Foreword

This series documents the scientific basis for the evaluation of aquatic resources and ecosystems in Canada. As such, it addresses the issues of the day in the time frames required and the documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

TABLE OF CONTENTS

ABSTRACT	xiii
1. INTRODUCTION	1
2. METHODS	2
2.1. COMPARATIVE FISHING.....	2
2.2. COMPARATIVE FISHING DATA ANALYSIS	3
2.2.1. Binomial models.....	3
2.2.2. Beta-binomial models.....	4
2.2.3. Tweedie model for biomass data	5
2.2.4. Model fitting, selection and validation	6
2.2.5. Data treatment prior to analysis	8
2.2.6. Interpretation of analysis results and application of conversion factors	8
3. RESULTS	9
3.1. PRESENTATION OF RESULTS.....	9
3.2. SOME SPECIFIC RESULTS.....	10
3.2.1. Atlantic cod (<i>Gadus morhua</i>)	10
3.2.2. White hake (<i>Urophycis tenuis</i>)	10
3.2.3. Redfish (<i>Sebastes sp.</i>).....	10
3.2.4. Atlantic halibut (<i>Hippoglossus hippoglossus</i>).....	10
3.2.5. Greenland halibut (<i>Reinhardtius hippoglossoides</i>)	11
3.2.6. American plaice (<i>Hippoglossoides platessoides</i>).....	11
3.2.7. Witch flounder (<i>Glyptocephalus cynoglossus</i>)	11
3.2.8. Yellowtail flounder (<i>Limanda ferruginea</i>).....	11
3.2.9. Winter flounder (<i>Pseudopleuronectes americanus</i>).....	11
3.2.10. Atlantic herring (<i>Clupea harengus</i>)	12
3.2.11. Atlantic mackerel (<i>Scomber scombrus</i>)	12
3.2.12. Atlantic wolffish (<i>Anarhichas lupus</i>)	12
3.2.13. Thorny skate (<i>Amblyraja radiata</i>).....	12
3.2.14. Snow crab (<i>Chionoecetes opilio</i>)	12
3.2.15. Lobster (<i>Homarus americanus</i>).....	13
3.2.16. Other results of note.....	13
3.2.17. Recommendations for the application of conversion factors.....	13
4. DISCUSSION.....	14
5. ACKNOWLEDGEMENTS	15
6. REFERENCES CITED.....	15
7. TABLES	17
8. FIGURES	36

LIST OF TABLES

Table 1. Details for the relevant set pairs in the 2021 and 2022 comparative fishing of the sGSL, where columns indicated by TEL represent values for the CCGS <i>Teleost</i> and those indicated by CA represent values for the CCGS <i>Capt. Jacques Cartier</i>	17
Table 2. A set of binomial models with various assumptions for the length effect and station effect in the relative catch efficiency.	22
Table 3. A set of beta-binomial models with various assumptions for the length effect and station effect in the relative catch efficiency, and the length effect on the variance parameter.....	23
Table 4. Taxonomic groupings employed for the analyses of the sGSL comparative fishing data. The codes are those used routinely in DFO's Gulf region, commonly called RVAN codes.	24
Table 5. Summary of the catches at length excluded from the length-disaggregated analyses.	25
Table 6. Total number of relevant set pairs (those with at least one capture), and pairs in which the taxon was captured only by the CCGS <i>Capt. Jacques Cartier</i> or only by the CCGS <i>Teleost</i> , along with a reference to the number of the figure in which results are plotted.	25
Table 7a. Relative evidence for length-disaggregated binomial and beta-binomial models based on delta values of the Akaike Information Criterion (AIC).	29
Table 7b. Relative evidence for length-disaggregated binomial and beta-binomial models based on delta values of the Bayesian Information Criterion (BIC) values.	30
Table 8. P-values associated with tests for a smooth effect of depth, a smooth effect of time and a fixed effect of day on the normalized quantile residuals from the length-disaggregated selected best model.	32
Table 9. Relative evidence for size-aggregated binomial and beta-binomial models for catch counts based on Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC) values, and estimates of the conversion factor Rho, and approximate 95% confidence intervals, for catches in numbers and in weights for taxa for which length-disaggregated analyses were also undertaken.	33
Table 10. Relative evidence for size-aggregated binomial and beta-binomial models for catch counts based on Akaike's Information Criterion (AIC) and the Bayesian Information Criterion (BIC) values, and estimates of the conversion factor Rho, and approximate 95% confidence intervals, for catches in numbers and in weights for taxa for which only size-aggregated analyses were also undertaken.	34

ABSTRACT

Bottom-trawl surveys provide key inputs to stock assessments for groundfish stocks and other taxa, for ecosystem monitoring and reporting, and for research. These surveys can produce annual indices of abundance that are proportional to stock size, provided that the proportionality constant, typically called catchability, does not change over time. This is typically achieved through the use of standardized survey design and procedures. Periodically it becomes necessary or desirable to change one or more aspects of the protocol, and calibration experiments are typically required to estimate adjustments for possible changes in catchability. From 2004 to 2022, the CCGS *Teleost* fishing a Western IIA bottom-trawl was used for the annual survey of the southern Gulf of St. Lawrence (sGSL). This vessel will soon be retired and is being replaced by the CCGS *Capt. Jacques Cartier*, fishing a different trawl. Paired-trawl comparative fishing experiments involving these two vessels and gear pairs were conducted in September in 2021 and 2022 to obtain data for catch required to estimate their relative fishing efficiency for a large number of fish and invertebrate taxa that are routinely sampled in this survey. In this document we briefly describe these comparative fishing experiments and report on analyses of the resulting data for 116 fish and invertebrate taxa routinely sampled by the sGSL survey. The analyses employed a suite of contemporary statistical models used previously in extended comparative fishing analyses in the eastern United States and which were recently extensively tested using simulations. Relative catchability as a function of individual lengths (fish, lobster and squid) or carapace width (crabs) was evaluated and estimated for 38 taxa, whereas size-aggregated estimates were derived for the others. Given considerable differences between the old and replacement survey protocols, which include a substantial change in the fishing gear and tow length, important differences in length-dependent and independent relative catchability were expected for this comparative fishing experiment and were estimated for a number of taxa. Recommendations for the application of the conversion factors are provided. Use of these conversion factors will maintain the integrity of the over five decade long time series for various southern Gulf marine taxa.

1. INTRODUCTION

Worldwide, bottom-trawl surveys provide key inputs to stock assessments for groundfish stocks and other taxa, for ecosystem monitoring and reporting, and for research. These surveys can produce annual indices of abundance that are proportional to stock size, provided that the proportionality constant, typically called catchability, does not change over time. Failure to achieve this consistency via proper sampling design and standardization increases the risk of confounding changes in abundance with changes in catchability. Maintaining consistency in survey protocols, and the survey vessel and gear (hereafter, simply the protocol) is key to maintaining a constant catchability. However, periodically it becomes necessary or desirable to change one or more aspects of the protocol, and calibration experiments are typically required to estimate adjustments for possible changes in catchability. The most common and effective form of these experiments is comparative fishing, which usually involves paired trawling of vessels constituting the former and replacement protocol as close together as safety permits. This design minimizes the difference in fish densities sampled by the trawls, such that differences in catches over replicates of paired-trawl sampling will reflect the difference in catchability.

Fisheries and Oceans Canada (DFO) is undertaking comparative fishing in each of its six Atlantic bottom-trawl surveys from 2021 to 2023 to calibrate two new offshore fisheries survey vessels that will replace two retiring longstanding vessels. In some surveys, the change in vessel will also be accompanied by a change in survey trawl and survey procedures (e.g., tow duration), and the joint effect of all of these factors on relative catchability should be reflected in results of the comparative fishing experiments. In the survey of the southern Gulf of St. Lawrence (sGSL), which has taken place annually in September since 1971, the CCGS Capt. Jacques Cartier (63.4 m; 2 975 t gross tonnage) will replace the CCGS Teleost (63 m; 2 405 gross tonnage), which has been used to conduct the survey since 2004. During the sGSL survey, the CCGS Teleost has fished the Western IIA trawl (Hurlbut and Clay 1990), while the CCGS Capt. Jacques Cartier will be using the a slightly modified version of the Northeast Fisheries Science Center Ecosystem Survey Trawl, NEST (trawl details in Denton 2020; modifications outlined in Ricard et al. 2023). A standard tow aboard the CCGS Capt. Jacques Cartier is fished at 3.0 knots for 20 min, in contrast to a standard CCGS Teleost tow of 3.5 knots for 30 min. In addition, tow duration aboard the CCGS Capt. Jacques Cartier is measured from trawl touch-down to lift off, whereas aboard the Teleost it is measured from the time the winches stop deploying warp, to when haul-back is initiated (Ricard et al. 2023). Comparative fishing between the two vessels, with their respective trawls, took place during the regular survey of the sGSL in 2021, and in 2022. The design employed, sometimes termed a shadow survey design (Thiess et al. 2018), involved paired trawling at sites selected as part of the routine stratified random design for the survey (Fig. 1). Such a design best ensures that comparative fishing results will reflect the environmental conditions of the survey area, principally depths and bottom substrate, which can affect catchability. It also ensures that data will be available to estimate relative catchability adjustment factors for as many as possible of the taxa that are sampled by the survey and for which standardization is required for ongoing research and reporting.

In this document we briefly describe the 2021-2022 comparative fishing experiments for the sGSL (see Ricard et al. 2023 for a more detailed description) and report on analyses of the resulting data for 116 fish and invertebrate taxa routinely sampled by the sGSL survey. The analyses employed contemporary statistical models used previously in extended comparative fishing analyses in the eastern United States (Miller et al. 2010; Miller 2013), and applied recently to analyses of past comparative fishing data for some stocks in the Gulf of St. Lawrence (Yin and Benoît 2022a; Benoît et al. 2022). These models were extensively tested in

a simulation context and were confirmed appropriate for analyses such as those employed in the present case (Yin and Benoit 2022b). As part of the analyses, estimates of relative catchability as a function of individual lengths (fish, lobster and squid) or carapace width (crabs) were derived for 38 taxa, whereas size-aggregated estimates were derived for the others. Given considerable differences between the old and replacement survey protocols, which include a substantial change in the fishing gear and tow length, important differences in length-dependent and independent relative catchability were expected for this comparative fishing experiment.

2. METHODS

2.1. COMPARATIVE FISHING

Comparative fishing between the CCGS Teleost and the CCGS Capt. Jacques Cartier took place between August 31 and September 26 in 2021, and between September 17 and 30 in 2022 (Table 1). The initiation of comparative fishing in 2022 was delayed to allow completion of comparative fishing experiments in the survey of the Estuary and northern Gulf of St. Lawrence, which also involved the CCGS Teleost. A total of 127 and 53 paired sets considered as valid comparative pairs were completed in 2021 and 2022 respectively and retained for analysis. Of the set pairs from 2022, the catch for hauls 53 and 54 was accidentally physically combined prior to catch sorting aboard the CCGS Capt. Jacques Cartier (Ricard et al. 2023). These data were included in subsequent analyses by matching them to the combined data for the same hauls for the CCGS Teleost, and assuming a trawl swept area for each vessel that was the sum of swept areas for the individual hauls.

Details of the comparative fishing experiments are presented in Ricard et al. (2023) and are therefore only briefly summarized here. At pre-selected stations, the CCGS Capt. Jacques Cartier and the CCGS Teleost fished as close together in space and in time as was safe and practical. The majority of paired sets were done side-by-side along parallel tracks. Across stations, the vessels alternated between having the other vessel on their port or starboard side. Efforts were made to ensure similar depths between the two locations fished at a station. The distance separating the vessels was typically no more than 0.5 nautical miles. In some instances in which the difference in depths between potential parallel tracks was too great (> 10 m), the vessels fished along the same track, separated by 1.5 miles.

The CCGS Teleost fished standard tows targeting a tow time of 30 minutes at 3.5 knots, while the CCGS Capt. Jacques Cartier fished standard tows of 20 minutes at 3.0 knots. Tow durations of at least $2/3$ the target time were considered acceptable. Both vessels employed an auto-trawl system using Scanmar sensors in which trawl geometry is dynamically adjusted during the tow to keep the trawl square to the trawl path. The data from the Scanmar sensors were additionally used to monitor trawl performance and to potentially invalidate a tow, but were not used to calculate the swept area of each tow for use in the data analyses. Instead, tow distance was used as the sole standardizing factor for swept area.

Standard procedure in the sGSL survey is to obtain a total catch weight for each taxon in each haul. Additionally, a representative length frequency is obtained in each survey haul for all fish taxa, all crab taxa excluding hermit crabs, and for lobster and squid. Catch counts are also produced for each measured taxon.

Further details on the comparative fishing experiments are available in Ricard et al. (2023).

2.2. COMPARATIVE FISHING DATA ANALYSIS

2.2.1. Binomial models

In the analysis of comparative fishing data, the goal is to estimate the relative fishing efficiency between a pair of vessel-gear combinations (referred to as vessel in this section for simplicity). We assume the expected catch from vessel v ($v \in \{A, B\}$) at length l and at station i is

$$E[C_{vi}(l)] = q_{vi}(l)D_{vi}(l)f_{vi}$$

where, $q_{vi}(l)$ is the catchability of vessel v , D_{vi} is the underlying population density sampled by vessel v , and f_{vi} is a standardization term which usually includes the swept area of a tow, and if applicable, the proportion of sub-sampling for size measurement on-board. In a binomial model (e.g., Miller 2013), the catch from vessel A at station i , conditioning on the combined catch from both vessels at this station, $C_i(l) = C_{Ai}(l) + C_{Bi}(l)$, is binomial-distributed

$$C_{Ai}(l) \sim BI(C_i(l), p_{Ai}(l))$$

where $p_{Ai}(l)$ is the expected proportion of catch from vessel A . Tows in a pair are generally assumed to fish the same underlying densities at the station, as the paired vessels typically fish within a small distance of each other: $D_{Ai}(l) = D_{Bi}(l) = D_i(l)$. Then the logit-probability of catch by vessel A is

$$\text{logit}(p_{Ai}(l)) = \log\left(\frac{E[C_{Ai}(l)]}{E[C_{Bi}(l)]}\right) = \log(\rho_i(l)) + o_i$$

Where $\rho_i(l)$ is the ratio of catchabilities between vessels A and B at length l and at station i , or the conversion factor, the quantity of interest,

$$\rho_i(l) = q_{Ai}(l)/q_{Bi}(l)$$

and $o_i = \log(f_{Ai}/f_{Bi})$ is an offset term derived from known standardization terms for tow length relative to the standard tow lengths and for subsampling..

For a length-based conversion factor, we consider a smooth length effect based on a general additive smooth function,

$$\log(\rho(l)) = \sum_{k=0}^K \beta_k X_k(l) = \mathbf{X}^T \boldsymbol{\beta},$$

where $\boldsymbol{\beta}$ are the coefficient parameters and are estimated, \mathbf{X} , or $\{X_k(l), k = 0, 1, \dots, K\}$, are a set of smoothing basis functions, and K is the dimension of the basis that controls the number of coefficient parameters and is usually pre-defined. Here a cubic spline smoother was used (Hastie et al. 2009), with the basis functions and penalty matrices generated by the R package `mgcv` for R (Wood 2011; R core team 2021).

The estimation of a cubic spline smoother is based on the penalized sum of squares smoothing objective, but in practice, this is usually replaced by a penalized likelihood objective (Green and Silverman 1993):

$$\mathcal{L}(\boldsymbol{\beta}, \lambda) = f(\mathbf{Y}|\mathbf{X}, \boldsymbol{\beta})e^{-\frac{\lambda}{2}\boldsymbol{\beta}^T \mathbf{S} \boldsymbol{\beta}}$$

\mathcal{L} denotes the likelihood objective function. $f(\mathbf{Y}|\mathbf{X}, \boldsymbol{\beta})$ is the joint probability function of the survey data \mathbf{Y} conditional on the basis functions and coefficient parameters. \mathbf{S} is the penalty matrix defined by the smoother and the dimension of the basis, and λ is the smoothness parameter. This smoothness parameter is estimated by maximum likelihood along with other model

parameters but may be sensitive to the data. In such cases, it can be determined by other criteria such as generalized cross-validation (Wood 2000).

The penalized maximum likelihood smoother can also be re-parameterized into a mixed effects model (Verbyla et al. 1999; Wood 2017) to facilitate implementation as well as incorporation of additional random effects:

$$\log(\rho_i(l)) = \mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b}$$

where $\boldsymbol{\beta}_f$ are fixed effects and \mathbf{b} are random effects. \mathbf{X}_f and \mathbf{X}_r are transformed from the basis functions \mathbf{X} and an eigen-decomposition of the penalty matrix \mathbf{S} , $\mathbf{X}_f = \mathbf{U}_f^T \mathbf{X}$ and $\mathbf{X}_r = \mathbf{U}_r^T \mathbf{X}$, where \mathbf{U}_f and \mathbf{U}_r are the eigenvectors that correspond to the zero and positive eigenvalues of \mathbf{S} . The random effects $b \sim N(0, \mathbf{D}_+^{-1}/\lambda)$ where \mathbf{D}_+ is the diagonal matrix of the positive eigenvalues of \mathbf{S} . In the mixed effects model representation of the cubic spline smoother, the number of fixed effects is 2 and the number of random effects is bounded by $K - 2$. Smoothing effects are transformed into shrinkage of random effects in the fitting of random deviations, and can be integrated into complex mixed effects models commonly used in fisheries science (Thorson and Minto 2015).

Additional random effects can be incorporated into the mixed effects model to address variations in the relative catch efficiency related to each station,

$$\log(\rho_i(l)) = \mathbf{X}_f^T (\boldsymbol{\beta}_f + \boldsymbol{\delta}_i) + \mathbf{X}_r^T (\mathbf{b} + \boldsymbol{\epsilon}_i).$$

where $\boldsymbol{\delta}_i \sim N(\mathbf{0}, \boldsymbol{\Sigma})$ and $\boldsymbol{\epsilon}_i \sim N(\mathbf{0}, \mathbf{D}_+^{-1}/\xi)$. From a similar re-parameterization of the cubic spline smoother, these random effects allow for deviations of the length-based conversion at each station. $\boldsymbol{\Sigma}$ is the covariance matrix of the random effects corresponding to the random deviations and contains three parameters. ξ controls the degree of smoothness of the random smoothers and the smoother at each station can differ.

A summary of the above binomial mixed model is as follows,

$$\begin{aligned} C_i(l) &= C_{Ai}(l) + C_{Bi}(l) \\ C_{Ai}(l) &\sim BI(C_i(l), p_{Ai}(l)) \\ \text{logit}(p_{Ai}(l)) &= \log(\rho_i(l)) + o_i \\ \log(\rho_i(l)) &= \mathbf{X}_f^T (\boldsymbol{\beta}_f + \boldsymbol{\delta}_i) + \mathbf{X}_r^T (\mathbf{b} + \boldsymbol{\epsilon}_i) \end{aligned}$$

The model is estimated via maximum likelihood and the marginal likelihood integrating out random effects is

$$\mathcal{L}(\boldsymbol{\beta}_f, \boldsymbol{\Sigma}, \lambda, \xi) = \int \left(\prod_{i=1}^m \int \int f(\mathbf{Y}_i | \mathbf{X}_f, \mathbf{X}_r, \boldsymbol{\beta}_f, \mathbf{b}, \boldsymbol{\delta}_i, \boldsymbol{\epsilon}_i) f(\boldsymbol{\delta}_i | \boldsymbol{\Sigma}) f(\boldsymbol{\epsilon}_i | \xi) d\boldsymbol{\delta}_i d\boldsymbol{\epsilon}_i \right) f(\mathbf{b} | \lambda) d\mathbf{b}$$

The binomial mixed model can be adapted for various assumptions on the smoother and potential station variation to accommodate different underlying density of a species and data limitations especially in length measurements. A set of binomial models considered in the present analyses is provided in Table 2.

2.2.2. Beta-binomial models

The binomial assumption of the catch can be extended to a beta-binomial distribution to account for over-dispersion at the stations (Miller 2013):

$$C_{A,i}(l) \sim BB(C_i(l), p_{A,i}(l), \phi_i(l)).$$

The beta-binomial distribution is a compound of the binomial distribution and a prior beta distribution. More specifically, it assumes a beta-distributed random effect in the expected proportion of catch from vessel A across stations. As a result, the expected catch by vessel A has a variance of

$$\text{var}(C_{A,i}) = C_i p_i (1 - p_i) \frac{\phi_i + C_i}{\phi_i + 1}$$

where ϕ is the over-dispersion parameter that captures the extra-binomial variation.

The same smoothing length effect can be applied to the over-dispersion parameter,

$$\log(\phi_i(l)) = \mathbf{X}_f^T \boldsymbol{\gamma} + \mathbf{X}_r^T \mathbf{g}$$

where $\boldsymbol{\gamma}$ are fixed effects and \mathbf{g} are random effects, $\mathbf{g} \sim N(0, \mathbf{D}_+^{-1}/\tau)$. This length effect models the variance heterogeneity and is particularly useful for projecting uncertainty to poorly sampled lengths. However, estimation of a length-based variance parameter typically requires sufficient catch at length data, which is usually not available for less abundant species.

A summary of the beta-binomial mixed model is as follows,

$$\begin{aligned} C_i(l) &= C_{Ai}(l) + C_{Bi}(l) \\ C_{Ai}(l) &\sim BB(C_i(l), p_{Ai}(l), \phi_i(l)) \\ \text{logit}(p_{Ai}(l)) &= \log(\rho_i(l)) + o_i \\ \log(\rho_i(l)) &= \mathbf{X}_f^T (\boldsymbol{\beta}_f + \boldsymbol{\delta}_i) + \mathbf{X}_r^T (\mathbf{b} + \boldsymbol{\epsilon}_i) \\ \log(\phi_i(l)) &= \mathbf{X}_f^T \boldsymbol{\gamma} + \mathbf{X}_r^T \mathbf{g} \end{aligned}$$

The marginal likelihood is

$$\begin{aligned} &\mathcal{L}(\boldsymbol{\beta}_f, \boldsymbol{\gamma}, \boldsymbol{\Sigma}, \lambda, \xi, \tau) \\ &= \int \int \left(\prod_{i=1}^m \int \int f(\mathbf{Y}_i | \mathbf{X}_f, \mathbf{X}_r, \boldsymbol{\beta}_f, \mathbf{b}, \boldsymbol{\gamma}, \mathbf{g}, \boldsymbol{\delta}_i, \boldsymbol{\epsilon}_i) f(\boldsymbol{\delta}_i | \boldsymbol{\Sigma}) f(\boldsymbol{\epsilon}_i | \xi) d\boldsymbol{\delta}_i d\boldsymbol{\epsilon}_i \right) f(\mathbf{b} | \lambda) f(\mathbf{g} | \tau) d\mathbf{b} d\mathbf{g} \end{aligned}$$

Likewise, various smoothing assumptions can be applied to the variance parameter. Table 3 presents a set of beta-binomial mixed models.

2.2.3. Tweedie model for biomass data

The binomial and beta-binomial models are appropriate for data constituted of catch counts, but are not appropriate for catch weight or biomass. Biomass indices are routinely derived from survey data for population trend monitoring. For taxa that are measured, biomass values adjusted for the change in relative catchability are most reliably derived by applying the results of the analyses described above to length specific catch numbers and employing a length-weight conversion. However, individual measurements are not made for numerous invertebrate taxa, and were not made for some years or some specific survey hauls for many of the remaining taxa. Estimates of relative catchabilities were therefore required for size-aggregated catch weights for all taxa.

The analysis of catch weights required a probability distribution with a mass at zero, but that is otherwise continuous and can accommodate some overdispersion in catch weights. Unlike the models for catch counts, it was not possible to condition model estimates on the total catch. We employed the following model, which assumed that catch weights were a Tweedie (TW) distributed random variable:

$$W_{i,v} \sim TW(\mu_{i,v}, \varphi, \tau)$$

$$E[W_{i,v}] = \mu_{i,v} = \exp(v + S_i + o_{i,v})$$

$$Var[W_{i,v}] = \varphi(\mu_{i,v})^\tau$$

where $W_{i,v}$ is the catch weight at station i by vessel v , $\mu_{i,v}$ is the expected catch weight at station i for vessel v , φ is the dispersion parameter of the Tweedie distribution, τ is a power parameter, restricted to the interval $1 < \tau < 2$ (Dunn and Smyth 2005), v is the fixed vessel effect, where $\exp(v) = \rho$, S_i is a fixed effect that accounts for the biomass at station i , and $o_{i,v}$ is the offset. Unlike the model for catch numbers in which the offset term was the log of the ratio of sampling efforts (tow distance and catch sampling fraction), the offset term in the Tweedie model is the log of sampling effort at station i for vessel v , relative to the standard effort for that vessel.

A version of the model in which the station effect was treated as a random effect of the following form was initially investigated:

$$E[W_{i,v}] = \mu_{i,v} = \exp(v + \delta_i + o_{i,v})$$

$$\delta_i \sim N(0, \sigma^2)$$

However, the assumed normal distribution for the random effect in the linear predictor was found to be inappropriate in the application to the data.

2.2.4. Model fitting, selection and validation

The binomial and beta-binomial models in Tables 2 and 3 for analyses of length-disaggregated catches were implemented using the Template Model Builder (TMB) package for R (Kristensen et al. 2016). TMB uses the Laplace approximation to integrate the joint negative loglikelihood (nll) over the random effects to calculate the marginal nll (mnll). Optimization of the mnll is then undertaken in R using the *nlm* function. The basis functions for the cubic smoothing spline and the corresponding penalty matrices were generated using the R package *mgcv* (Wood 2011) based on 10 equally-spaced knots ($K = 9$) within the pre-specified length range depending on the range of lengths observed proper to each taxon. TMB automatically calculates a standard error for the maximum likelihood estimation of the conversion factor via the delta method (Kristensen et al. 2016).

Analyses were also undertaken for length-aggregated catch numbers, for those taxa or instances where length-aggregated conversion factors are required. Contrary to the analyses described above that treat the catch of a taxon at a station and in a length class as the basic datum, these length-aggregated analyses modelled the total catch numbers at each station. For simplicity, these analyses were implemented using the *glmmTMB* function from the homonymous R package (Brooks et al. 2017). Models BI0, BI1, BB0 and BB1 (Tables 2 and 3) were fitted by specifying `family=binomial(link = "logit")` or `family=betabinomial(link = "logit")`, as appropriate, maintaining the same assumptions as the length-disaggregated models. Note that conversion factor estimates for these four models obtained from the length-aggregated analyses are likely to differ from those obtained from the length-disaggregated analyses when there is strong underlying length-dependency in relative catchability between the two vessels. Furthermore, because sample sizes are greater in the length-disaggregated analyses, standard errors on the conversion factors are generally expected to be smaller.

The analyses of catch weights were also implemented using the *glmmTMB* function. The option `family = tweedie` was specified.

Length-disaggregated models were fitted only for taxa for which there were data for at least 25 relevant set pairs (pairs with catch by at least one vessel). Size-aggregated model were only

fitted for taxa for which there were data for at least 15 relevant set pairs. While these thresholds are somewhat arbitrary, they are reasonable in light of the complexity of the models (number of fixed and random parameters estimated) and are consistent with minimum requirements evident from the simulation study of Yin and Benoît (2022b).

There were in total 13 candidate models of length-disaggregated catches for estimating the conversion factors, although convergence could not be attained for any of the taxa for the most complex model, BB7. There were four candidate models for length-aggregated catch numbers. The best model for each set of analyses was selected by BIC (Bayesian information criterion) to maximize model fitting, while avoiding over-fitting of more complicated models, especially in cases without adequate data. We also examined values for Akaike information criterion (AIC), which tends to select slightly more complex models compared to BIC (Hastie et al. 2009), but which in the present applications, largely supported decisions based on BIC.

In each length-disaggregated analysis, the estimated μ function (length-dependent expected proportion of catch by vessel A) from all converged models were compared along with the sample proportions (aggregated by stations and averaged for each length) to provide a more rigorous interpretation of the results. The estimated $\rho(l)$ (expected relative catch efficiency, or conversion factor function) and associated approximate 95% confidence interval from the best model is then shown over the range of lengths contained in the input data. Normalized quantile model residuals (Dunn and Smyth 1996) were produced and plotted using boxplots against length and survey station to visually assess the adequacy of model fit. Given the potentially large number of stations for some species, which would otherwise generate a crowded boxplot, we plotted only the residuals for the first 60 tows to provide an indication of possible lack of fit. Finally, we plotted model residuals against depth and the time at which a station was fished, two factors known to affect catchability (e.g., Benoît and Swain 2003), to evaluate whether these effects might interact with the vessel effect under study. To flag possible cases where these effects may have been influential we also fit the following gaussian models (presented using pseudo equations) to the normalized quantile model residuals (NQR):

1. $\text{NQR} \sim s(\text{depth}) + (1|\text{station})$
2. $\text{NQR} \sim s(\text{time}) + (1|\text{station})$
3. $\text{NQR} \sim \text{factor}(\text{day}) + (1|\text{station})$

where $s(x)$ denotes a smooth function of variable x , $(1|\text{station})$ denotes a random effect for the station and $\text{factor}(\text{day})$ is a factor delineating day and night, where $\text{day} = 7:00 < \text{time} \leq 19:00$, consistent with Benoît and Swain (2003). Both smoothed and discrete effects of time were considered to flag cases of a possible diel effect on relative catchability (e.g., Benoît and Swain 2003). We examined the p-values associated with the effects of depth, time and day, and further investigated the residuals patterns in cases with $p < 0.01$.

The fit of catch-aggregated analyses for counts and weights was assessed by plotting the conversion factor and associated approximate 95% confidence interval in biplots of the catch of one vessel over the other. Additionally, we examined the scaled quantile residuals obtained using the R package DHARMA (Hartig 2021). Unlike the normalized quantile residuals used in the length-disaggregated analyses above, which have an expected Gaussian distribution when model fit is adequate, the quantile residuals from DHARMA have an expected uniform distribution. The choice was dictated in part by the fact that it was easier to examine residuals using boxplots in the former case, which has more residual values. Residuals for the catch-aggregated analyses were examined for uniformity and possible overdispersion, and plotted as a function of the fitted values, station depth and time. The evaluation of residuals was in size-aggregated analyses was limited to a visual inspection.

2.2.5. Data treatment prior to analysis

Data for some taxa were grouped prior to analysis due to perceived inconsistencies in identification during the surveys or due to small sample sizes amongst related and morphologically similar taxa. *Gadus sp.* (code 251) individuals ≤ 20 cm are processed separately during catch sampling because of difficulties in distinguishing *G. morhua* and *G. ogac* at these sizes in the field. Normally samples are brought back to the laboratory for identification; however, such lab-based identification was not available in time for the comparative fishing data analyses. Given the relative prevalence of Atlantic cod in the ecosystem, the fact that confirmed catches of *G. ogac* were not sufficiently frequent to include in any of the analyses, and the assumption that the catchability of small *Gadus sp.* should be the same as that of same-sized individuals of the specific species, we combined these data with the catches for *G. morhua*. This and the other taxonomic groupings are outlined in Table 4.

In a very small number of instances, the catch of one or two individuals at the very smallest or very largest lengths had undue influence on the shape of the length-dependent conversion factor function at and around those lengths. This results from the flexibility inherent in the cubic spline functions and is a known problem for these models (Cadigan et al. 2022). Although Cadigan et al. (2022) present an alternative and likely more robust approach, it is only applicable to monotonic length-dependent relative catchability functions and was not appropriate for the results of the sGSL comparative fishing where more complex, non-monotonic, functions were prevalent. Instead we excluded the catches for these extreme lengths from the analysis. These cases are summarized in Table 5.

2.2.6. Interpretation of analysis results and application of conversion factors

Two general patterns observed in the model selection and model results motivated the adoption of additional screening criteria in determining whether a conversion factor (function) should be applied, and which should be chosen for application in future analyses of the survey data. First, there were four taxa for which the 95% confidence intervals for a length-dependent conversion factor function overlapped with a value of one across all lengths, indicating no significant statistical difference with the case of equivalent vessel catchability, despite a length-dependent model being selected. This likely resulted from the use of marginal AIC and BIC values, for which the effective number of parameters may not be correctly calculated for the model random effects, causing more complex models with smoothed length effects to be favoured. We therefore recommend not adopting conversion factor functions for which the confidence interval overlaps unity over the range of length. In these cases, we examined the results for non-length dependent analyses but found that these were typically not statistically significant either.

As noted above, the estimation of length-specific conversion factor functions can be sensitive to the sparseness of data in the tails of the length frequencies. Despite eliminating some extreme lengths, there were still cases where conversion factor values diverged considerably from the overall length-dependent trend as lengths tended toward the smallest and largest lengths. We therefore adopted the following procedure. We first identified the lengths that constituted the 0.5th and 99.5th percentiles of the taxon-specific total length frequency distribution for the 2021-2022 experiment for taxa with at least 20 length classes, and used the 2.5th and 97.5th percentiles for taxa with fewer classes. We then identified the conversions factor function values at these percentiles for each taxon, and assumed these values as constants for lengths below and above these percentiles, respectively. These constant values were projected respectively to the taxon-specific smallest and largest lengths observed since 1971 in the survey.

3. RESULTS

The results of the various analyses for the numerous taxa covered in this report are simply too voluminous to interpret in detail. Instead we aimed to provide detailed figures and tables that describe the results and support decisions for the application of conversion factors, and provide some interpretation of results only for key harvested species and species of conservation concern. These species are ones for which reporting on survey results is likely to be most consequential and frequent, and therefore where the need for careful examination and interpretation of comparative fishing results is arguably greatest. We begin by explaining the structure for the presentation of results, and then address results for these specific species, as well as other cases involving notable results.

3.1. PRESENTATION OF RESULTS

The following tables and figures provide taxon-specific results.

Table 6 provides the total number of relevant set pairs (i.e., pairs in which the taxon was caught by at least one of the two vessels), the number of pairs for which only the CCGS Capt. Jacques Cartier caught the taxon, and the number of pairs for which only the CCGS Teleost caught the taxon. Notably, the table provides a reference to the number for the figure(s) in which the results are presented for that taxon. Taxa for which length-disaggregated analyses were supported are presented first, followed by those for which size-aggregated analyses were employed.

Table 7 provides details of the model evidence and selection (ΔAIC and ΔBIC values) for the length-disaggregated analyses.

Table 8 presents the p-values for the smooth effect of depth, the smooth effect of time and the fixed effect of day on the normalized quantile residuals from the best length-disaggregated model. Values < 0.01 are indicated in bold.

Table 9 provides details of the model evidence and selection (AIC and BIC values) for the length-aggregated analyses of catch numbers, and the estimated conversion factors (ρ) and 95% confidence intervals for the analyses of catch numbers and of catch weights for taxa that were otherwise also considered in length-disaggregated analyses.

Table 10 provides the same types of results as Table 9, but for those taxa that were not considered in length-disaggregated analyses, either because representative length sampling was not undertaken or because the total number of relevant set pairs was $15 \leq n < 25$.

Plots for the results of the length-disaggregated analyses are presented in multiple panels across three pages for each taxon. Figs. 3-5 provide an explanation of the content of each page. Briefly, the first page (labelled a.) provides a summary of the data from a spatial, size-aggregated and length-specific perspective (details in Fig. 3). Results for the size-aggregated analyses are plotted in one of the panels in an effort to reduce the total number of figures contained in this report. The second page (labelled b.) provides a plot of the fit of all converged models and a plot of the selected conversion factor function and 95% confidence interval, along with the projected constant values we propose for the smallest and largest lengths (details in Fig. 4). Finally, the third page (labelled c.) provides various boxplots for the normalized quantile residual values for the selected model (details in Fig. 5).

Plots for the results of the length-aggregated analyses, including the fitted model and model quantile residuals, are presented on a single page for each taxon for the analyses of catch counts (left column) and catch weights (right column) for measured taxa, and catch weights only (single column) for taxa that aren't measured (details in Fig. 6). Figures are presented only for taxa that were not subjected to length-disaggregated analyses to reduce the total number of

figures in this report. Nonetheless, fits of the selected length-aggregated model for catch for the remaining taxa are presented in the plots for length-disaggregated analyses and the estimated conversion factor values are in Table 9. Detailed residual plots were created and examined even though they are not formally presented here.

3.2. SOME SPECIFIC RESULTS

3.2.1. Atlantic cod (*Gadus morhua*)

With the exception of the very smallest sizes (< 8 cm) and larger sizes (> 45 cm), standardized catches by the CCGS Capt. Jacques Cartier were consistently larger than those by the CCGS Teleost (Fig. 7a). Model BB5 provided the best fit to the data and predicted an asymmetric concave relative catch efficiency function that declined steeply for sizes up to about 10 cm, reaching levels below 0.2, before rising more or less continually to a level consistent with equivalent catchability around 50 cm (Fig. 7b). The plots of normalized quantile residuals indicate that the model fit was adequate (Fig. 7c).

3.2.2. White hake (*Urophycis tenuis*)

White hake were mainly captured in the eastern Northumberland Strait and off northern Cape Breton, and to a lesser extent along the Laurentian channel (Fig. 8a). Standardized catches by the CCGS Capt. Jacques Cartier were greater in almost all instances. While model BB1 was selected by BIC, models BB4 and BB5 were favored by AIC. The latter two models estimate a nearly identical catchability function (Fig. 8b), which also corresponds roughly with the function estimated for cod (Fig. 7b), a related species for which a similar relative catchability might be expected and for which there were considerably more observations with which to produce estimates. Given these results and the fact that BB4 was the second most likely model according to BIC, with a delta value suggesting the model is not implausible, we recommend using the estimate from that model. Specifically, BB4 predicted a slight curvilinear relative catchability function that fluctuated around a value of around 0.6 across most lengths, but with higher values at small lengths (Fig. 8b). Model fit appeared to be adequate (Fig. 8c).

3.2.3. Redfish (*Sebastes sp.*)

Overall standardized catches of redfish were largely similar between vessels and were characterized by a strong mode in the catches that peaked at 24 to 25 cm (Fig. 9a). Redfish at sizes below the mode were more prevalent in standardized catches by the CCGS Capt. Jacques Cartier, and those above the mode in catches by the CCGS Teleost. Model BB4 was selected and predicted a sigmoidal monotonically increasing relative catch efficiency function for which equal efficiency (a value of 1) was predicted at 30 cm, with increasingly large confidence intervals thereafter (Fig. 9b). Model fit appeared to be adequate (Fig. 9c).

3.2.4. Atlantic halibut (*Hippoglossus hippoglossus*)

Atlantic halibut were captured infrequently and only in small numbers during the comparative fishing experiments (Fig. 10a). Length-aggregated analyses resulted in no significant difference in relative efficiency between the two vessel, and confidence intervals for the length-disaggregated analyses were very close to a value of 1 (Fig. 10b; Table 9). Jointly these results do not provide a compelling case for a significant difference in catchability between vessels.

3.2.5. Greenland halibut (*Reinhardtius hippoglossoides*)

Standardized catches of Greenland halibut were generally similar between the two vessels (Fig. 11a). There was a tendency for the CCGS Teleost to catch more of this species at lengths around 40 cm. There was similar support for all BI models based on BIC (Table 7), while the only beta-binomial model to converged was BB0. Length-independent models suggest no significant difference between vessels (e.g., B10, Fig. 11b). While the residuals for B10 indicate a lack of fit at length ≥ 42 cm (Fig. 11c), there were few individuals caught at these sizes in the experiments (Fig. 11a). Application of a conversion factor is not recommended for this species.

3.2.6. American plaice (*Hippoglossoides platessoides*)

American plaice were captured frequently and broadly in the experiments (Fig. 12a). Standardized catches by the CCGS Capt. Jacques Cartier were consistently larger overall. However, the CCGS Teleost was much more efficient at catching very small plaice (< 5 cm) and the vessels were about equivalent at catching large plaice > 32 cm. Model BB5 was select and seemed to fit the data well (Figs. 11b,c). The model predicted that the CCGS Teleost was about 10 times more efficient at catching very small plaice, but that relative efficiency dropped rapidly with increasing length to a low at about 10 cm, increasing gradually subsequently to reach a level close to equivalent catchability around 32-35 cm. The relative efficiency above 40 cm was associated with considerable uncertainty and a constant value is recommended for these sizes in future applications.

There was a significant difference in residuals according to the diel period (Table 8), but the distribution of residuals as a function of hour indicates that the effect size is very small and likely inconsequential (Fig. 12c).

3.2.7. Witch flounder (*Glyptocephalus cynoglossus*)

Standardized catches of witch flounder, and the associated length frequencies were similar between vessels (Fig. 13a.). The length-aggregated analysis of catch numbers and catch weights concluded that the CCGS Capt. Jacques Cartier was more efficient (Table 9; see also the blue line and shaded area in the biplot in Fig. 13a). A similar result was obtained in the length-disaggregated analysis (model BB1) although the effect was just marginally different from equal catchability (Fig. 13b).

3.2.8. Yellowtail flounder (*Limanda ferruginea*)

Standardized catches of Yellowtail flounder were generally greater for the CCGS Capt. Jacques Cartier, particularly for sizes < 25 cm (Fig. 14a). Model BB4 was selected and appeared to provide an adequate fit to the data (Figs. 14b,c). The CCGS Capt. Jacques Cartier was relatively most efficient at catching yellowtail flounder < 10 cm, and the relative efficiency of the two vessels became increasingly more similar as length increased to about 20 cm, where the estimated relative efficiency was close to 1 and the confidence intervals overlapped with that value (Fig. 14b). The relative efficiency was highly uncertain for lengths > 28 cm, and a constant relative efficiency with a value of around 0.9 is recommended for adjusting the survey data in future analyses.

3.2.9. Winter flounder (*Pseudopleuronectes americanus*)

Standardized catches of winter flounder by the CCGS Capt. Jacques Cartier were routinely larger, particularly at lengths around 15 cm, which constituted the mode of the length frequency (Fig. 15a). Model BB5 was selected, and estimated that the relative efficiency of the CCGS Teleost declined as length increased to just over 10 cm, and then increased again to values

consistent with equivalent efficiency around 28 cm (Fig. 15b). Estimated relative efficiencies below about 5 cm and above 32 cm were quite uncertain and constant values are recommended for these sizes. There were no patterns in the model residuals suggesting an inadequate fit (Fig. 15c).

3.2.10. Atlantic herring (*Clupea harengus*)

Standardized catches of herring by both vessels were generally quite variable and appeared to be of comparable magnitude between vessels except for those of herring 10-16 cm, which constituted one of three length modes in the data, and which were relatively larger for the CCGS Teleost (Fig. 15a). Model BB5 was selected and appeared to provide an adequate fit to the data (Figs. 16b,c). It estimated an irregular relative catch efficiency function characterized by a peak in relative efficiency for the CCGS Teleost at 15 cm. For lengths on either side of this peak, the CCGS Capt. Jacques Cartier was estimated to be more efficient at catching herring, although the confidence intervals overlapped with a value of 1 at all of those sizes.

3.2.11. Atlantic mackerel (*Scomber scombrus*)

Standardized catches of mackerel were generally quite variable. The CCGS Teleost tended to make larger catches, although there was a high incidence of cases in which the CCGS Capt. Jacques Cartier caught a small number of individuals, while the CCGS Telesot caught none (Fig. 20a). Model fits diverged considerably amongst candidate models, particularly those that included site-specific random-effects (Fig. 20b). While model BB4 was favored by AIC and BB5 by BIC, the predictions from these models differ considerably from the empirical estimates. Overall these results suggest that a reliable conversion function cannot be estimated for mackerel with the data available.

3.2.12. Atlantic wolffish (*Anarhichas lupus*)

Atlantic wolffish were captured infrequently and only in small numbers during the comparative fishing (Fig. 46). Estimates of relative catchability for both catch number and weight were not statistically significant (Table 10).

3.2.13. Thorny skate (*Amblyraja radiata*)

Thorny skate were captured principally along the Laurentian Channel and in the Cape Breton trough (Fig. 22a). The CCGS Capt. Jacques Cartier tended to catch more thorny skate at all sizes. Model BB1, which provided a reasonable fit to the data (Figs. 22b,c) estimated that the CCGS Capt. Jacques Cartier was about twice as efficient at capturing thorny skate.

Too few smooth skate (*Malacoraja senta*) and no winter skate (*Leucoraja ocellata*) were captured during the comparative fishing experiments to allow for the estimation of relative catchability between the two vessels.

3.2.14. Snow crab (*Chionoecetes opilio*)

Snow crab were consistently captured in greater standardized numbers by the CCGS Teleost, with an apparent complex size-dependency involving greater catch proportions for this vessel at carapace widths < 40 mm and between about 45 mm and 90 mm (Fig. 41a). Model BB5 provided a strong and apparently adequate fit to the data (Figs. 41b,c). The estimated relative efficiency function is multi-modal, yet associated with fairly elevated precision. It estimates that very small snow crab and individuals between about 50 and 70 mm are 4 to 6 times more catchable by the CCGS Teleost, while the largest individuals are much more catchable by the CCGS Capt. Jacques Cartier.

3.2.15. Lobster (*Homarus americanus*)

Standardized catches of lobster were generally greater for the CCGS Teleost, although not for smaller lobster < 50 mm (Fig. 43a). Model BB5 was selected and appeared to provide an adequate fit (Figs. 43b,c). The CCGS Teleost was estimated to be less efficient at catching lobster smaller than about 60 mm, but more efficient at larger sizes, although the confidence intervals increased considerably in width for lengths > 100 mm.

3.2.16. Other results of note

For smelt, *Osmerus mordax*, models BB1 and BB4, and to a lesser extent BB5 had similar support based on BIC, meanwhile there was only support for BB4 and BB5 based on AIC (Table 7). The relative catch efficiency based on BB4 is shown in Fig. 18b and indicates higher catchability by the Teleost for lengths < 15 cm, and equal catchability otherwise. This model provides an adequate fit to the data (Fig. 18c). The estimates from this model are recommended as conversion factors.

As was the case for mackerel, model predictions for sandlance *Ammodytes dubius* differed considerably amongst models depending on their assumptions (Fig. 33b). There were many set pair in which the species was caught by only one of the vessels, and four instance of fairly large catches that were mainly made by one of the two vessels. Obtaining a reliable conversion factor for this species with the available data does not appear possible.

3.2.17. Recommendations for the application of conversion factors

The preceding subsections provided recommendations for the application of conversion factors for a number of species of interest. Here we provide a brief summary of recommendations for the remaining taxa.

Based on the results of length-disaggregated analyses, there were no statistically significant differences in catchability and therefore no conversion factors for the following taxa:

- Gaspereau, *Alosa pseudo harengus* (Fig. 17b)
- Spiny lump sucker, *Eumicrotremus spinosus* (Fig. 32b)
- Shortfin squid, *Illex illecebrosus* (Fig. 44b)

In contrast, length-dependent conversion factors are recommended for the following taxa:

- Smelt, *Osmerus mordax* (Fig. 18b)
- Capelin, *Mallotus villosus* (Fig. 19b)
- Fourbeard rockling, *Enchelyopus cimbrius* (Fig. 21b)
- Mailed sculpin, *Triglops murrayi*, although the length-dependent function for the recommended lengths is essentially constant (Fig. 26b)
- Alligatorfish, *Aspidophoroides monopterygius* (Fig. 28b)
- Seasnails, *Liparidae* sp. (Fig. 30b)
- Foul line snakeblenny, *Eumesogrammus praecisus* (Fig. 37b)
- Stout eelblenny, *Anisarchus medius* (Fig. 38b)
- Arctic lyre crab, *Hyas coarctatus* (Fig. 40b)

While length-independent conversions are recommended for:

-
- Longhorn sculpin, *Myoxocephalus octodecemspinosus* (Fig. 23b)
 - Shorthorn sculpin, *Myoxocephalus scorpius* (Fig. 24b)
 - Arctic staghorn sculpin, *Gymnocanthus tricuspis* (Fig. 25b)
 - Sea raven, *Hemitripterus americanus* (Fig. 27b)
 - Sea poacher, *Leptagonus decagonus* (Fig. 29b)
 - Lumpfish, *Cyclopterus lumpus* (Fig. 31b)
 - Laval's eelpout, *Lycodes lavalaei* (Fig. 34b)
 - Snakeblenny, *Lumpenus lampretaeformis* (Fig. 35b)
 - Daubed shanny, *Leptoclinus maculatus* (Fig. 36b)
 - Rock crab, *Cancer irroratus* (Fig. 39b)
 - Great spider crab, *Hyas araneus* (Fig. 42b)

For taxa for which only size-aggregated analyses were undertaken, only those conversion factors that were significantly different from a value of one are recommended (Table 10). Overall, the values in Table 10 and the result shown in Figs. 62 to 112 indicate that the CCGS Teleost was more likely to catch benthic invertebrates, notably those closely associated with the bottom. For taxa such as *Ascidia* (Fig. 63), *Leptasterias* sp (Figs. 82, 83), *Henricia sanguinolenta* (Fig. 87), *Actinaria* (Fig. 98) and *Hydrozoa* (Fig. 106) there were many set pairs in which only the CCGS Teleost captured the taxon. These results suggest that the CCGS Capt. Jacques Cartier fishing the NEST may not provide a reliable survey for these taxa. The results presented in this document in Table 10 and the associated figures should be considered carefully before comparing survey results for years preceding and following the change in vessel and gear.

4. DISCUSSION

Overall, the data obtained in 2021-2022 appear sufficient to reliably test for differences in relative efficiency between vessels and to estimate conversion factors and length-dependent conversion factor functions for the most commonly captured taxa in the survey, which includes most commercially important species. While additional comparative fishing would improve the precision of estimates, particularly for infrequently captured taxa or those with variable catches, the benefits appear small relative to the financial and logistical costs of additional comparative fishing. The peer review meeting of the results of these comparative fishing experiments concluded that no additional comparative fishing was warranted based on these considerations.

Length-dependent conversions were estimated for 17 and length-independent conversions were estimated for 11 of the species that are routinely measured during the survey. As a general result, the CCGS Capt. Jacques Cartier fishing the NEST appeared to be more efficient at catching fishes of intermediate lengths (roughly 20-35 cm), but less efficient at catching very small fish (e.g., ≤ 5 cm) and about equally efficient for larger fish of most species.

The experiments in the southern Gulf of St. Lawrence employed a shadow survey design, which helps ensure that the estimated relative catchabilities are relevant for the habitat conditions in the survey area. Furthermore, analyses of survey residuals identified no significant instances where relative catchability was affected by depth and time of day, key factors that can affect overall survey catchability (e.g., Benoît and Swain 2003). These conditions lend support to the reliability of the conversion factor estimates.

The CCGS Capt. Jacques Cartier fishing the NEST was generally much less efficient at catching most benthic invertebrate taxa. For many of these, there were numerous instances where the CCGS Teleost caught the taxon while the CCGS Capt. Jacques Cartier caught none, such as was observed for example for most echinoderms (e.g., Figs. 82, 83, 87, 89), all sponges (Figs. 108-112), hydrozoa (Fig. 106) and actinaria (Fig. 98). Although the estimated conversion factors account for this to some extent, it is likely that catches for many benthic invertebrates will be less frequent with the new vessel and trawl. This will generate a discontinuity in the survey data for the affected taxa whereby it will be difficult to reliably compare catch indices and catch properties (e.g., spatial distribution and habitat associations) between years in which the different vessels were employed for the survey.

5. ACKNOWLEDGEMENTS

Numerous DFO Science and CCG staff participated in the planning and implementation of comparative fishing in the sGSL. We are indebted to Jordan Ouellette-Plante for providing R Markdown code that greatly simplified the process of compiling the numerous figures into the document, and to Paul Regular and Andrea Perreault for identifying and correcting an error in the calculation of AIC and BIC values in earlier analyses. We wish to thank Pablo Vergara for assistance in obtaining the data, and François-Étienne Sylvain, Nicolas Rolland and Daniel Ricard for guidance for the interpretation of the data from the comparative fishing experiments and discussions on the analyses.

7. TABLES

Table 1. Details for the relevant set pairs in the 2021 and 2022 comparative fishing of the sGSL, where columns indicated by TEL represent values for the CCGS Teleost and those indicated by CA represent values for the CCGS Capt. Jacques Cartier. Tow start times (Time) are expressed in decimal hours, latitudes and longitudes are expressed in decimal degrees, and the Distance values represent the trawled distance for each vessel in nm. The date is that of the beginning of the tow by the CCGS Teleost, and the entries for CA Time denoted by ¹ indicate that the tow by the CCGS Capt. Jacques Cartier was started the day previous before midnight. The catch for stations 53 and 54, fished on September 18 and 19, 2022 respectively, were inadvertently physically combined aboard the CCGS J. Cartier prior to catch sorting. Data for these stations from the CCGS Teleost were combined for the analysis and the tow distances for each vessel were summed for the two stations.

Table 2. A set of binomial models with various assumptions for the length effect and station effect in the relative catch efficiency. A smoothing length effect can be considered and the station effect can be added to the intercept, without interaction with the length effect, or added to both the intercept and smoother to allow for interaction between the two effects.

Model	$\log(\rho)$	Length Effect	Station Effect
BI0	β_0	constant	not considered
BI1	$\beta_0 + \delta_{0,i}$	constant	intercept
BI2	$\mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b}$	smoothing	not considered
BI3	$\mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b} + \delta_{0,i}$	smoothing	intercept
BI4	$\mathbf{X}_f^T (\boldsymbol{\beta}_f + \boldsymbol{\delta}_i) + \mathbf{X}_r^T (\mathbf{b} + \boldsymbol{\epsilon}_i)$	smoothing	intercept, smoother

Table 3. A set of beta-binomial models with various assumptions for the length effect and station effect in the relative catch efficiency, and the length effect on the variance parameter. A smoothing length effect can be considered in both the conversion factor and the variance parameter. A possible station effect can be added to the intercept, without interaction with the length effect, or added to both the intercept and the smoother to allow for interaction between the two effects.

Model	$\log(\rho)$	$\log(\phi)$	Length Effects	Station Effect
BB0	β_0	γ_0	constant/constant	not considered
BB1	$\beta_0 + \delta_{0,i}$	γ_0	constant/constant	intercept
BB2	$\mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b}$	γ_0	smoothing/constant	not considered
BB3	$\mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b}$	$\mathbf{X}_f^T \boldsymbol{\gamma} + \mathbf{X}_r^T \mathbf{g}$	smoothing/smoothing	not considered
BB4	$\mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b} + \delta_{0,i}$	γ_0	smoothing/constant	intercept
BB5	$\mathbf{X}_f^T \boldsymbol{\beta}_f + \mathbf{X}_r^T \mathbf{b} + \delta_{0,i}$	$\mathbf{X}_f^T \boldsymbol{\gamma} + \mathbf{X}_r^T \mathbf{g}$	smoothing/smoothing	intercept
BB6	$\mathbf{X}_f^T (\boldsymbol{\beta}_f + \boldsymbol{\delta}_i) + \mathbf{X}_r^T (\mathbf{b} + \boldsymbol{\epsilon}_i)$	γ_0	smoothing/constant	intercept, smoother
BB7	$\mathbf{X}_f^T (\boldsymbol{\beta}_f + \boldsymbol{\delta}_i) + \mathbf{X}_r^T (\mathbf{b} + \boldsymbol{\epsilon}_i)$	$\mathbf{X}_f^T \boldsymbol{\gamma} + \mathbf{X}_r^T \mathbf{g}$	smoothing/smoothing	intercept, smoother

Table 4. Taxonomic groupings employed for the analyses of the sGSL comparative fishing data. The codes are those used routinely in DFO's Gulf region, commonly called RVAN codes.

Taxon	Taxon code	Codes in group
<i>Gadus morhua</i>	10	10, 251
<i>Arteidiellus sp.</i>	323	323, 306, 880
Liparidae	500	500, 505, 512, 520, 868
Shrimp (Decapoda)	2100	2100 - 2421
<i>Pagurus sp.</i>	2560	2560, 2561, 2562
Polycheatae	3000	3000 - 3104
<i>Aphrodita hastata</i>	3200	3200, 3210
<i>Buccinum sp.</i>	4210	4209, 4210, 4211, 4212
Nudibranchia	4400	4400. 4410
<i>Pycnogonida sp.</i>	5100	5100, 5101, 5102
Ophiuroidea	6200	6200, 6211, 6213
Euryalida	6300	6300, 6310
<i>Strongylocentrotus sp.</i>	6400	6400, 6411
Holothuroidea	6600	6600, 6601, 6611
Scyphozoa	8500	8500, 8511
Porifera	8600	8600-8612, 8614, 8617-8623, 8628-8632, 8637-8699

Table 5. Summary of the catches at length excluded from the length-disaggregated analyses.

Taxon	Lengths excluded
<i>Clupea harengus</i>	< 5 cm, > 35 cm
<i>Scomber scombrus</i>	< 6 cm
<i>Osmerus mordax</i>	> 25 cm
<i>Cyclopterus lumpus</i>	< 5 cm
<i>Eumesogrammus praecisus</i>	> 30 cm
<i>Illex illecebrosus</i>	< 10 cm

Table 6. Total number of relevant set pairs (those with at least one capture), and pairs in which the taxon was captured only by the CCGS Capt. Jacques Cartier or only by the CCGS Teleost, along with a reference to the number of the figure in which results are plotted. The lists are sorted by the type of analysis (length-disaggregated vs size-aggregated) and roughly taxonomically.

Taxon	Code	Pairs	Cartier only	Teleost only	Figure number
Fishes (length-specific)					
<i>Gadus morhua</i>	10	161	19	5	7
<i>Urophycis tenuis</i>	12	56	13	0	8
<i>Sebastes sp.</i>	23	60	23	3	9
<i>Hippoglossus hippoglossus</i>	30	51	15	24	10

Table 9. Relative evidence for size-aggregated binomial and beta-binomial models for catch counts based on Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC) values, and estimates of the conversion factor Rho, and approximate 95% confidence intervals, for catches in numbers and in weights for taxa for which length-disaggregated analyses were also undertaken. Recall that a single model was used for catch weights and thus AIC and BIC values are not shown.

8. FIGURES

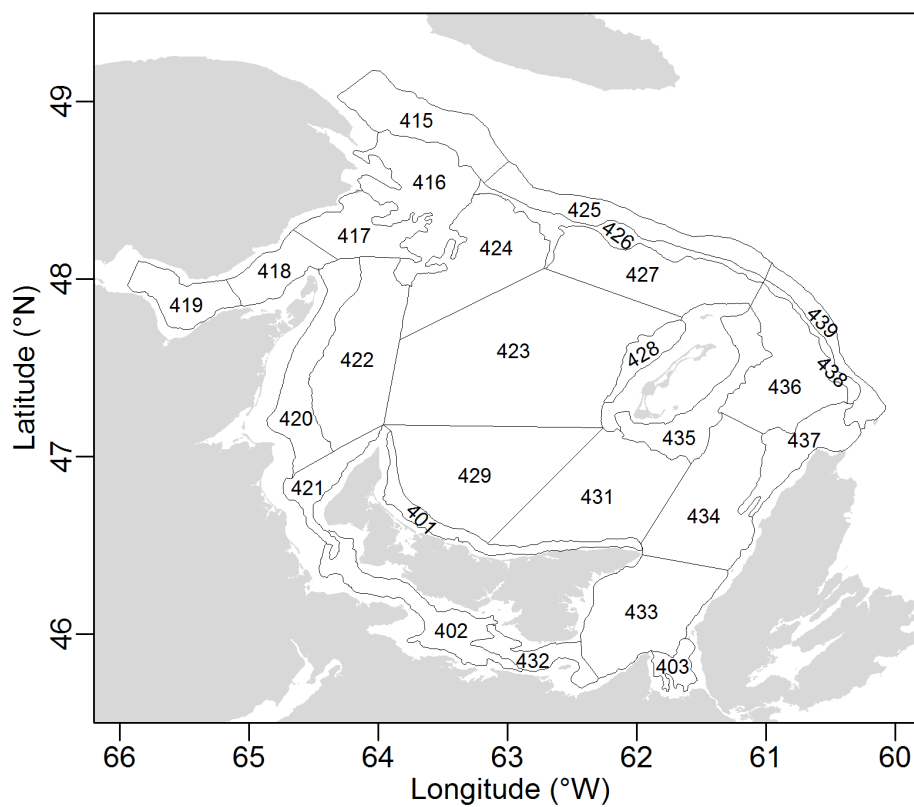

Figure 1. Stratification scheme for the southern Gulf of St. Lawrence multi-species bottom-trawl survey.

Figure 2. Location of comparative fishing set pairs fished in 2021 and in 2022.

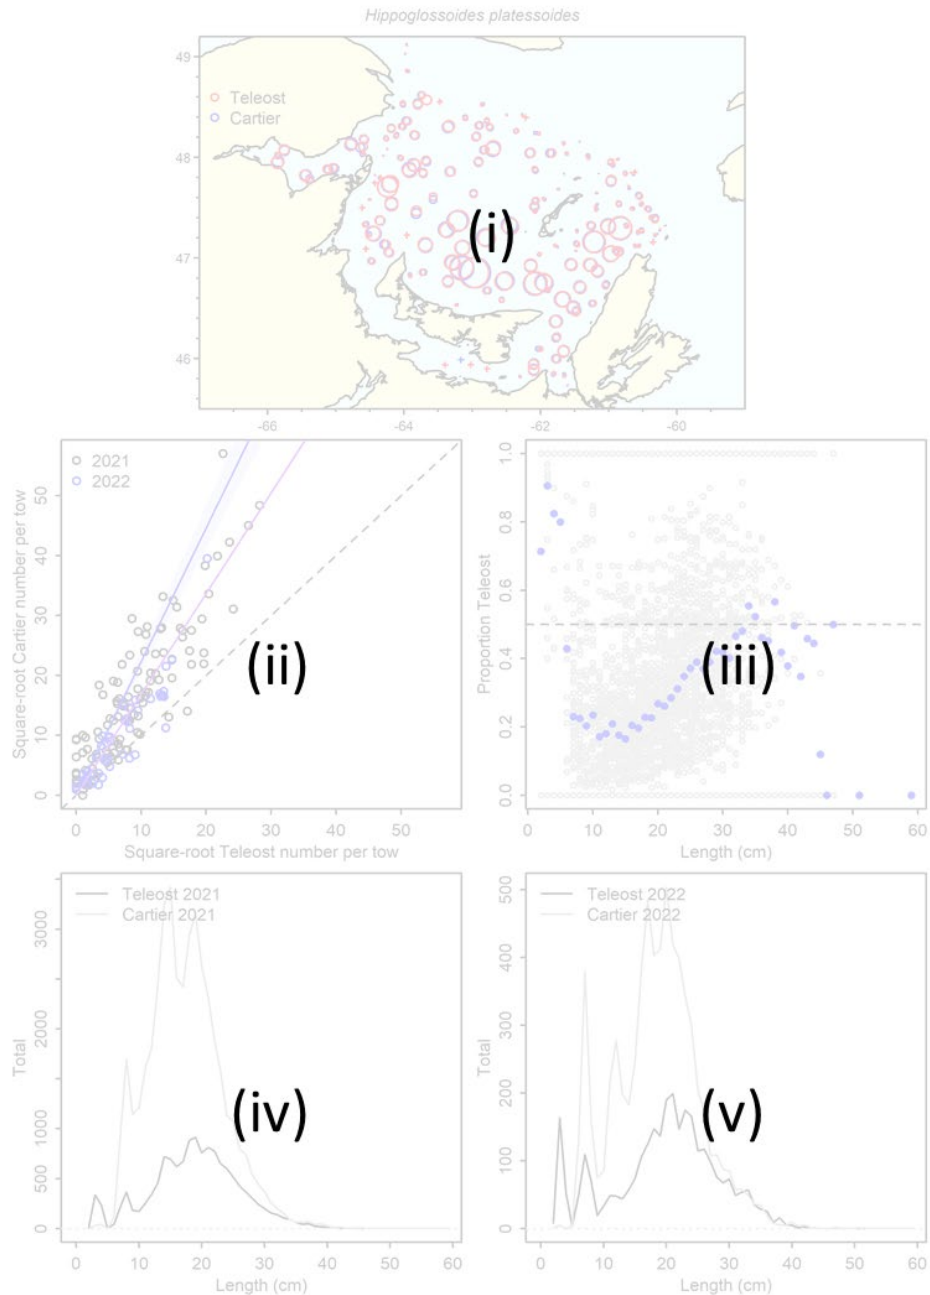

Figure 3. Interpretation for the first of three sets of figures presenting the data and results for taxa for which length-disaggregated analyses were undertaken. (i) Presents a map of catches by the CCGS Teleost (red circles) and by the CCGS Capt. Jacques Cartier (blue circles) in comparative fishing sets, where circle size is proportional to the square root of the number caught and nil catches are indicated by +. (ii) Biplot of the square-root of CCGS Capt. Jacques Cartier catch numbers against the square-root of CCGS Teleost catch numbers, where the blue line and shaded interval show the estimated conversion and approximate 95%CI from the best length-aggregated model, and the purple line shows the estimated length-independent conversion and approximate 95%CI from the best length-based model. (iii) Plot of the empirical proportion of total catch in a pair made by the CCGS Teleost as a function of length for each set pair (grey dots) and averaged across set pairs in each length interval (blue dots). (iv) Total length frequencies for catches made by the CCGS Teleost (black line) and by the CCGS Capt. Jacques Cartier (grey line) in 2021. (v) Same as (iv) except for 2022.

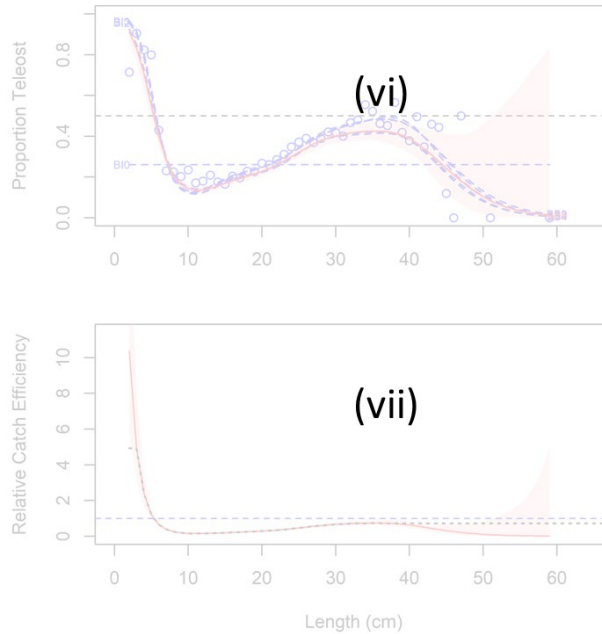

Figure 4. Interpretation for the second of three sets of figures presenting the data and results for taxa for which length-disaggregated analyses were undertaken. (vi) Estimated length-specific catch proportion functions, $\text{logit}(p_{Ai}(l))$, for each converged model, with the selected model plotted using a red line along with its approximate 95% CI (shaded area), as well as the length class-specific mean empirical proportion of total catch in a pair made by the CCGS Teleost (blue dots). (vii) Estimated relative catch efficiency (conversion factor) function from the best model (with 95% CI). The horizontal dashed blue line indicates equivalent efficiency between vessels and the dotted black line indicates the relative catch efficiency function that assumes a constant efficiency at small and large sizes.

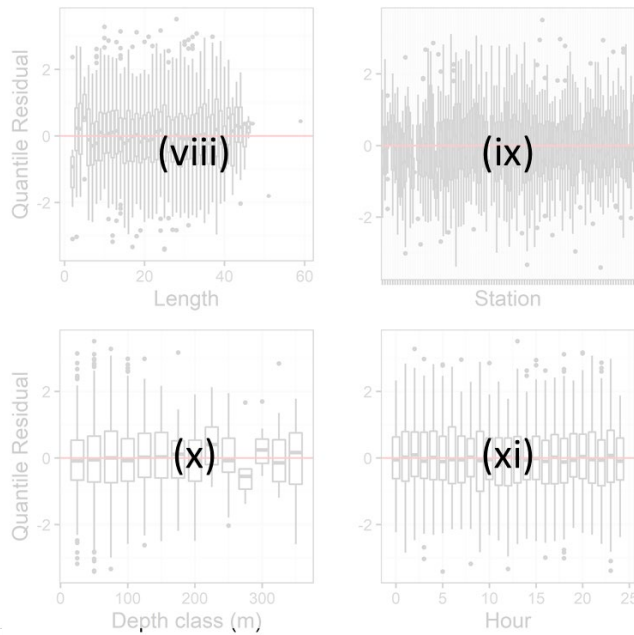

Figure 5. Interpretation for the third of three sets of figures presenting the data and results for taxa for which length-disaggregated analyses were undertaken. Boxplot of normalized quantile residuals as a function of (viii) length, (ix) station, (x) depth class, and (xi) hour.

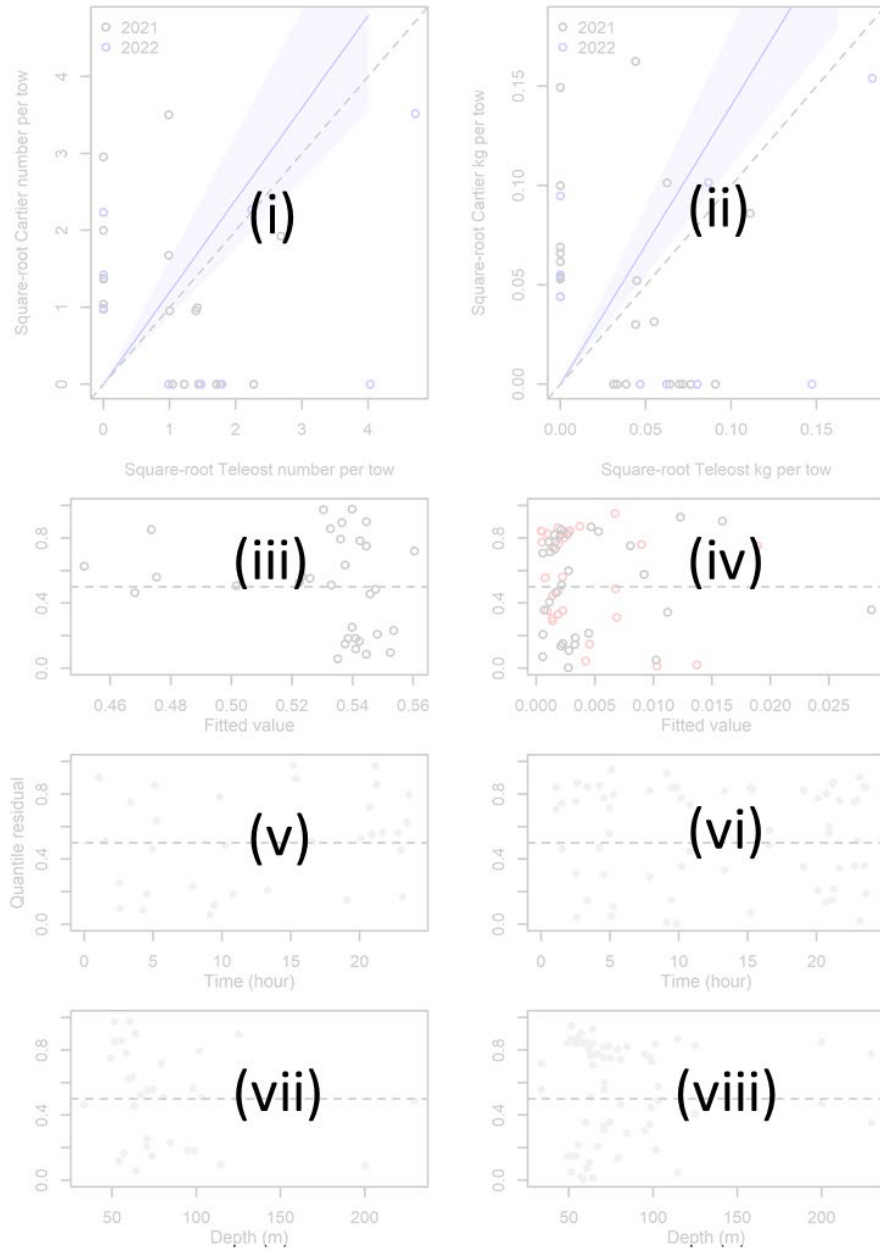

Figure 6. Interpretation for the figures presenting the data and results for taxa for which size-aggregated analyses were undertaken. (i) Biplot of the square-root of CCGS Capt. Jacques Cartier catch numbers against the square-root of CCGS Teleost catch numbers, where the blue line and shaded interval show the estimated conversion and approximate 95% CI from the best size-aggregated model, and where the pairs made in 2021 and 2022 are distinguished by colour. (ii) As in (i), except for catch weights. Quantile residuals from the analysis of catch numbers are plotted as a function of (iii) fitted values, and the (v) time and (vii) depth of the paired set, where values are coloured according to the same scheme as in panel (i). Similarly, quantile residuals from the analysis of catch weights are plotted as a function of (iv) fitted values, with values for the CCGS Teleost plotted with red circles and those for the CCGS Capt. Jacques Cartier in black, and the (vi) time and (viii) depth of the paired set, again where values are coloured according to the same scheme as in panel (i). Note that for taxa that are not measured, only panels (ii), (iv), (vi) and (viii) are shown.
