1 This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the timeframes required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

1 Cette série documente les bases scientifiques des consells de gestion des pêches sur la côte Atlantique du Canada. Comme tel, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de Recherche qu'elle contient ne doivent pas ètre considērēs comme étant des énoncés finals sur les sujets traités mais plutōt comme des rapports d'êtape sur des ëtudes en cours.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

Les Documents de Recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secretariat.

#### Abstract

Although recent tagging studies have show the west coast of Newfoundland to be a discrete herring stock area, studies conducted in the early 1970's showed an overlap between the west coast stock and southern Gulf of St. Lawrence herring stock. These studies indicated that the overlap was probably most extensive during the spring in the area of the St. George's Bay. In formulating the initial catch matrix for analysis of the west coast stock this fact was accounted for by partitioning the St. George's Bay catch between the two stock areas with all catches prior to 1975 being assigned to the southern Gulf and all catches from 1975 onward to the west coast.

Recent analyses of the status of the west coast herring stock have shown anomalles between the catch matrix and the results of cohort analysis, most notably for the period prior to 1975. Potential errors in the catch matrix were investigated using three sources of data: (1) age and spawning type frequencies fron sampling data, (2) magnitude and distribution of purse seiner activity in St. George's Bay from interviews and (3) catch data from southwest Newfoundland.

These data support the view that the main area of overlap was St. George's Bay and that the fisheries along southwest Newfoundland and north of the Bay of Islands exploited different stocks. It was also shown that the southern Gulf stock had ceased to be a significant contributer to the $5 t$. Goerge's bay fishery by 1973. A detailed partitioning of the $5 t$. George's Bay catches from 1966 to 1973 was conducted. The data also indicated that the gillnet fishery in the St. George's Bay area has always explolted fish of the west coast stock.

Based on these findings a new catch matrix was generated. Using the new matrix and the previously utilized matrix cohort runs were performed and the results compared.

#### Abstract

Rēsumé Bien que des expériences de marquage récentes aient montrē que la côte ouest de Terre-Neuve possède un stock distinctif de harengs, des études effectuëes au début des années 1970 indiquaient un chevauchement entre le stock de la côte ouest et celui du sud du golfe du Saint-Laurent. D'après ces ētudes, le chevauchement êtait propablement maximal au printemps dans la région de la baie Saint-Georges. Lors de l'ëtablissement initial de la matrice des prises commerciales pour l'analyse du stock, on a tenu compte de ce fait en répartissant les prises effectuēes dans la baie Saint-Georges entre les stocks des deux rēgions, toutes les prises antërieures à 1975 ētant attribuëes au sud du golfe et toutes les prises effectuēes à partir de 1975, à la côte ouest.

Des analyses rēcentes de l'état du stock de harengs de la côte ouest rēvèlent des anomalies entre la matrice des prises et les résultats de l'analyse des cohortes, en particulier pour la përiode antërieure à 1975. On a cherché à déterminer les erreurs possibles dans la matrice des prises à l'aide de données êmanant de trois sources: 1) fréquences des âges et des types de reproducteurs établies à partir d'échantillons commerciaux 2) ampleur et rēpartition de la pêche à la senne coulissante dans la baie Saint-Georges, d'après des renseignements recueillis lors d'interviews et 3 ) données sur les prises au sud-ouest de Terre-Neuve.

Ces données confirment que la baie Saint-Georges est l'endroit oũ le chevauchement des stocks est le plus important et que les prises effectuées au sud-ouest de Terre-Neuve et au nord de la baie des Iles proviennent de stocks diffërents. On constate aussi que la part émanant du stock du sud du golfe dans les prises effectuēes dans la baie Saint-Georges a cessē d'ētre importante dès 1973. On a également procédé à un dëmembrement dētaillé des prises effectuẻes dans la baie Saint-Georges de 1966 à 1973. Il apparait que les prises effectuées avec des filets maillants sont toujours provenues du stock de la cōte ouest.

Compte tenu de ces constatations, on a établi une nouvelle matrice des prises commerciales. A l'aide de la nouvelle matrice et de l'ancienne, on a procēdé à des analyses de cohortes, dont on a ensuite comparē les rësultats.

## Introduction

The first analytical assessment of the west coast herring stock was performed in 1977 (Moores and Winters 1977). The definition of the management unit to encompass this stock was based primarily on external tagging studies, conducted since 1975, which indicate that the west coast of Newfoundland was discrete from adjacent stock areas. However, earlier tagging studies (Winters and Parsons 1972, Winters and Hodder 1975) conducted in the early 1970's indicated that some portion of the overwintering southern Gulf of St. Lawrence herring stock was being exploited along the west coast of Newfoundland particularly during the spring in the St. George's Bay area. The absence of southern Gulf fish in St. George's Bay since 1975 reflects a change in the overwintering distribution and range of this stock due to the reduction of its numbers.

The overlap of these two stocks presents problems in accurately assigning the catch to the appropriate stock particularly for St. George's Bay. In constructing the first catch matrix for this stock Moores and Winters (1977) examined the pattern of fishing effort in St. George's Bay as shown by log records and compared the spawning-type composition of herring sampled in the St. George's Bay spring fishery and that occurring along the "edge". These analyses indicated that there was a marked change in both sets of data from the period prior to 1975 and since 1975. On this basis all catches from St. George's Bay (Area K) (Fig. 1) prior to 1975 were assigned to the southern Gulf of St. Lawrence stock complex while all catches from 1975 onward were attributed to the west coast stock complex.

In recent years it has been noted that there are inconsistencies between the population composition produced by cohort analysis and other pieces of available data. For example, the cohort analysis indicates that from 1966 to 1972 the autumn-spawning component represented $3 / 4$ of the total stock yet with the exception of one year represented less than half the catch. Also the fall purse-seine fishery which is expected to be most representative of the stock composition indicates a lower percentage of autumn-spawners in the stock than does cohort analysis (with M and F the same for both components). The problems are most noticeable for the early years of the analysis (Moores et al. 1982).

Possible explanations for these inconsistencies included a different level of natural mortality acting on the two spawning components or removals from the stock which were not accounted for by the catch matrix. Before any detailed analysis of mortality rates can be attempted the catch matrix should be re-examined. Previous analyses of $F$ and effort, CPUE and biomass indicate a marked difference between the historical period (1966-73) and the recent period (1975-81). This change coincides with the decline of the southwest coast fishery and the development of the St. George's Bay fishery on pre-spawning concentrations of spring-spawning herring. The main emphasis of the following analyses was therefore directed at trying to perform a more precise assignment of the pre-1975 St. George's Bay catches between the two Gulf stocks.

## Data Sources

Data from three sources were utilized to examine the question of how the St. George's Bay catch should be partitioned. These were: 1) the commercial sampling data from which age and spawning type frequencies were available, 2) interview records of seiner captains and plant personnel for the years 1966-73 which provided information on the size and location of purse-seine catches made in St. George's Bay and 3) detailed catch statistics for southwest Newfoundl and.

## Gillnet Catches

There are two main gear components in the St. George's Bay herring fishery: gillnets and purse-seiners. The gillnet fishery is a traditional near-shore fishery which occurs primarily in the spring of the year. Samples from this component are almost exclusively spring-spawners. The timing and spawning-type composition of these catches indicate that the gillnet fishery exploits a locally spawning population of spring-spawners. Therefore, all gillnet catches should be included with the west coast stock complex rather than the southern Gulf stock.

## Purse Seine Catches

The only catches requiring detailed examination therefore are those of the purse-seine fleet which operated along both the west and southwest coasts of Newfoundland. All three data sources are utilized to examine this gear component.

## (1) Age and Spawning Type Composition

Sampling data were available since 1966 for the west coast and southwest coast herring fisheries. These purse-seine fisheries can be broken down into three components: 1) the winter-spring southwest coast fishery, 2) the fall-winter fishery north of Bay of Islands and 3) the spring fishery in St. George's Bay. If one assumes that the southwest coast samples are representative of the overwintering population of the southern Gulf stock, and that the samples from the winter fishery north of the Bay of Islands are representative of the west coast population, then by comparing these frequencies to those of the St. George's Bay fishery, it would be possible to assign the St. George's Bay catches to the appropriate stock. The age distributions, adjusted to correspond to a fall fishery, and the spawning type composition for each of the three fisheries for the period 1965-75 are shown in Fig. 2 and 3.

Looking first at the autumn-spawning component it is apparent that in all cases, except for the 1973-74 data, there is a lower proportion of autumn-spawners in the fishery north of the Bay of Islands than for the southwest coast. In the northern fishery the $10+$ age-group is dominant in all years indicating that year-classes older than 1955 are important in
this area. Along the southwest coast the 1958 year-class was dominant and is probably the major contributor to the + group in subsequent years. The 1958 year-class does not appear to be a significant contributor in the northern Gulf.

The percentage of autumn-spawners in St. George's Bay is highly variable. In 1967-68 it is identical to southwest Newfoundland and in 1970-71, 1972-73, and 1973-74 it is higher than the southwest coast and lower in the remaining years. The percentage of autumn-spawners is however generally higher than in the northern fishery. The presence of the 1958 year-class in the early years suggests a relation to southwest Newfoundland while from 1970-71 to 1972-73 it is difficult to detect differences between all three areas due to the dominance of the + group. By 1973-74 however the St. George's Bay samples are most similar to the west coast northern samples.

For the spring-spawner component the data support the findings seen for autumn-spawners. Springs form a larger portion of the west coast catch than southwest Newfoundland with St. George's Bay tending to be intermediate. The 1959 year-class is dominant in both fisheries, however, it represents a lower part of the catch in the northern area. Prior to 1971-72 the small sample size in St. George's Bay does not allow for a definitive comparison with the other fisheries. In the northern fishery the 1968 year-class becomes a significant contributor in 1971-72 but does not appear in the other areas until 1972-73. The age compositions since 1973-74 appear to be most closely related between the northern and St. George's Bay fisheries.

It should also be noted that between 1971-72 and 1972-73 the southwest Newfoundland fishery switches from predominantly autumn-spawners to predominantly springs. This may indicate a reduction in the size of the migratory southern Gulf stock present in the area which is supported by the reduction in catch.

Some caution, however, should be exercised in interpreting these data as regards the St. George's Bay samples. First, it should be remembered that the St. George's Bay and southwest Newfoundland fisheries were exploited at the same time and by the same fleet with mixed catches from both areas being landed at the same plant. Some samples assigned to St. George's Bay therefore may be from southwest Newfoundland. Second sample composition may be influenced by the location in the bay the fish were caught. It would be expected that samples from Cape Anguille would more probably be related to the southwest coast than would catches from the Cape George or Sandy Point area.

Additionally, the spawning type composition from St. George's Bay may be influenced by two factors other than sample location. Firstly, the period of the fishery (spring) occurs during the period when maturity assignment is most difficult (Cleary et al. 1982) and also the proportion of each component in the fishable poputation is affected by the timing of the spring-spawners separating from mixed schools to go to the spawning grounds. Under these conditions the purse seine fishery could show a bias
towards autumn-spawners and overestimate the abundance of this component in St. George's Bay.

Bearing these considerations in mind, the data do suggest that the northern and southwest Newfoundland fisheries exploited different stocks and that the St. George's Bay fishery has exploited primarily west coast fish probably as early as 1973.

## (2) Fleet Activities

Data on the location and magnitude of purse-seine catches from 1966 to 1973 were available from interviews with purse-seine captains and plant personnel. On the basis of these interviews catches can be assigned to one of the six subdivisions which constitute the St. George's Bay area(Area K) (Fig. 1). The information from these interviews is summarized in Table 1. From 1966 to 1968 the purse-seine fishery occurred in the southern portion of Area K around Cape Anguille. Moores and Winters (1977) suggested that Cape Anguille was a reasonable division line between the west coast and southwest coast stocks. These catches therefore are most probably from the southern Gulf stock.

From 1969 and 1970 the catches from St. George's Bay occur in the north of the bay and early in the year when the southern Gulf fish most probably occur along southwest Newfoundland, thereby, implying that these are west coast fish.

From 1971 to 1973 the areas fished are much more diversified but occur primarily further in the bay than in the $1966-68$ period and also along the northern side of the bay. This would indicate a higher proportion of west coast fish should be in the catch. This would be particularly true for catches in K 41-1 which corresponds to the Sandy Point spawning grounds.

These records are more comprehensive than the data obtained from 10 g records utilized previously (Moores and Winters 1977) and which were not available prior to 1972. The $\log$ records however do not show as extensive an area of fishing activity and show a higher concentration in area $\mathrm{K} 40-1$ and K 40-2 than do the interviews for 1972 and 1973. While these ambiguities may temper ones faith in either data set the more extensive coverage of the interviews and the degree of personal contact involved would tip the scales in favor of the interview records.
(3) Catch Records for the Southwest Coast

The fishery along southwest Newfoundland exploited migratory southern Gulf fish and to some degree local populations (Winters and Hodder 1975). The fleet followed the migrating fish as they moved along the southwest coast. Tagging studies (Winters and Beckett 1978) showed that the fleet followed the schools westward as they migrated back along the southwest coast to cross the Cabot Strait to the spawning grounds in 4T. An examination of the catch from each of the two subareas along southwest

Newfoundland (Fig. 1) should give some indication of the presence of the extent of overwintering southern Gulf fish along southwest Newfoundland.

Catch records (Table 2) show Area J catches increasing from 1964 to 1969 and decreasing thereafter. By 1973 catch levels were only $2 \%$ of peak and from 1974 onward catches were back to historical inshore levels. Catches in $J_{1}$ were initially largest peaking in 1968 with $J_{2}$ not peaking until 1970. $\mathrm{J}_{2}$ represents the more western area and should therefore support a fishery as long as southern Gulf fish are migrating to southwest Newfoundland. George's Bay fishery. This fishery ended in 1972 suggesting that since 1973 the St. George's Bay fishery has primarily been supported by west coast fish.

## Proposed Revisions to West Coast Catch

Based on the preceding information a series of revisions to the purseseine catch assigned to the west coast stock can be proposed. All changes relate to St. George's Bay (Table 3). It appears from the southwest coast catch data supported by the spawning composition data that no major migration of southern Gulf fish to southwest Newfoundland has occurred since 1972, therefore all catches from 1973 onward should be attributed to the west coast stock. Based on seiner interviews the 1966-68 catches should be assigned to the southern Gulf stock and the small 1969-70 catches to the west coast stock. The 1971 and 1972 data are more ambiguous. In 1971 the bulk of the catch comes from K 41 and are assigned to the west coast stock but as there was an active fishery in $J_{1}$ the catch from $K 40-1$ was assigned to the southern Gulf stock. In 1972 the St. George's Bay catch occurs throughout the area. The K 41-1 and K 40-3 catches are assigned to the west coast stock due to their proximity to the spawning grounds as are the catches from $K 41-3$ which is still an important purse-seining location. Although much decreased the fishery in $J_{1}$ was still substantial and catches from $\mathrm{K} 40-1$ and $\mathrm{K} 40-2$ were assigned to the southern Gulf of St. Lawrence stock.

The revised catch figures for the Newfoundland west coast stock are shown in Tables 4 and 5 and also include all St. George's Bay gillnet catches.

## Revision of the Catch Matrix

Adjustments were made to the previous catch matrix (Table 6, Moores et al. 1982) to account for the changes in catch. The gillnet catches were assumed to be $100 \%$ spring-spawners and were broken down using either the gillnet samples from Area $K$ for that year or else using the age frequency for the springspawning component present in the purse-seine catches. The purse-seine catch was broken down by the appropriate purse-seine samples. The applicability of some of the earlier samples is suspect however due to small sample size and limited spatial coverage within St. George's Bay. For 1966 and 1970 no samples of either purse-seine or gillnet were available for St. George's Bay. For 1966 the catch frequency and average weight for the west coast area was utilized while for 1970 otter trawl samples for Area $K$ in April were used. The revised catch matrix is given in Table 7.

## Comparison of Population Effects

In order to examine the effect of these changes in the catch matrix on the population parameters of the west coast stock, a series of cohort runs were performed. First, the catch matrix was expanded in the fashion explained in previous years such that for the period 1966-81 ages ran from age-groups 2-26. All. runs were performed at $F_{T}=0.35$ the level of $F$ deemed most appropriate in the previous assessment (Moores et al. 1982). Natural mortality was assumed to be 0.20 for spring-spawners while two options of M (0.20 and 0.10 ) were utilized for autumn-spawners. The results of these runs in terms of population $(2+)$ biomass and $F_{5+}$ are summarized in Fig. 4 and Table 8 , respectively.

As can be seen in Fig. 4 the new matrix produces higher biomass estimates in all cases than the old matrix. There is however no major deviation from the trends of biomass generated by the old matrix.

Table 8 shows the $F_{5+}$ generated for each option. The most significant differences appear in the period 1971-74 when mortalities essentially double using the revised matrix. This would be expected from the additional catch in this period.

The relationships of $F$ and effort and biomass and CPUE were also examined. The correlation coefficients are given in Tables 9 and 10 and illustrative plots are shown in Fig. 5 and 6.

In the comparison of $F$ and effort the most significant difference occurs for spring-spawners with the $R^{2}$ value improving from .001 to .570 when using the old and revised catch matrices. In Fig. 5, it can be seen that the relationship still shows a separation between the $1971-73$ period and the previous points in spite of the improved relationship. For autumns alone there is no real difference between the results produced using either of the matrices. The combined runs show a higher correlation for the revised matrix as would be expected from the higher correlation of spring-spawners under this option. The relationships are also marginally better for the options utilizing an $M$ of 0.20 for both spawning components.

The relationship of biomass and CPUE is shown in Fig. 6 and Table 10. No major differences were produced using the two matrices. However, the level of biomass (ie. $2+$ or $5+$ ) utilized in the analysis produces conflicting results as to which option of $M$ is most appropriate: $2+$ biomass indicates an $M$ of 0.10 for autumn-spawners is best while $5+$ biomass indicates an M of 0.20 is more appropriate. This conundrum may be resolved if exploitable biomass is used.

## Conclusions

This proposed revision to the west coast catch matrix reflects a more detailed analysis of the available data than was previously undertaken. As such it appears to be a more realistic interpretation of the St. George's Bay fishery than was shown by the previous catch matrix. In spite of substantial changes in the catch level the revised matrix has relatively little impact on
the output of cohort analysis. The proposed changes also are insufficient to resolve the inconsistencies previously mentioned. The problem may lie in the actual sampling data available for the early 1970's. As has been previously stated the sample size and spatial and temporal distribution of these samples may introduce biases into the catch matrix which are impossible to quantify. Also the comparisons which have been reported assume that $F$ is the same for both spawning components. Such an assumption is probably unjustified, especially in recent years when the spring fisheries have formed the bulk of the catch and are directed toward spring-spawners. The use of different levels of $F_{T}$ for each spawning component appropriately fine-tuned would have an impact on the interpretation of the total stock situation.

## Acknowledgements

I would like to thank the members of the Pelagic Section, St. John's who were involved in the collection and preparation of much of the data presented here, particularly Mr. R. Chaulk who explained the background to much of the historical data base.
