The 1984 assessment of 4Vsw cod:
a completely revised procedure

by

¹This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

¹Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé du secrétariat.

Abstract

Provisional statistics indicate that only 82% of the 64,000 t TAC was caught in 1983. Several year-classes were well represented in the catch with the 1977, 1978, and 1979 year-classes each contributing more than 20% of the total. A new standardized commercial catch rate series was developed to take into account the uncertainties associated with the Canadian offshore otter-trawler fleet data for the periods 1968-1973 and 1978-1979. The new series shows high catch rates since 1980 and an increasing trend between 1981 and 1983. The research vessel surveys indicate that the recruiting year-classes are from strong to very strong and that the abundance of the fully-recruited age groups is stable. A sequence of flat-topped and dome-shaped partial recruitment vectors was used to compute non-small-mesh mid-year fishable biomasses from cohort analysis runs. Calibration of the cohort analysis, performed only with the new standardized commercial catch rate, indicated a fishing mortality of 0.35 for the fully-recruited ages (6+). If the 55,000 t TAC is taken in 1984, the projected F_{0.1} catch for 1985 is 52,000 t.

Résumé

Selon les statistiques provisoires, les prises en 1983 ont totalisé seulement 82% du TPA de 64,000 tonnes. Plusieurs classes d'âge y étaient bien représentées, en particulier celles de 1977, 1978 et 1979 qui chacune contribuèrent plus de 20% du total. Une nouvelle série standardisée de taux de capture commerciaux fut développée afin de tenir compte de l'imprécision des données en provenance des grands chalutiers canadiens pour les périodes 1968-1973 et 1978-1979. Cette nouvelle série montre que les taux sont élevés depuis 1980 et même à la hausse depuis 1981. Selon les levées des navires de recherche, l'abondance des classes d'âge qui rejoignent présentement le stock exploité varie de grande à très grande alors que celle des groupes plus âgés serait stable. Une séquence de vecteurs de recrutement partiel en tranchet et en forme de dôme fut utilisée pour calculer, à partir des résultats d'analyse de cohortes, des biomasses exploitables de milieu d'année pour les pêcheries autres que celle utilisant les chaluts à petites mailles. La calibration de l'analyse de cohortes, effectuée uniquement à l'aide des taux de capture commerciaux standardisés, indique que le taux de mortalité par pêche subi par les âges pleinement recrutés (6+) en 1983 fut de 0.35. Si le TPA de 55,000 tonnes est atteint en 1984, les prises au niveau F_{0.1} pour 1985 sont évaluées à 52,000 tonnes.

Introduction

Concluding their analysis of the status of the cod stock complex in NAFO Division 4VsW, Gagné et al. (MS 1983) stated that this complex had recovered from low levels in the 1970s. Nevertheless, the calculated $F_{0.1}$ catch for 1984 was 53,000 t and as a result Fisheries and Oceans reduced the TAC by 14%, from 64,000 t in 1983 to 55,000 t in 1984. CAFSAC (Advisory Document 83/19) attributed this reduction to errors in the fisheries statistics used to perform the 1982 assessment (Maguire et al. MS 1982); clearly, the reduction did not reflect a deterioration of the status of the Scotian Shelf cod stock complex, one of the major groundfish resources in Atlantic Canada. Unfortunately, it was widely perceived as such within and outside the Department.

At its 1984 meeting, the Groundfish Subcommittee requested that the procedure followed in the two preceding assessments be modified in several major ways. This document, in addition to describing the overall 1984 assessment, details and discusses these modifications. It also evaluates last year's conclusion on the status of the stock complex. Finally, it briefly comments on the biological advice provided in recent years and on the use of that advice by the managers of the fishery.

Nominal Catches

The overall catch of cod in 4VsW was down 3,400 t in 1983 from 1982 (Table 1) and for the first time since 1976, the TAC was not taken. In 1983, Portugal became the first foreign nation since extension of jurisdiction in 1977 to receive a directed allocation for cod on the Scotian Shelf; it caught 80% of the 1,500 t allocated. By-catches of cod by other foreign nations were up slightly from 1982 but remained below the average level since 1977.

Canadian landings in 1983 were 4,800 t less than in 1982. Again catches in 4Vs exceeded those in 4W continuing a trend which began in 1980 (Table 2). However, the 1983 4Vs catches were 6,900 t less than in 1982 while those in 4W increased by 3,500 t. Similarly, landings from trawlers fell by 5,500 t in 4Vs but increased by 4,700 t in 4W. This was mainly due to the exploitation of different fishing grounds by the spring fishery; in 1982, it was concentrated north of the Gully in 4Vs but was more active south of Sable Island in 4W in 1983. Overall trawler catch dropped by 850 t.

With a reduction of 4,000 t in their reported landings, the longliners suffered the largest overall decrease in 1983, 64% of which was experienced in 4Vs. Catches by other Canadian gears were back to the 1980 level, a decrease of about 20% from the high values of 1981 and 1982.

Age Composition of the Commercial Catch

Sampling of the Fishery

The cod fishery in 4VSW was again well sampled in 1983 with a total of 178 samples collected. In general, the sampling followed properly the activities of the major gears as shown in Table 3 (see also Appendix 1). With 74% of the Canadian catch, the otter trawls received 64% of the samples. Each quarter of that fishery was well covered although a few more samples in the second and third quarters in 4Vs would have resulted in a more even distribution of the catch to sample ratios. The "line" fishery (longline and handline) landed 18% of the Canadian catch and received 25% of the samples. The second quarter in 4Vs and especially the fourth quarter in 4W should have been covered more intensively. Thirteen percent of the samples were collected from the Scottish and Danish seine catches which represented 5% of the total domestic removal. Of all the major gears, the seines were the most intensively sampled. Finally, 3% of the sampling effort was devoted to the gillnet fishery in 4W which landed only 1% of the total catch. Even though the overall coverage of the fishery could have benefited from some adjustments, the sampling of the major gears was adequate.

Construction of the Age-Length Keys

Of the 178 samples collected in 1983, only 85 had been entirely processed at assessment time. The otoliths of the 93 remaining samples had yet to be read. Samples length frequencies which were not aged were not used in the age-length keys. If the sampling of the fishery was adequate, the coverage obtained from the processed samples was much less so. Indeed only 25 samples were available for the second half of the year and only six for the last quarter. In the next section, we use the 1982 data to illustrate how such a situation may impact the results of the analysis.

We summarize in Table 4 the data used to generate each key. As in last year's assessment, at least 20 otoliths were read in each sample used. The 55 otter trawl samples were grouped on a quarterly basis. The longline and the seine samples, 18 and 11 respectively, were divided in two half-year periods. The a and b coefficients required for the length-weight relationships were obtained from the 1983 summer research survey data. Depending on the origin of the majority of the catch apportioned to each key, the divisional or the combined coefficients were used (Table 4a).

Age-length keys were also generated for the catch of the three major foreign countries that caught cod in 4VSW in 1983. Fishing for cod in 4Vs, a Portuguese trawler fleet caught 961 t in April-May and 257 t between October and December. We determined the length composition of their catch from length frequencies collected by the International Observer Program which had full coverage of the fleet activities. We compared the length frequencies of the Portuguese catch to those of the Canadian trawler fleet fishing in 4Vs at the same time. The frequencies for the April-May period were different and a separate key was produced. The frequencies for the

October-December period were very similar and the Portuguese catch of 257 t was lumped with the Canadian trawler catch and used with key 4 of Table 4a.

The small-mesh fishery, pursued by Cuba and the Soviet Union at the edge of the shelf in 4W, had a cod by-catch of 226 t in 1983. As in the past, we used length frequencies collected by the International Observer Program and length-weight coefficients from the summer research survey to construct a separate key for that fishery. In the 1983 assessment, the small-mesh key was not included in the calculations of the mean weights at age and the numbers at age generated from it were merely added to the catch numbers. This year we used all the keys to estimate the mean weights at age. In this way we obtained a value for age one which came from the small-mesh key.

The ten keys were used to generate the age composition of 97% of the total catch. Those estimates were bumped up to 100%. The resulting removals at age, mean weights at age and catch biomasses at age are presented in Tables 5 to 9.

Each of the 1977, 1978 and 1979 year-classes contributed more than 20% to the total numbers caught; together, they add up to 77%. Over three million fish i.e. - 11% of the total, came from the 1980 year-class. This is the second largest proportion of age 3 fish in the catch since 1977, closely behind the 1978 year-class in 1981.

The mean weights-at-age show slight or no variations for ages 1 to 5 between 1982 and 1983. With the exception of age 7, the weights for ages 6 to 11 are lower in 1983 than in 1982.

Update of the 1982 Catches At Age

The otoliths of 42 samples collected in 1982 were not read in time for the 1983 assessment. Processing of these samples was completed in 1983 and they were available for the present assessment. The new samples were distributed as follows:

Quarter	Otter Trawl	Lines	Seines
1	16	3	
2	4		
3	1		3
4	11		4
Total	32	3	7

We used 38 of those samples to update three otter trawl keys as well as the unique key for the seines. The longliner keys were not modified since the three additional samples had been collected in March, at a time when the longliner catches were very low. Details on the construction of these keys are presented in Table 4b. The 1982 data included in Tables 7 to 9 incorporate these updated numbers.

We compare in Figure 1 the 1982 removals at age as calculated for the 1983 assessment (Gagné *et al.* MS 1983) and the updated values. The differences are small, the updated curve showing 36% more age 3, 16% more age 4, and 11%, 15%, and 15% less age 6 to 8 fish respectively.

The age composition of the commercial catch is of paramount importance in stock assessment since the estimate of population size is derived from it. We therefore decided to repeat the 1983 assessment following the procedure adopted by the Subcommittee but with the updated catch-at-age matrix. A new estimate of population size was calculated assuming a fully-recruited fishing mortality of 0.25. The partial recruitment for ages 1 to 3 was readjusted so that the size at age 1 of the year-classes 1979 to 1981 be approximately equal to the long-term geometric mean of 107 million fish. The partial recruitment at age 4 was not modified since a variety of calibration exercises have all indicated a value around 0.56 (see section on partial recruitment further in this document).

In Figure 2, we compare the updated 1982 population numbers with those of last year's assessment. Again differences are small. However, the updated numbers-at-age 3 and 4 are higher than estimated last year.

We also recalculated the projected age composition of the 1983 catch using the actual total of 52,332 t. Two runs were made, one with the parameters as evaluated last year, the other with the updated 1982 catch and population numbers, weights at age and partial recruitment. The input parameters are presented in Table 10 and the results summarized in Figure 3. The observed catch numbers at age 3 and particularly at age 4 are higher than all the predicted values, the update resulting in estimates virtually identical to the original values for those ages. However, the update produced a higher population number at age 4 which resulted in higher projected catches at age 5, in close agreement with the observed data. In conclusion, increasing the number of samples used to calculate the age composition of the 1982 catch by 60% resulted in a marginal improvement of the agreement between projected and observed 1983 catch-at-age.

The reason for the important discrepancies observed at age 3 and 4 between the projected and the observed catch can be found elsewhere. In the last two assessments (Maguire *et al.* MS 1982; Gagné *et al.* MS 1983), population sizes and projected catch numbers have been estimated assuming that the 1979 and 1980 year-classes were of average size. Gagné *et al.* (MS 1983) noted that the limited evidence available to them suggested that these two year-classes were better than average. We shall demonstrate later that the 1979 year-class (age 4 in 1983) now appears to be the largest observed since 1958. As for the 1980 year-class, it is now believed to be at least equal to the 1979 year-class at age 3 and might be even larger. CAFSAC apparently very much underestimated the size of these year-classes in its 1983 assessment and consequently their importance in the catch of that year. Interpreting these results requires caution

however since only 48% of the samples collected could be used to determine the 1983 removals at age.

Stock Size Indices

Commercial Catch-Per-Unit of Effort

As in 1983, the multiplicative catch rate standardization model (Gavaris 1980) was used to generate a commercial catch rate series. Data from Spanish pair trawlers, TC 4 and TC 5, Canadian (M&Q) longliners, TC 2-4 combined, side draggers TC 4 and stern draggers TC 5 were used for the period 1968-1983. Semi-annual values of total catch and effort were entered as observations.

The resulting catch rate series is presented in Figure 4. The 1983 value is above the 1982 and is virtually equal to 1979, being the highest values in the series. This catch rate is almost identical to that used last year (Gagné et al. MS 1983).

Previous assessments noted the possibility of substantial misreporting of catch and effort by the Canadian offshore trawler fleet in 1978 and 1979. This prompted the rejection of a commercial catch rate series as a method of tuning the Sequential Population Analysis (SPA) and the sole use of research survey results (Gray MS 1979; Maguire MS 1980; Maguire MS 1981). Since it is not possible to correct these data for misreporting it was decided to remove the 1978 and 1979 values for side and stern otter trawlers. Furthermore data from Canadian (M & Q) otter trawlers between 1968 and 1973 did not seem to be indicative of fishable biomass. While the catch rate series for Canadian (M & Q) longliners and Spanish pair trawlers were declining, the two otter trawler series were either level (stern, TC 5) or increasing (side, TC 4) (Figure 5). The results from previous SPA runs indicated a decreasing trend in fishable biomass over the same time period. The replacement of the Western IIA trawl with the more efficient Engel high lift trawl in 1974-75 and the opportunistic nature of the Canadian offshore fishery during this time period (Gray MS 1979) may be partly responsible for this discrepancy. Consequently it was decided to remove the data for Canadian (M & Q) side and stern otter trawlers for 1968 to 1973 from the analysis. The standardized catch rate series obtained using Spanish pair-trawlers TC 4 and TC 5 separately (1968-76), Canadian longliners TC 2-4 combined (1968-83) and Canadian (M & Q) side otter trawlers TC 4 and stern otter trawlers TC 5 (1974-77, 1980-83) is given in Figure 6.

The 1978 and 1979 points are substantially lower than in the former series. While both series show a decline from 1968 to 1975 followed by an increase to current high levels, the relative heights of the two peaks differ. In the initial series the catch rate in 1969 was 64% of the 1982 level while in the second series the 1969 catch rate is 88% of the 1983 level. The authors and the Groundfish Subcommittee consider the later

series to be consistent with both the general consensus regarding data quality and the trend in fishable biomass during the 1968-1975 time period. Consequently only this series is used hereafter.

Groundfish Research Surveys

For the first time in the summer of 1983, the main vessel to conduct the groundfish survey in 4VsW was the Alfred Needler, the new research trawler of the Scotia-Fundy Region. Comparative fishing experiments have been conducted between the Needler and her predecessor the Lady Hammond but their analysis is not completed yet. Both vessels fished together for parts of the 1983 summer survey, but as shown in Table 11, the insufficient coverage of 4VsW by the Hammond compels us to use the Needler's data for this assessment.

Results of preliminary analyses of the comparative fishing experiments between the Needler and the Hammond were presented at the May meeting of the Groundfish Subcommittee (Fanning, pers. comm.). Using these results and others presented last year on connecting the Hammond and the A.T. Cameron data (Koeller and Smith MS 1983), the Subcommittee investigated the problem of amalgamating data from three different research vessels into a coherent time series. It was agreed that for cod, the series for the Cameron and the Hammond should remain unadjusted and that the numbers caught by the Needler should be increased by a factor of 1.39. Although this is a temporary measure which may be modified as more conclusive information becomes available, we adhere to it for the analyses presented here unless otherwise indicated.

As was the case last year, the survey gear encountered unusually high concentrations of cod in several strata of 4W (Table 12). In three of the four strata where that occurred, large sets were experienced by both the Needler and the Hammond which were then fishing close to each other (Table 13). The high numbers caught were the results of heavy concentrations of cod between ages 1 and 4 and especially ages 2 and 3. The population estimates (Table 14 and 15) consequently indicate that the 1979 and 1980 year-classes are very strong, particularly in 4W, and that the 1981 and 1982 year-classes may be above average. A rare sequence of strong year-classes seems to be recruiting to the 4VsW cod population. As for the older ages, the survey data suggest a situation stabilized at a level higher than prior to 1978 (Figure 7). Population estimates from the Hammond for 1980 and 1981 are included in Table 15b for comparison.

In 1979 a spring groundfish survey was initiated using the Lady Hammond on the Scotian Shelf. We now have four years of data available which we present in Tables 16 to 18. In the spring of 1982, large numbers of cod were caught in those strata 55, 56 and 59 where very big sets were recorded in the following summer survey. However no such unusually large set was brought in in the spring (Table 16).

For no obvious reason, the spring cruises have consistently caught less 2 to 4 year-old cod than the summer ones. However these age groups follow the same annual trends in both series (Figure 8). The spring survey data indeed agree with the summer survey in indicating the presence in the 4VsW cod population of very strong 1979 and 1980 year-classes, surrounded by strong ones for 1978 and 1981.

Fall groundfish surveys also began in 1979. However the data on 4VsW cod are too sparse to warrant a meaningful analysis.

Estimation of Stock Size

Sequential Population Analysis (SPA)

We followed the procedure used in the previous assessment of 4VsW cod (Gagné et al. MS 1983) to perform our initial sequential population analysis. Cohort runs (Pope 1972) were carried out with fully recruited fishing mortalities (F) ranging from 0.15 to 0.40 in 0.025 increments. We used the final partial recruitment vector from the 1983 assessment as our input partial recruitment for the most recent year (PR82 in Table 19). Starting F for the oldest age class (age 16+) was set at 0.250 and iterations were continued until the differences between F at age 16 and the mean F for the fully recruited ages 7 to 10 were 0.001 or less. Technically the oldest age class should include only catch at age from a specific year-class (i.e. age 16 rather than 16+) however to be consistent with previous assessments we chose the method described. Although not analysed it is unlikely that this will have a noticeable effect on the assessment. The instantaneous rate of natural mortality (M) was assumed to be constant at 0.2.

The resulting population number and F matrices were used to calculate the mean population numbers as in Ricker (1975 p.12). For the purpose of this assessment, we assumed that mean population numbers was equal to mid-year population numbers.

Fishable biomasses were calculated as follows: F values were weighted by population numbers and averaged across fully recruited ages 6 to 10 unless indicated otherwise. The F matrix was divided by these mean F s to produce a matrix of annual partial recruitment vectors. The yearly estimates of population biomass at age were then multiplied by these partial recruitment vectors and the products summed over ages to obtain the estimates of fishable biomass for each year. A matrix of partial recruitment vectors is presented in Table 20.

The analysis of that matrix led the Subcommittee to the following conclusions:

- 1) 4VsW cod appears not to be fully recruited to the commercial fishery until age 6, not age 5 as assumed in previous assessments.

- 2) The general shape of the partial recruitment changed during the period 1968-1983; it was flat-topped from 1968 to 1976, dome-shaped between 1977 and 1981 and flat-topped again in 1982-83.

These had to be considered in calculating fishable biomasses for SPA calibration purposes.

In recent assessments of 4VsW cod, cohort runs were initiated with the final partial recruitment vector from the previous year's analysis. Even though this is a legitimate and accepted procedure it was decided that a second series of cohort runs be done with a new starting partial recruitment vector. Mean values were calculated using the vectors of Table 20 for the period 1977 to 1981. In agreement with the preceding analysis, full recruitment was assumed for ages 6 and older. The resulting vector appears as PRAV in Table 19. Before this vector could be used to initiate cohort analysis runs, it was decided to change the values for ages 1 to 3 as follows, assuming a fully recruited fishing mortality of 0.2: the values for ages 1 and 2 were adjusted to make the size of the 1981 and 1982 year-classes approximately equal to the long-term geometric mean at age 1 (107×10^6 from the results of the 1983 assessment, 1958-1980). The 1980 year-class (age 3) was made equal to the largest observed since 1968 i.e. the 1979 year-class. This partial recruitment vector is presented as PRSUB in Table 19.

Calculation of Partial F Matrices

The small mesh fishery in 4VsW is not cod directed. Consequently there is no catch rate information available to incorporate in the commercial catch rate standardization process. To improve the calibration of the SPA results with the standardized catch rate, it was decided to remove the influence of that fishery's catches from the estimates of fishable biomasses.

From their analyses of the cod catches in the small mesh fishery, Maguire et al. (MS 1982) concluded that the removals at age calculated by Gray (MS 1979) for the period 1966-78 were probably as accurate as possible. They were therefore used in the last two assessments. Maguire et al. (MS 1982) also provided estimates for 1979 to 1981. Gagné et al. (MS 1983) revised the 1980 and 1981 estimates from more recent statistics and provided one for 1982. An estimate for 1983 is presented in Table 6 of this document. From these various sources, we constructed a catch-at-age matrix for the small mesh fishery for the period 1968 to 1983 (Table 21). We then subtracted these numbers from the catch-at-age matrix for the entire fishery. Dividing the resulting array by the total catch-at-age matrix gave us the proportion of the total fishing mortality generated by all the gears combined except the small-mesh gear (Table 22). A partial F matrix representing all the non-small-mesh gears can be obtained by multiplying a total F matrix by these proportions.

In order to calculate biomasses exploitable by the non-small-mesh gears, we needed a partial recruitment matrix derived from a partial F matrix. From the second series of cohort runs, we took the F matrix generated for a fully recruited F of 0.25 and multiplied it by the matrix of proportions described above (Table 22). From that matrix of partial Fs (Table 23) we produced a partial recruitment matrix by following the procedure outlined earlier. The mean weighted Fs were calculated on ages 7 to 10.

Calculation of Partial Fishable Biomasses

As indicated before, the analysis of Table 20 revealed that vectors of different shapes were required to describe the overall availability of the fish to the commercial gears during different periods. From the partial recruitment matrix just described (Table 23), partial recruitment vectors were derived for the periods 1968-76 and 1977-81.

The individual vectors of the first period were averaged across the years and these averages deemed to be representative of that period. Ages 6 and older were assumed to be fully recruited.

The recruitment pattern for the 1977 to 1981 period appeared to be domed-shaped and thus required a different procedure. The annual vectors were averaged and the mean of the averages for the fully recruited ages 6 and 7 calculated. The inverse of that mean ($1/1.12 = 0.89$) was then multiplied by the mean PR for ages 1 to 5 as well as 8 and 9. This procedure is not sensitive to the value of input terminal fishing mortality. For instance a terminal F value of 0.35 would have generated partial recruitment values of 0.35 and 0.78 for ages 4 and 5 respectively rather than 0.34 and 0.79 as obtained with a terminal F of 0.25. Recruitment was set at 0.45 for ages 10 and older.

For the 1982-83 period we used the starting partial recruitment vector of the second series of cohort runs (PRSUB).

These three vectors (Table 19) were then deployed into a partial recruitment matrix to be used as a constant in the calculation of fishable biomasses. That matrix is characterized by the alternation of flat-topped and dome-shaped partial recruitment patterns and is free from the influence of the small mesh fishery.

Mid-year fishable biomasses were calculated by multiplying the product of that matrix and the mean weights-at-age of Table 8 by the mid-year population numbers derived from the second series of cohort runs.

Calibration of SPA

a) WITH COMMERCIAL CATCH RATE

Gagné et al. (MS 1983) used estimates of the beginning-of-the-year fishable biomass to calibrate the SPA results against a standardized

commercial catch rate. However more of the total annual catch of 4VsW cod is taken during the spring to fall period than during other times of the year. The commercial catch and effort statistics are therefore likely to be more representative of the mid-year period. Mid-year estimates of fishable biomass should then be the appropriate representation of population size to calibrate against the standardized commercial catch rate. The results of such calibration runs are presented in Table 24 and Figure 9.

The criteria used by Gagné et al. (MS 1983) to identify the best relationship were the coefficient of determination, the intercept and the ratio between the predicted and the cohort analysis values for the two most recent years. From the statistical point of view, the coefficient of correlation and not its squared value is the proper index to consider in analyses like this one. Using either one however will lead to the same conclusions. Mohn (1983) evaluated various ways of calibrating cohort analyses and concluded that the use of the intercept as a tuning criterion should be discouraged. We therefore adopted the following criteria to select the best relationship: the maximization of the correlation coefficient (r) and the minimization of the residuals for 1981-1983.

Table 24 shows that r is highest (0.92) at fully recruited F values ranging from 0.3 to 0.375 although there was little difference for $F_t = 0.275$ to $F_t = 0.4$. The residuals for 1981-1983 are collectively minimized when the mean of the ratios between the predicted and observed values is closest to 1.0. This is obtained for $F_t = 0.35$. This value of 0.35 is also in the middle of the range of terminal F s suggested by the correlation coefficient. The calibration with the commercial catch rate therefore indicates a fully-recruited fishing mortality for 1983 of 0.35.

b) WITH RESEARCH SURVEY ABUNDANCE ESTIMATES

We attempted to calibrate the mid-year population estimates of the fully-recruited ages from the second series of cohort runs with those of the research vessel surveys. The survey data were not corrected for the unusually large sets since the influence of these sets is negligible for age 6 and older (Table 13). As indicated by the analysis of the comparative fishing experiment results summarized earlier, we used the unadjusted survey 6+ estimates for 1982 and the 1983 data were first multiplied by 1.39 as in Table 15a.

We summarize the results of the calibration runs in Table 25. Using the same criteria as earlier with the commercial catch rate we see that r values of 0.87 and 0.88 are obtained for terminal F ranging from 0.125 to 0.200. The mean residuals for the 1981-83 period are minimized for F_t between 0.25 and 0.30.

The two criteria therefore indicate different ranges of F values. Similar situations occur when other sets of criteria are considered e.g. r and 1983 residuals, r and mean residuals for 1982-83, etc.. Even though

the relationships between the two variables are very good as evidenced by the r values, we were unable to discriminate amongst them. The Subcommittee therefore concluded that research survey population estimates could not be used to evaluate the 1983 fully-recruited fishing mortality. As for last year, terminal F was estimated on the basis of the commercial data only. The value of $F_t = 0.35$ was therefore adopted.

F on Partially Recruited Ages

For the 1982 and 1983 assessments of 4Vsw cod, Maguire et al. (MS 1982) and Gagné et al. (MS 1983) used an index of year-class size derived from the commercial catch rate data to evaluate the partially-recruited F at age 4. Following the same procedure with the new standardized catch rate calculated for the present assessment produces very good relationships for ages 4 and 5 (r values around 0.9).

The Subcommittee recognized the potential of that approach which utilizes the most recent information from the fishery to estimate parameters for the most recent year. Partial recruitment values however should remain stable over periods of time when no major changes occur in a fishery. On that basis, the Subcommittee requested that the final partial recruitment be calculated as for the second series of cohort runs, assuming a terminal F of 0.35. Averages for the period 1977 to 1981 were therefore used rather than estimates from calibration runs to set the partial recruitment for ages 4 and 5. The resulting vector is PRFIN of Table 19. The corresponding population numbers, fishing mortalities and population biomasses are presented in Tables 26 to 28. Based on these results, it now appears that the 1979 year-class is the largest observed since the 1965 year-class. The 1980 year-class may be even more abundant as the partial recruitment at age 3 had to be reduced to an unusually low level just to make this year-class equal to the largest previously observed at that age i.e. the 1979 year-class.

We discuss in Appendix 2 the effect of using average partial recruitment values for ages 4 and 5 rather than calibrated ones on the results of this assessment.

Catch Projections

Table 29 presents the input vectors used for catch projections. The population numbers at ages 1 and 2 were set to make the size of the corresponding year-classes at age 1 equal to the long-term geometric mean of 107 million fish. The numbers for the other ages are as in Table 26. The 1983 catches at age are from Table 7.

In the two preceding assessments of 4Vsw cod, the most recent weights at age were used for catch projections. Our data (Table 8) indicate that the mean weight of a cod (age 1+) in 4Vsw increased from 1975 to 1980. For the last three years, it has been fluctuating around 5.5 kilograms with the

1983 value being lower than that of 1982. It is possible that these fluctuations are not real but only result from the uncertainty associated with the available sampling data. For that reason it was decided to use the averages for these three years instead of the most recent weights at age as in previous assessments.

The partial recruitment vector used is the vector of means (PRAV of Table 19) from which we derived PRFIN, the vector used to estimate the fishable biomasses for 1982 and 1983. $F_{0.1}$ was set to 0.2, the accepted value for cod stocks in the Northwest Atlantic.

The results of these projections are summarized in Table 30. If the TAC of 55,000 tons is taken in 1984, the projected 1985 catch resulting from fishing at $F_{0.1}$ would be 52,000 tons. Fishing at $F_{0.1}$ in 1984 would drastically reduce the catch to 42,000 tons and marginally increase the 1985 $F_{0.1}$ catch to 54,000 tons.

Discussion and Conclusion

The results of our analysis corroborate last year's conclusion that the 4VSW cod stock complex is currently quite large. The fishery is supported by a good array of year-classes. The research vessel surveys indicate that the current abundance exceeds the highest levels observed in the 1970s. The 1979 and 1980 year-classes are reaching the ages of recruitment to the fishery and they both appear to be larger than the largest ones observed in 25 years. In 1982 and 1983, the research surveys have caught unprecedented quantities of ages 1 and 2 cod which suggests that the in-coming year-classes too will be much above average. The surveys also indicate that the abundance of the fully-recruited age-groups is remaining stable in spite of an increasing harvest. All these signs agree in identifying a large population.

Yet, the TAC dropped by 9,000 t between 1983 and 1984 and no increase can be anticipated for 1985. This contradiction can be explained by problems encountered in assessing the status of the stock complex. Errors in catch-per-unit-effort statistics of the Scotia-Fundy Region were responsible for overestimating the 1983 optimal yield (Gagné et al. MS 1983).

Table 31 compares the mean fully recruited Fs (ages 6-16) for the years 1977 to 1982 from the current analysis to the estimates produced by the corresponding annual assessments. For instance, it now appears that fully-recruited F in 1977 was 0.27 while Gray (MS 1978) estimated it to be 0.15. Table 31 demonstrates that CAFSAC has consistently underestimated the fishing mortality applied to the stock complex by an average of 54%. This realization was responsible for the dramatic increase in the estimated fully-recruited F between 1982 and 1983. It does not represent a real increase in F but only reflects CAFSAC's new perception of the reality. Had the stock complex not been much larger than a few years ago, this would have generated an equally dramatic reduction in the proposed catch levels.

With the current status of the stock however, it is likely to translate into stable TACs for 1984 and 1985.

Our analysis therefore indicates that fully-recruited fishing mortalities have been well in excess of $F_{0.1}$ since 1977, even exceeding $F_{MAX}=0.3$ in all but one year. Concurrently fishable biomass has doubled undoubtedly due to the succession of good to very good year-classes. Thus exploitation rates in excess of $F_{0.1}$ for this time period have not prevented the rebuilding of the stock. In fact the actual exploitation levels may have been appropriate to take advantage of the yield potential of these good year-classes while they were of optimal age.

It must be cautioned however that since 1977, restrictions imposed by Fisheries and Oceans were aimed at keeping fishing mortality rates at or below $F_{0.1}$. In spite of these efforts, the resulting F values have always been near or above F_{MAX} .

Table 19. Various partial-recruitment vectors used in our Sequential Population Analysis. Details given in text.

PR82: final vector from 1983 assessment; used in first series of SPA runs.
 PRAV: mean partial recruitment values for ages 1 to 5, calculated for the period 1977-1981 from Table 20.
 PRSUB: vector derived by CAFSAC Groundfish Subcommittee and used in second series of SPA runs.
 PRFB's: three vectors used to calculate mid-year fishable biomasses.
 PRFIN: vector used to produce the final estimates of population size and fishing mortalities.

Age	PR82	PRAV	PRSUB	P R F B			PRFIN

Table 22. Ratios of catch-at-age by gears other than small mesh trawls to the total catch-at-age in the 4VsW cod fishery.

Table 23. Partial recruitment matrix derived from a matrix of partial F values. The original population numbers and F matrices came from a cohort run with PRSUB for input partial recruitment vector and $F_t = 0.25$. Mean F values calculated on ages 7 to 10.

^a The first number is the number of fish measured and the second, the number of fish aged.

^b Only samples completed by April/84 are included for 1983.

Appendix 2: Partial recruitment values for ages 4 and 5; effect of using averages rather than values indicated by a calibration procedure.

Partial recruitment values based on averages would smooth out trends that may have developed in recent years which can then proceed unnoticed. This procedure however is much less sensitive to spurious changes that may result from erroneous catch and effort statistics. Erratic variations do not seem to be a problem in the present case since calibration based on the regression of SPA numbers against a variety of standardized catch rates over the last three years all suggest a partial recruitment around 0.55 at age 4. When we used this procedure for age 5 with the two standardized effort series described in this document, we obtained estimates around 0.9 in both cases. This procedure therefore appears to be fairly robust when used with our data set and has indicated a stable partial recruitment at age 4 for the last three years.

For both ages 4 and 5, the estimates derived from the calibration procedure (PRCAL in Table A.2.1) are higher than those based on averages. In the previous two assessments, the population size and the catch projections were calculated with the same partial recruitment values. Had we done this in the current analysis, the 1983 population estimates for ages 4 and 5 would have been 38% and 11% lower (Table A.2.1).

Larger partial recruitment values increase the projected catches over the short run. However, as shown in the table, that increase would have been insufficient to offset the reduction in population size, resulting in a projected 1985 $F_{0.1}$ catch biomass 6% less than that using PRFIN, assuming a 1984 catch of 55,000 tons.

Unfortunately, it remains unknown which partial recruitment series is better. A good knowledge of the recent trends in partial recruitment would certainly be very useful in analyzing the dynamics of the partially-recruited year-classes as well as the behaviour of the fisheries exploiting them. Such information can certainly not be obtained by averaging over passed periods of time.

Table A.2.1. Effects of using calibrated values (PRCAL) rather than averages (PRFIN) for the partial recruitment at ages 4 and 5. ($F_t = 0.35$; PRFIN and PRCAL used in cohort runs and projections; other input values as in Table 30.)

Partial Recruitment	PRFIN	PRCAL	Differences	
			Number	Percent
age 4	.34	.56		
age 5	.79	.90		
1983 Population Numbers				
age 4	89001	55562	33439	38
