```
\({ }^{1}\) This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.
```

Research Documents are produced in the official language in whion they are provided to the Secretariat by the author(s).
${ }^{1}$ Cette série documente les bases scientifiques des consells de gestion des pêches sur la cote atlantique du Canada. Comme telle elle couvre les problèmes actuels selon les echéanciers voulus et les Documents de recherche qu'elle contient ne dolvent pas être considérés comme des enoncés finals sur les sujets traités mais plutót comme des rapports d'étape sur les etudes en cours.

Les Documents de recherche sont publlés dans la langue officielle utilisée par les auteur (s) dans le manuscript envoyé au secrétariat.

The 1984 fishery reflected another year of depletion of a resource which has not experienced good recruitment since the 1977 year class. The Canadian catch was $1,945 t$, which is the lowest catch for the Canadian fleet since 1959. This was taken from a biomass that is estimated to be the lowest since research surveys were initiated. Yield per recruit and stock projections show that the stock is seriously overfished. The effects of the currently used catch restriction of an average of 35 meats/pound and proposed alternatives of 45 and $30 /$ pound are compared to assess their conservation impact. None of these management measures is adequate by itself to significantly aid stock reconstruction.

## RÉSUMÉ

La pêcherie de 1984 reflète une autre année de diminution d'une ressource qui n'a pas été l'object d'un bon recrutement depuis 1977. Les prises Canadiennes sont de l'ordre de $1,945 t$, valeur la plus basse pour la flottille Canadienne depuis 1959. Ces prises ont origine d'une biomasse qu'on estime être la plus basse depuis qu'on a commencé à faire des inventaires de stocks. Le rendement par recrue et des projections de stock établissent que le stock est sérieusement surexploité. On compare l'effet du compte de chairs (35) en vigueur et des alternatives proposées de 45 et 30 compte par livre afin d'évaluer l'impact sur la conservation. Aucune de ces mesures de gestion n'est adéquate par elle-même pour contribuer, d'une façon significative, à la reconstruction du stock.

## INTRODUCTION

Two strong year classes, those of 1957 and 1972, produced major peaks in landings in the last 30 years of the Georges Bank scallop fishery (Fig. 1 and Table 1). The more recent peak occurred in 1977 to 1978 with landings of over $17,000 \mathrm{t}$. Landings fell to about $10,000 \mathrm{t}$ in 1980 but increased by almost 6,000 t to $16,000 \mathrm{t}$ in 1981 as a result of increased Canadian and U.S. fishing effort and a relaxation of the enforcement of the meat count regulation on the Canadian fleet. In 1981, the Georges Bank scallop fishery relied on age 4 scallops for $60 \%$ of its catch, older scallops having become scarcer through the year. In 1982, the fishery relied mainly on the 1977 year class, and landings by the Canadian fleet decreased by $50 \%$ in comparison to 1981. U.S. catch levels have shown an upward trend since the early 1970's to over $8,000 \mathrm{t}$ in 1981, representing an increase of $400 \%$ from 1976 to 1981 and a parallel increase in effort. Effort in 1984 was slightly lower than 1983, and the Canadian catch fell to $1,945 \mathrm{t}$, its lowest level since 1959.

For this document, the standard assessment techniques (research survey abundance, yield per recruit analysis, cohort analysis, and stock projections) are applied to the Georges Bank scallops. It is shown that the stock is depleted and that the currently discussed management options are inadequate for stock reconstruction.

## METHODS

Catch and effort data are compiled from logbooks. Those logs with complete effort data are called Class 1 and are used to determine catch rates (see Table 2). Also, data on size distribution of meats from the commercial fleet are derived from port samples. Canadian port sampling data were applied to the Canadian and U.S. total catch east of the ICJ line. This assumes similar fishing practices for both fleets. The annual changes in fishing practice can be seen in Table 3 which contains weight distribution in 2 g intervals for the last 6 years. Month-by-month port sampling data are given in Table 4.

Catch in numbers at age (Table 5) for the cohort analysis are derived from these port sampling data and the sum of U.S. and Canadian catches in the new Canadian zone. For more details on the method used to derive catch at age see Roddick and Mohn 1985. The total catch (U.S. and Canadian) from the Canadian zone is decomposed into weight frequencies. The weights were converted to shell heights using the allometric relationship derived from 1982 research cruise data. The values expressing meat weight as a function of shell height use the parameters $1.027 \mathrm{E}-5$ for the constant and 3.090 for the exponent of height. The values agree closely with those of Serchuck et al. (1982) for the same stock. Von Bertalanffy growth coefficients relating shell height and age were taken from Brown et al. (1972) having the values of $145.5,1.5$, and 0.38 respectively for $L^{\infty}, T_{0}$, and $k$.

Traditionally, catch statistics are compiled on an annual basis and recruitment to a fishery is discussed in terms of year class strengths. It is generally accepted that Georges Bank scallops are born in October and the first annual ring is laid down the following March. This ring is typically less than 10 mm and becomes difficult to discern as the animal grows. For
this reason the ring, which is approximately 25 mm from the umbo, is often referred to as the first annulus (see, for example, Naidu 1970). The convention which we shall adopt is that animals born in the fall of a year will be of that year class and it will be further assumed that they were born on January 1 of that year. The deposition of the ring less than 10 mm will mark the first birthday and the approximately 25 mm annulus will mark the second birthday. The date of the deposition will be assumed to take place on April 1. A back calculation is then made to estimate the shell height for January 1. The annual growth rates for weights given below are converted into rates for heights and this results in a $16 \%$ reduction of the ring size being used for the January 1 size. For example, an animal born in the fall of 1978 is of the 1978 year class and will be approximately 25 mm on its second birthday (January 1, 1980) although the ring would not occur for a few months. Table 5, as well as all other age data, uses this convention, with correction of ring sizes back to January 1.

The values for the columns of meat and ovary weights as a function of size, given in Table 6, are derived from data published in Serchuck et al. (1982). An allometric equation was fitted from the log of shell height and ovary weight giving $3.875 \mathrm{E}-7$ for the constant and 3.617 for the exponent. This value is used as an index of reproductive potential. It is not known what the relationship is between pre-spawning ovary weight and viable gamete production; therefore, this simple index is presented. It is realized that there are many factors which would influence subsequent recruitment even if gamete production could be estimated.

As was done last year (Mohn et al. 1984), the standard cohort analysis was augmented by the separable VPA of Pope and Shepherd (1982). The results are presented in Tables $7 a$ and $b$.

A research survey was carried out on Georges Bank during August 1984. The design of the survey was based on a stratification by commercial effort. The logbooks of the commercial fleet in the preceeding 9 months were analyzed to determine areas of high and low fishing intensity. The areas of high intensity were sampled more heavily as they represent the area most important to the fleet (and presumably the areas of greatest abundance). The estimate of abundance was formed by contouring the catch rates at age of the survey tows and expanding the mean by the area enclosed by a given contour (Robert et al. 1982).

A Thompson-Bell yield per recruit analysis was not carried out again this year as the same growth and selectivity are appropriate as for last year. The values of 0.56 for $F_{0.1}$ and 0.89 for $F_{\max }$ would still be applicable.

The regulations operant on the offshore fleet are that the average weight of samples taken from the catch cannot be less than 13 g , which corresponds to 35 meats/pound. Placing a limitation on the average instead of stipulating a minimum means that the fishermen may take small animals and then balance them with larger ones. Such a practice, called blending, renders the use of most yield models inappropriate. If there are not enough larger animals to blend in, then the mortality on the small ones will have to be reduced. Thus, the partial recruitment is a function of abundance at age. In order to take this practice into account, a stock projection program was written in which the mortality on the animals beneath the stipulated average is adjusted until the mean weight of the catch is within $1 \%$ of the required
average. The only other way in which this program differs from the normal stock projection is that the variables are updated quarterly because of the very rapid growth of young scallops. The annual growth is divided into quarterly components of $10,35,35$ and $20 \%$. The annual effort is also partitioned into quarters at the rates of $15,40,30$ and $15 \%$. Selectivity for the projections follows the pattern of the fishery as revealed from the cohort analysis instead of that of the gear (Caddy 1972).

## RESULTS

The catch-at-age matrix (Table 5) does not extend back beyond 1972 because of the lack of reliable data. There are very few animals caught above the age of 9. Therefore, the catch at age is truncated at this age which is not a plus group. The results of the cohort analysis are given in Table 7 and show that the stock was in a very depressed state in 1984. The last apparent good recruitment was the 1977 year class; and subsequent recruitment, as defined by the 3 year olds (see Table 7), has been very poor. The fishing mortality has been highest on the 5 year olds in recent years, and the high mortality of 4 year olds in 1981 reflects the relaxation of regulations in the fishery for that year. Again one notes the difference between the selectivity of the gear (Caddy 1972) and fishing mortality as a function of age as determined by the cohort analysis. The difference in patterns is a result of the behaviour of the fishermen who direct their effort against the younger animals because they occur in higher densities. In tuning the VPA, F was regressed against effort as defined in terms of hours and crew-hours-meters (crhm) as.given in Table 2. The $F$ was unweighted and the fit was poor ( $r<0.57$ ) for both indices. The estimated biomass was also used in tuning against the CPUE. The regression coefficient between biomass of ages 4 to 9 and CPUE as defined by hours fished was 0.90 and 0.86 for crhm. The last point fell just beneath the regression line and the penultimate fell just above it (see Fig. 2). A range of starting $\mathrm{F}^{\prime} \mathrm{s}$ was tried; but the regression coefficients were'virtually unaffected, falling with decreasing F ; and further reduction would have taken the last point further from the regression line. Also the effort decreased from 1983 to 1984 but the weighted $F$ did not. Taking these observations into account led us to adopt the value of 0.8 for the fully recruited $F$ which is slightly lower than last year's estimate. The numbers at age estimated from the research survey (Tables 8 and 9) for $3+$ drop approximately $4 \%$ while the cohort $3^{+}$numbers fall about 20\%. Lower starting F's would increase this discrepancy. The $4+$ biomass (Table 10) from the cohort analysis and the recruitment from that stock are plotted in Figure 3 to display what appears to be a compensatory stock-recruit relationship.

The research survey data (Table 9) show the depletion of the stock which has taken place in recent years. The survey results are not considered to be reliable for age 2 animals because of their low partial recruitment to the research gear and should not be considered as always an accurate predictor of the following year's recruitment. Nonetheless, the five-fold increase in 2 year olds estimated from 1983 to 1984 is an unmistakable sign of a significant improvement in recruitment which will be better estimated this fall. The biomass estimates from the research data are not corrected for efficiency of the gear. The $3+$ biomass from the research surveys and the cohort analysis follow:
$3+$ biomass estimates ( $10^{6} \mathrm{t}$ ).

|  | 1978 | 1979 | 1980 | 1981 | 1982 | 1983 | 1984 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
|  |  |  |  |  |  |  |  |
|  |  |  |  |  |  |  |  |
| Research | 14.2 | 5.7 | 1.4 | 3.8 | 2.6 | 1.6 | 1.2 |
| Cohort | 41.0 | 35.6 | 33.7 | 33.9 | 24.2 | 17.7 | 12.2 |

The simulations for the three meat count levels are given in Table 11. The program is the same as last year. Table 11a contains the results for the 45 meat count ( 45 MC ). As is seen in the first row of this table the fishing intensity on small animals is not restricted compared to even the 1981 mortality which was. used as a basis pattern for this run. As would be expected, by mid 1986 the standing stock biomass is much smaller than for the other runs. These are not meant to predict actual catches but are only used as relative indices to compare the three meat counts. One sees a slight disruption in pressure on small animals with a 35 MC and severe restriction (up to $18 \%$ of full rate) for 30 MC . If proper discounting rates and market values as a function of meat size were known a net present value calculation would be useful in comparing strategies. Figure 4 shows the meat size distribution for 45 MC and 30 MC .

Last year's yield per recruit analysis had an $F_{0}$ at 0.56 and $F_{\max }$ at 0.89 (Mohn et al. 1984). The fully recruited $F$ leveis are just below the $F_{\text {max }}$ value, and in the face of poor recruitments the biomass has not been able to support this intensity of fishing. These target $F$ levels are based on the selectivity from the cohort analysis. It was argued last year that such selectivities are more appropriate than those based on the gear. Also one should recall that significant improvements in yield per recruit are obtained iff the fishing pressure is applied to older animals than is now the practice. Last year the relative amounts of ovary pre-spawning biomass in a stable age distribution at various fishing levels were incorrectly estimated. The revised values are less sensitive to F and are:

| $F$ | 0 | 0.1 | 0.2 | 0.3 | 0.4 | 0.5 | 0.6 | 0.7 | 0.8 | 0.9 | 1.0 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $B(\%)$ | 100 | 79 | 64 | 51 | 42 | 35 | 30 | 25 | 22 | 19 | 17 |

## CONCLUSIONS

All indices show that the 5Ze stock is at or near an all-time low level. Fishing mortality on young animals approaches unity and has been at this level for years, resulting in a depleted stock. All relevant indices show that fishing mortality is at too intense a level for this stock. This is
compounded by the failure of a strong year class to appear in the last few years. However, the abundance of 2 yr olds in the 1984 research survey predicts a strong recruitment to the fishery in the fall of 1985 . The value that this recruitment gives to the fishery will depend on whether this year class is fished while still young or allowed to grow. The fishing mortalities on young animals in 1981 should not be repeated. Because of the depletion of the standing stock, the data available suggest that 1985 will be bleak until the recruitment is felt. The actual time of recruitment will depend on growth rates and the legal size limit.
