## Introduction

The fishery for the Gulf of St. Lawrence (4T) American plaice (Hippoglossoides platessoides F.) increased substantially in the early 1950's with the advent of otter trawling which increased the effort through the 1960's declining slightly thereafter. Simultaneously, the fishing effort by Danish seiners has increased steadily from the late 1950's through the present. The total landings have fluctuated around the present (1977) quota of $10,000 \mathrm{MT}$ over the same period (Fig. 1). The present work represents the first comprehensive assessment of the stock since the initial study by Powles (1964,1965, 1969). A major concern of this earlier study and others (Powles 1969, Jean 1963) was the discarding of small plaice taken as bycatches in the preferred cod fishery. The magnitude of this wastage ( $25-50 \%$ by weight) was felt to be a cause for concern relative to longterm yield to the fishery. The present work incorporates information collected on contract by MacLaren Atlantic Ltd. (MS 1976) on discarding into a model of the stock dynamics. The effects of various rates of exploitation on the dynamics of the plaice stock were then simulated to determine the optimal management strategy for maximum longterm stability and yield to the fishery.

## Material and Methods

The basic information on the population size and structure came from commercial sampling for age and length frequencies that were applied to total commercial landings to derive information on the catches at age. If no age information was available in a particular year the data from an adjacent year was applied to the landings. The data on length at age was used to describe the von Bertanlanffy growth curve for this species emphasizing the sexual dimorphism of the species exemplified by disparate longevity and growth (Fig. 2). The aforementioned discarding of small plaice was estimated from numbers landed and discarded at various lengths (Fig. 3). The lengths from Fig. 2 were used to estimate percent by number discarded at age (Table 1).

Fisheries Systems and Data Processing Group Contribution No. 22.

No plaice younger then age 5 are landed but the numbers of 3 and 4 year olds caught was estimable frem their selection relative to 5 year old fish.

TABLE 1. Percent of male and female plaice discarded at each age by the fishery.

| Age | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| Male | 100 | 100 | 97 | 91 | 81 | 67 | 31 | 17 | 9 | 4 | 1 | 0 | 0 |
| Female 100 | 100 | 95 | 86 | 69 | 27 | 9 | 2 | 0 | 0 | 0 | 0 | 0 |  |

The number of fish discarded at each age (Table 2) was then combined with the landings at age to provide an estimate of the total catch at age for both sexes for each year from 1964-1977 (Tables 3,4) The total effort expended in this fishery was estimated by determining the total number of trips made by the 25-50 ton Danish seiners and their total catch and using their catch-per-unit-effort as an index of total effort to apply to the total catch of plaice in the Gulf of St. Lawrence (4T) and thereby to estimate the total effective effort for each year. This was necessary because flatfish are frequently not separated in landings or are bycatches of the trawler fisheries for cod. Seiners generally concentrated on plaice and land little of other species thus providing a relatively unbiased estimate of effort (Table 5).-Total landings are the actual revised estimates from ICNAF Statistical Bulletin (Vol. 23; 1973); up to 1971 thereafter being estimated, as the sum of known plaice landings and the estimated proportion of plaice in the unspecified flounder landings. Results from 1964-71 indicate this to be a good estimate of total known plaice landings.
No reasonable estimates of natural mortality were obtained so the earlier estimates of. 13 for females and. 17 for males (Powles 1969) were used in this study. The method of sequential population analysis or cohort analysis (Pope 1972) was used to determine numbers at age (Tables 6, 7). The resulting estimates of fishing mortality (F) (Table 8,9 ) at age were weighted by numbers and regressed against an estimate of effective total effort (Fig. 4) to determine the terminal F for 1977 where fishing was not complete on all cohorts. The ordinary rather then geometric regression was assumed correct. The biomass caught per tow in the research cruises was also regressed against the biomass estimates from the cohort analysis (Fig. 5) to estimate the terminal fishing mortality. It should be noted that even a terminal F of zero in 1977 would not make this relationship linear through the origin suggesting that there may be an effect of the different selection patterns in the research and commercial data. The strength of recruiting year-classes was also correlated with the catch-per-tow of 3 year olds (Fig. 6) from the annual fall research cruises in the Gulf of St. Lawrence.

Sampling during 1968-1970 did not cover the entire Gulf as did the subsequent cruises so the catches in these years were corrected on the basis of the relative catches at the same stations.
An attempt was made to estimate recruitment to the plaice stock from egg and larval information collected on the annual ichthyoplankton cruises in the southern Gulf of St. Lawrence since 1965. The methodology is described in detail by Lett et al. (1975). The only two gear types considered were the one meter nets and 6 ft Isaacs-Kidd trawl. The geometric mean number of egg and larvae for each cruise was assumed to be an index of abundance. Egg abundance was estimated from the 1 meter net on the spring cruise. Only cruises after July 1 were considered to estimate larval abundance catches as eggs were felt to be incompletely hatched prior to this date (Powles 1964). Catches from the two gears were averaged to obtain an index of larval abundance for the various cruises (Table 10). The production of eggs was previously shown to be related to the growth rate of the mature segment of the population (Lett 1977). Maturity ogives are available from research cruises for 1969-1976. As no trends were apparent a combined ogive (Fig. 7.) was used to determine the weighted mature female growth rate (㱏).

$$
\begin{equation*}
\hat{W}=\frac{\sum\left(W i-W_{i-1}\right) \times N_{i} \times M_{i}}{\sum N_{i} \times M_{i}} \tag{I}
\end{equation*}
$$

Where $W$ is the mean weight at age, $N_{i}$ the numbers at age from cohort analysis and the $M_{i}$ the maturity at age.

This growth rate was related to the egg production per mature female (Fig. 8) by the function:

$$
\frac{\mathrm{E}}{\mathrm{~N}}=93.11 \hat{\mathrm{~W}} 2.935
$$

Where $E$ is the egg catch from the spring research vessel cruise, $N$ the number of mature females and $\hat{W}$ the weighted female growth rate.

The regression was significant at the $5 \%$ level with $F=10.58$ ( $F$ 1,7/5.59). This relationship was used to predict the number o eggs caught on a cruise and this was related to the larvae catches from Table 7. numerous models have been proposed to describe larval mortality (Cushing 1975, Ware 1975) but no concensus is evident. The proportion of larvae (Larv) surviving from the initial number of eggs (Eg) was regressed against elapsed time ( $T$ ) in days and an interaction term to describe the effects of temperature ( $t p=$ mean June-July) on egg survival:

$$
\operatorname{Larv}=4635 \text { eggs } e^{-.0955186 T-.882115 t p}+.000269 t \times t p^{2}
$$

The relationship is significant at the $5 \%$ level $F=4.91$ ( $\mathrm{F}_{3.12 / 3.49 \text { ) }) ~(3)}$ accounting for $55.09 \%$ of the variation in larval numbers.

The number of larvae was estimated on August 1 ( $t=90$ ) and related to the number of recruiting 3 year olds with a Ricker-type recruitment function incorporating the mean summer (May-October) temperature for the years from the larval to recruiting stage:

$$
N_{3}=11499568 \text { Larv }-.32695 \mathrm{~L} \cdot \mathrm{arv}-.36296 \text { Temp. }
$$

Where $\mathrm{N}_{3}$ is the number of three year old recruits, Larv is the number of larvae, and temp is the mean temperature at Entry Is. from May to October inclusive for the three years preceding and including year i, the relationship accounts for $91.14 \%$ of the variation in the number of recruits with $F=36.02\left(F_{2}, 7 / 4.74\right)$ although the fitting procedure is autocorrelated so the goodness of fit is somewhat exaggerated.

The general information on the various biological parameters of the plaice stock cited above and their effect on the dynamics of the population are incorporated into a stochastic computer simulation.

Simulation of Stock Dynamics
A system simulation written in A Programming Language (APL) was constructed to describe the dynamics of the Gulf of St. Lawrence plaice stocks and determine the potential long-term yields under various exploitation regimes. The simulation is initialized by entering the number of 3-21 year old males and females estimated by cohort analysis. Various instantaneous fishing mortality rates ( $F$ ) may be applied to the stock. The value entered is applied to the female subpopulation since they represent the greatest proportion of the landings while the $F$ applicable to the male subpopulation is calculated from the geometric regression of male and female fishing mortality:

$$
\begin{equation*}
\mathrm{F}_{\mathrm{m}}=-.003579+1.83297 \mathrm{~F}_{\mathrm{f}^{\prime}} \mathrm{r}=.893 \tag{5}
\end{equation*}
$$

where $F_{m}$ is the male fishing mortality and $F_{f}$ the female mortality. The relationship is significant at the $1 \%$ level, ${ }_{F}=31.45$ ( $\mathrm{F}_{1}, 8 / 532$ ). The catch in numbers by the fishery may then be calculated using the catch equation from Beverton and Holt (1957) and the respective male and female natural mortalities (M):

$$
\begin{equation*}
C_{a}=\frac{N_{a} \cdot \partial_{a} F}{\partial_{a} F+M}\left[1-e^{\left(-\partial_{a} F+M\right)}\right] \tag{6}
\end{equation*}
$$

where $C$ is the catch at age in numbers, $F$ and $M$ the fishing and natural mortality rates, and $\partial_{a}$ the selection factor at age.

The numbers discarded at age were then determined by applying the proportion discarded at age (Table l) to the catches. It should be noted that discards averaged 48 percent by number and 26 percent by weight for the period 1964-1977 with no obvious trends relative to the various catch levels. This is somewhat less then estimates by Powles (1969) and Jean (1963) but very comparable to estimates from the computer simulation for yellowtail (Sissenwine 1977) using a linear discard model and estimating discarding at 39.5 percent by number and 26.3 percent by weight. The discards at age are then subtracted from the catch at age to determine landings at age in numbers. The weight landed was obtained as the product of the numbers landed at age and weight at age from commercial samples.

The growth of the population is interpolated from a curve of average weight increments at age since no viable relationship to predict growth could be defined. Instead, the weight next year ( $W_{t+1}$ ) for males and females is calculated from:

$$
\begin{equation*}
W_{t+1}=W_{t}\left(1+\frac{\Delta W}{W_{t}}\right) \tag{7}
\end{equation*}
$$

where $\frac{\Delta W}{W}$ is interpolated from an empirical curve of $\Delta W / W_{t}$ versus $W_{t}$ based ${ }_{t}$ on weights from research cruises. The change in weight may then be calculated as:

$$
\begin{equation*}
\Delta W=W_{t+1}-W_{t} \tag{8}
\end{equation*}
$$

The weight of the individuals in the initial or age 3 group was obtained by calculating a length stochastically. The length at age three was assumed to be normally distributed and determined by the mean plus a random normal deviate times the standard deviation of the length. This length $\left(L_{3}\right)$ is converted to weight $\left(W_{3}\right)$ at age three by:

$$
\begin{equation*}
\mathrm{W}_{3}=.00445 \mathrm{~L}_{3} 3.22137 \tag{9}
\end{equation*}
$$

and added to the front of the vector describing weight at age in year $t+1$.
The weighted growth rate may then be determined from the $\Delta W$ in equations (8) and (1). The numbers at age in year $t+1$ are obtained from the numbers at age in year $t$ and the total mortality rate:

$$
\begin{equation*}
N_{t+l}=N_{t} e^{-\left(\partial_{a} F+M\right)} \tag{10}
\end{equation*}
$$

The index of the number of eggs produced per mature female is then predicted from (2) and larvae caught on August 1 from (3). The number of age 3 recruits is calculated from (4). The two temperature variables in the simulation were assumed normally distributed and were therefore determined for each year as the sum of the mean and the standard deviation times a random normal deviate. Recruits were subdivided into male and female assuming 39.54 percent of the former and added to the front of the vector of numbers at $t+l$ calculated by (l0). The number of males and females were truncated at ages 17 and 21 , respectively. The population biomass was then calculated as the sum of the products of numbers at age and weights at age from research cruise samples.

Results of the Simulation
The simulation was run ahead for 50 years at a variety of levels of fishing mortality at which time an equilibrium or stable situation was assumed. The mean catch and biomass were determined for the last 20 years of each run and used to describe a Graham-Schaeffer plot of average yield and biomass (Fig 9). The maximum sustainable yield is approximately 17000 tons at a $3+$ biomass of about $1.35 \times 10^{5} \mathrm{mt}$ slightly below the present level of $1.48 \times 10^{5} \mathrm{mt}$. Variances in the catch are small which is the rule in the historical landings by the fishery (Fig. 1) where effort has varied considerably (Table 5). The optimal fishing mortality level needed to reach MSY is $F=.27$ which is comparable to the $F_{0,1}$ levels from the yield per recruit formulation (Fig. 10) of Beverton and Holt (1957) who applied it to North Sea plaice and found it useful because of the small variation in recruitment in that stock. However, the yield per recruit estimate is considerably above the $2 / 3 \mathrm{~F}_{\mathrm{msy}}=.18$ necessary to obtain the optimal biomass estimated by simulation. The management objective of $2 / 3 \mathrm{~F}_{\mathrm{msy}}$ biomass equal to $175,000 \mathrm{mt}$ was evaluated by doing a number of catch projections for different quota levels based on our knowledge of recruitment to the stock. A stochastic element was added to the discard component of the quota based on the mean estimated weight discarded, its standard deviation and a random normal deviate to account for variations in the degree of discarding from year to year. The optimal biomass will be attained under a range of quotas from the present $10,000 \mathrm{mt}$ to $15,000 \mathrm{mt}$ although of course the latter will require I $1 / 2$ years longer then the former (Fig. lo). It is therefore recommended that the quota be retained at $10,000 \mathrm{mt}$ to allow the continued rebuilding of the stocks to obtain an optimal level of biomass.
