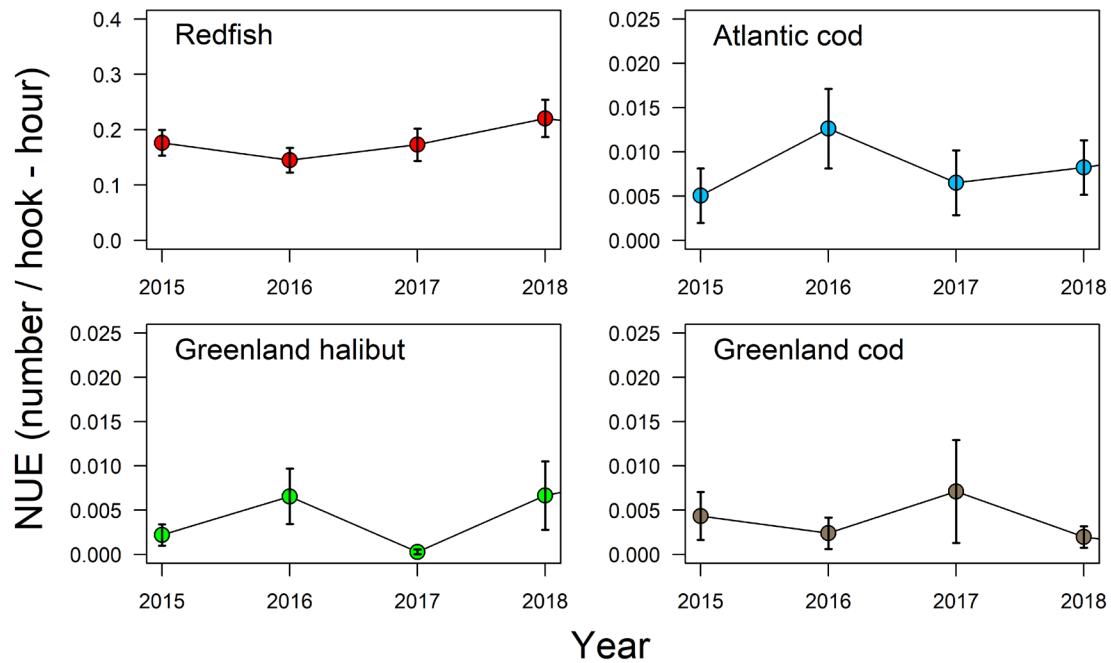

Figure 17. Catch rate in number of fish per unit of effort according to logbook data for redfish, Atlantic cod, Greenland halibut and Greenland cod.

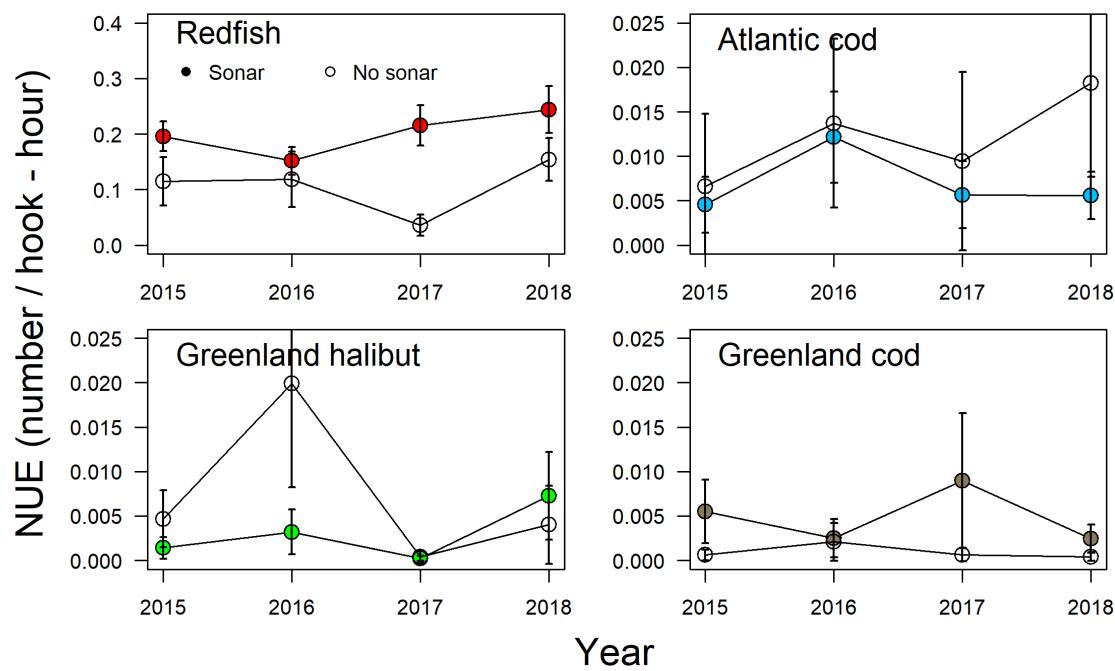

Figure 18. Number per unit of effort by species for fishers completing the logbook who use sonar (solid symbols) or do not use sonar (empty symbols).

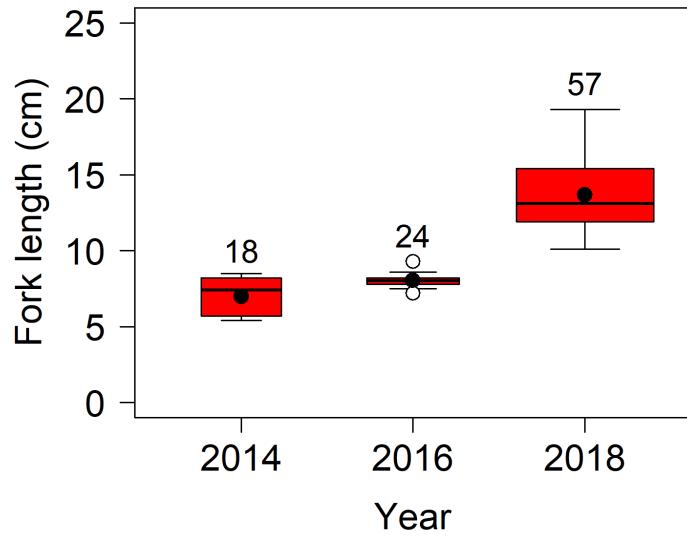

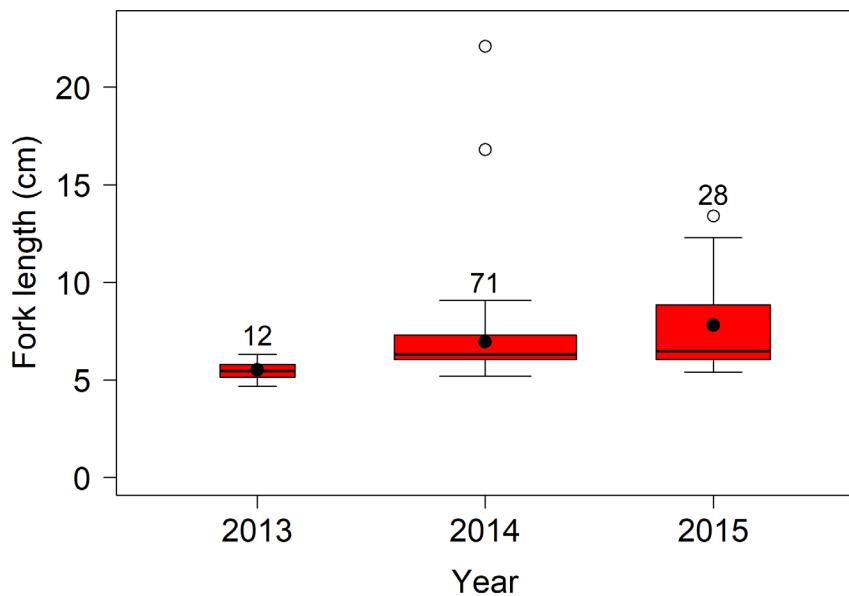

Figure 19. Size frequency distribution (fork length in cm) for redfish sampled during the winter recreational smelt fishery in the Saguenay Fjord. Graphic representation in box-and-whisker plots: the line inside the box represents the median and the solid circle is the average. The box ranges from the 25th to the 75th percentile, the whiskers range from the 5th to the 95th percentile and the empty circles represent outliers. The width of the boxes is proportional to the annual number of fish. The value above each box indicates the number of fish.

*Figure 20. Size frequency distribution (fork length in cm) of redfish sampled in the Saguenay Fjord for genetic testing (see Appendices 7 and 8 for genetic data). Graphic representation in box-and-whisker plots: the line inside the box represents the median and the solid circle is the average. The box ranges from the 25th to the 75th percentile, the whiskers range from the 5th to the 95th percentile and the empty circles represent outliers. The width of the boxes is proportional to the annual number of fish. The value above each box indicates the number of fish for the year.*

## APPENDICES

*Appendix 1. Total number of cabins set up by site during the winter recreational fishery in the Saguenay Fjord, smelt and groundfish areas combined (data provided by Guy Girard, Promotion Saguenay, pers. comm.).*

Appendix 7. Small redfish stranded at Saint-Fulgence in the Saguenay. Photos taken on December 28, 2014, by index fisher Yvon Roy.

*Appendix 8. Results of the genetic testing using 13 microsatellites on redfish caught in winter in the Saguenay Fjord. The identifier (ID) refers to the same fish in Appendices 7 and 8. The columns represent the genotypes observed at each of the 13 loci; each locus is defined by 2 alleles. A "0" indicates missing data.*

*Appendix 9. Information on redfish subject to genetic testing. The identifier (ID) refers to the same fish as in Appendix 7. The redfish samples were collected in the winter recreational fishery (source = WRF) or during a stranding event (source = S). The catch year, fork length (mm), and the number of soft rays in the anal fin (AFC) are indicated. The number of loci (Nb loci) used to determine the probability (Prob) of belonging to the species *Sebastes mentella* or *S. fasciatus* and the lower (IC90\_low) and upper (IC90\_up) limits of the 90% confidence intervals are shown in the table.*
