East Coast Newfoundland Herring
1984 Assessment

Abstract

Analysis of data collected during 1984 is presented for the three east coast Newfoundland stock complexes: 1) White Bay-Notre Dame Bay, 2) Bonavista Bay-Trinity Bay, and 3) Conception Bay-Southern Shore. Landings in 1984 were approximately 1250 t and came from a bait fishery and a limited gillnet fishery late in the year (November). Samples from these fisheries showed the increasing dominance of the 1979 yearclass. Samples from the research gillnet program showed similar trends plus the relative strength of the 1982 yearclass as two-year-olds. The acoustic purse seine survey showed significant concentrations of the 1982 yearclass in all areas. Catch rates from the research gillnet program showed a slight decline from 1983 to 1984. A normalized gillnet catch rate series, developed from commercial and research gillnet data, showed large catch rates in the late 1970's, bottoming out in 1981 and increasing in the 1980's. It was impossible to obtain a best estimate of F_t from total mortality coefficients (Z); however, total mortality rates derived from catch curves suggested a very low F_t. A method was developed to determine stock biomass from the acoustic survey. These biomass estimates and subsequent population vectors were projected to 1986 assuming a fixed catch in 1985. Trends in biomass, fishing mortality and recruitment were examined and management considerations are provided for 1986.

Résumé

L'analyse des données recueillies en 1984 est présentée pour les trois complexes de stocks de la côte est de Terre-Neuve : 1) baies Blanche et Notre-Dame, 2) baies Bonavista-de la Trinité, et 3) baie de la Conception, côte sud. Les débarquements de 1984, d'environ 1 250 t, provenaient de la pêche à la boëtte et, dans une moindre proportion, de la pêche au filet maillant en fin d'année (novembre). Une analyse d'échantillons a montré que la classe d'âge de 1979 domine de plus en plus. Des échantillons du programme de recherche sur la pêche au filet maillant ont révélé des tendances semblables ainsi que la force relative de la classe d'âge de 1982, composée de poissons de deux ans. Le relevé acoustique à la senne coulissante a indiqué d'importantes concentrations de la classe d'âge de 1982 partout. Les taux de capture déterminés dans le programme de recherche sur la pêche au filet maillant ont chuté légèrement de 1983 à 1984. Une série normalisée de taux de capture au filet maillant, établie à partir de données commerciales et de données de recherche sur la pêche au filet maillant, a révélé de forts taux de capture vers la fin des années 70, avec un minimum en 1981 et une reprise dans les années 80. Il a été impossible d'obtenir une meilleure estimation de F_t à partir des coefficients (Z) de mortalité totale; toutefois, les taux de mortalité totale dérivés des courbes des prises indiquent un F_t très faible. Une méthode a été mise au point pour déterminer la biomasse du stock à partir des relevés acoustiques. Ces estimations de la biomasse et les vecteurs subséquents de population ont été projetés jusqu'en 1986 en supposant un nombre fixe de prises en 1985. Les tendances de la biomasse, de la mortalité par pêche et du recrutement ont été examinés et l'on en tient compte pour planifier la gestion des stocks de 1986.

Introduction

1) Description of the Fishery:

During the 1970's there was rapid development of the herring fishery along the east coast of Newfoundland. From 1970-73, landings averaged 3500 t annually, mostly from fixed gear as was the case traditionally. By 1976, landings had increased to 25,000 t due to the recruitment of the very large 1968 yearclass and the involvement of a fleet of large purse seiners and small (< 65 ft) ringnet vessels. The mobile purse seiners were excluded from the fishery in 1977, the same year the ringnet fleet was first placed under quota control. All gears were placed under TAC's in 1980; however, in the interim, gillnet landings increased rapidly from 15% of total landings in 1976 to 50% in 1979. TAC's were substantially reduced in the early 1980's due primarily, to poor recruitment during the 1970's. The ringnet fishery was closed in 1982, likewise the entire fishery in 1983 with the exception of a limited fixed gear bait fishery and by-catches in the capelin and mackerel fishery. Despite advice that the fishery remain closed, a TAC of 2000 t was set in the fall of 1984. However, only approximately 50% of this amount was caught (Tables 1-3). It appeared that this may have been due to the late opening date (November) and poor market conditions.

2) Nominal Catches:

TAC's and landings ($x10^3$ t) are listed below for 1977-84.

	1977	1978	1979	1980	1981	1982	1983	1984
TAC	22.0	17.4	20.8	9.8	7.0	2.0	0.0	2.0
Catch	25.7	23.4	26.4	12.4	9.0	2.6	0.5	1.3*

*Preliminary

Input Data

1) Stock Delineation:

As was the case last year (Wheeler et al. 1984) east coast Newfoundland herring were considered as three stock complexes (Fig. 1): 1) White Bay-Notre Dame Bay (3Ka, 3Kd. 3Kh and 3Ki), 2) Bonavista Bay-Trinity Bay (3La and 3Lb), and 3) Conception Bay-Southern Shore 3Lf and 3Lj). These areas were defined after examination of tag returns of experiments conducted along the east coast from 1975-81 (Wheeler and Winters 1984a). However, due to the homing tendencies of the fish (Wheeler and Winters 1984b), the provision of scientific advice depends upon the nature of the fishery.

2) Biological Sampling:

The number of fish sampled, both commercial and research, dropped slightly from 1983 to 1984 (Table 4). This was due to the introduction of a program designed to reduce duplicate sampling of the commercial fishery. This program should lead to more efficient sampling again in 1985. Similar to 1983, research samples outnumbered commercial ones by 3:1 due primarily to the research gillnet program and acoustic purse seine survey. However, even excluding research samples, there were in excess of 200 herring sampled per 100 t of commercial catch.

Commercial catch-at-age data (Tables 5-7) for 1984 were generated by applying age compositions from the appropriate commercial samples to landings. However, similar to 1983, in certain cases, research samples collected from commercial mesh size (2 1/2" and 2 3/4") gillnets were used to generate catch-at-age data where no commercial samples were available.

3) Acoustic Purse Seine Surveys:

For the third consecutive year two commercial purse seine (< 65 ft) vessels were chartered for four weeks in October-November 1984. The survey commenced in Notre Dame Bay and proceeded southward through Bonavista and Trinity bays (Fig. 2-7); 1545 kilometers were effectively surveyed during 362.5 hours - 1957 schools of fish were identified and measured (length and depth) during this period (Table 8). Similar parameters have been calculated for the 1983 survey (1982 calculations have not yet been completed).

There were 47 successful sets during the 1984 survey; herring were caught in 39 of these, mackerel in 8 (Appendix 1). Juvenile herring predominated the sets in which herring were caught; 1982 yearclass in 32 sets, 1983 yearclass in 12 sets and 1984 yearclass in one set. Mature herring (age 5+) were caught in seven sets. As was the case in the preceding two years, the 1982 yearclass appeared in significant concentrations in all areas surveyed.

4) 1984 Age Compositions:

Age compositions of herring from the acoustic purse seine survey samples, 1982-84, show this dominance of the 1982 yearclass (Fig. 8). For 1983 and 1984, both unweighted (samples only) and weighted age compositions are given. Weighted percentages were derived by applying age compositions of samples from subareas to abundance estimates (m^2 of schools observed within the subareas) and then combining subareas within each stock area. Spring and autumn spawners have been combined in Figure 8; however, it appears that these juvenile fish (1982 and 1983 yearclasses) are predominantly spring spawners as, in all areas, greater than 90% of the fish sampled were spring spawners.

For the first time since the 1970's, age 11+ fish did not dominate the commercial fishery (Fig. 9). In all areas, the 1979 yearclass continued to show increasing dominance, representing 35% of the catch in White Bay-Notre Dame Bay, 50% in Bonavista Bay-Trinity Bay, and 65% in Conception Bay-Southern Shore. Once again, there was a slight increase in the percent of autumn spawners in the catch, and similar to that of the 1979 yearclass, percentages increased from north to south - 17% in White Bay-Notre Dame Bay, 23% in Bonavista Bay-Trinity Bay, and 46% in Conception Bay-Southern Shore.

The age composition of samples from the research gillnet program (Fig. 10) showed similar trends to that of the commercial catch, with the 1979 yearclass dominating in most areas. Unlike the commercial fishery age compositions, this trend was also evident last year in the research gillnet age compositions, thus illustrating the importance of the research gillnet range in mesh sizes (2"-3") as a predictor of incoming recruitment. Similarly, this year, the 1982 yearclass showed relatively strongly as two-year-olds, representing 8%, 13%, and 18% of the fish sampled in White Bay-Notre Dame Bay, Bonavista Bay-Trinity Bay, and Conception Bay-Southern Shore, respectively. This represented the greatest percentage of two-year-olds caught over the five year time series.

5) 1984 Age Specific Weights:

Mean weights at age for 1984 (Table 9) for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay were derived from samples collected from January to June. Samples collected throughout the entire year were used to determine mean weights at age for Conception Bay-Southern Shore. Both commercial and research samples were used in these calculations.

6) Abundance Indices:

Four abundance indices have been calculated for both the 1983 and 1984 acoustic purse seine surveys (Table 10). For each of the indices, 1) number of schools observed per kilometer, 2) number of schools observed per hour, 3) square meters of schools observed per kilometer, and 4) square meters of schools observed per hour, there was an increase from 1983 to 1984. These may be explained both by increased abundance and increased availability, i.e. fish of the 1982 yearclass were larger than in 1983 and were thus more readily accessible in the area surveyed.

The research gillnet program provided catch rates for the fifth consecutive year. In 1984, 12 east coast fishermen (Tables 11-13 and Fig. 1) were contracted to fish a fleet of five gillnets, ranging in mesh size from 2" to 3", for a period of one month (October-December), to maintain an accurate daily log record of catches and to collect and freeze samples from their catch.

However, in some cases, due to a change in the depth of nets provided to certain fishermen in 1980-82, total catch (Tables 11-13) and hence catch rates had to be adjusted before comparisons could be made. The adjustment factor chosen, (Deep = 3.50 x Shallow), was based upon comparisons of catch rates of shallow (old) and deep (new) nets conducted in 1983 and 1984 (Table 14). Further comparisons will be made in 1985 to more accurately define this factor.

Two catch per unit effort indices were calculated from the research gillnets: 1) number of herring caught per fishing day (Tables 15-17) and 2) number of herring caught per days hauled (Tables 18-20). In White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay, catch rates declined slightly from 1983 to 1984 for both of the indices. In Conception Bay-Southern Shore, both indices increased greatly from 1983 to 1984. Over the five year time series, the same general trends existed in all areas, i.e. decreasing catch rates from 1980 to 1981 or 1982, increasing to 1983 and slightly decreasing in 1984.

This year, a normalized gillnet catch rate series was developed (Table 21) for White Bay-Notre Dame Bay (1977-84) and for Bonavista Bay-Trinity Bay (1979-84). It includes commercial gillnet catch rates (Wheeler and Winters 1983) from either 1977-82 (White Bay-Notre Dame Bay) or 1979-82 (Bonavista Bay-Trinity Bay) and research gillnet catch rates from 1980-84. It was impossible to include Conception Bay-Southern Shore as research gillnet catch rates exist for 1983 and 1984 only. The commercial gillnet catch rates were converted from "kg/net/landing" to "number caught/net/landing" and then normalized. The research gillnet catch rates were converted from "number caught/2 1/2" and 2 3/4" nets/day hauled" to "number caught/net/days hauled" then logged to reduce the large fluctuations caused by small sample sizes (in particular White Bay-Notre Dame Bay in 1979 and Bonavista Bay-Trinity Bay in 1982) and then normalized to make them directly comparable to the commercial series. Only the 2 1/2" and 2 3/4" research gillnets were considered as they represent standard commercial mesh sizes. In order to avoid bias in choosing a common year (1980, 1981, or 1982) in which to normalize each series, each was normalized to the mean catch rate of the common years (1980-82). Both areas exhibit similar trends when the two time series are combined. Each shows large catch rates in the late 1970's, bottoming out in 1981, increasing to 1983 and decreasing in 1984.

Estimation of Parameters

1) Partial Recruitment:

In determining partial recruitment rates (Table 22), an attempt was made to empirically assess the younger age groups, in particular the 1982 yearclass. The weighted age compositions, derived from the 1984 acoustic purse seine survey (Table 8 and Fig. 8) were considered to represent the population age structures. Commercial catches at age were compared with these population age structures and the ratios that were derived were normalized to give partial recruitment patterns. For both areas, White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay, full recruitment occurred at age 5 or 6. As expected, since the 1984 commercial fishery was entirely by gillnets, recruitment of the 1982 yearclass was very low (0.001). Also, recruitment was dome-shaped with age 11+ fish (primarily 1968 and 1969 yearclasses) being only partially recruited (0.35). This is in agreement with Olsen (1959) and was similar to the selectivity pattern used in last year's assessment.

2) Calculation of Total Mortality (Z):

Instantaneous total mortality estimates (Paloheimo 1961) were calculated for ages 3+ for each of the research gillnet catch rate series (Tables 23 and 24). Age 3+ was chosen after examination of the catch-at-age data from the research gillnet program (Appendix 2) as it appeared that full recruitment to the research gillnets occurred at age 3. Although it was impossible to discern any trend in Z values due to numerous negative values, it did appear that total mortality and hence fishing mortality was low in most areas over the past two years.

Trial runs of cohort analysis were conducted for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay to determine the best relationship between biomass (5+) and catch per unit effort (normalized gillnet series) (Table 21). However, it was impossible to accurately define terminal fishing mortality (F_t) because of the sensitivity of sequential population analysis to input F.

A similar exercise involved the calculation of catchability coefficients using three different F_t values for each of the two stock areas (Table 25). The catchability coefficients were calculated by dividing the normalized catch rate by the estimate of exploitable biomass (5+). The aim was to determine a F_t which would give a stable catchability coefficient over the time series. Once again it was impossible to accurately define F_t other than to suggest it was low for each stock area.

Total mortality rates were then estimated from catch curves derived for each stock area (Tables 26 and Fig. 11). Only commercial gillnet catches of 1969 yearclass fish and older and total gillnet effort were considered over the time series. Results showed a very low total mortality for White Bay-Notre Dame Bay (Z = 0.17) from 1977-84. For Bonavista Bay-Trinity Bay, Z = 0.27 from 1979-84. Since total mortality estimates were extremely low, it was impossible to accurately estimate fishing mortality for either area.

3) Calculation of Stock Biomass from Acoustic Surveys:

A relationship was calculated (Fig. 12) between the area (length x depth) of schools as measured from the depth sounder and weight per school (kg) as estimated by vessel master from purse seine sets during the 1984 acoustic survey. Only those sets in shallow water (< 30 m), where it was considered likely that the entire school was caught, were considered in determining this relationship. Stock biomasses were then determined (Table 27) from acoustic surveys conducted in 1983 and 1984. An estimate of m^2 of schools observed was determined from length and depth measurements of all schools recorded on the depth sounder during the survey. This was considered to be a conservative estimate as not all schools observed by sonar were recorded on the sounder. An estimate of average school dimensions (m^2) was derived from total m^2 and number of schools observed. An estimate of tons/school and hence total tons observed was derived from the estimates of average school dimensions and the relationship in Figure 12. The estimates of tons observed were then converted to densities based on the area surveyed as determined from the estimate of distance travelled (Table 8) and cruise track width (0.30 km). The cruise track width was estimated as the distance covered by a sweep of the sonar as set during the acoustic survey. Total biomass (t) within 0-90 m of the area surveyed was calculated by prorating the density estimates by areal expansion. Since a significant number of schools were observed outside the 90 m contour, the biomass estimates are considered to be conservative. Since White Bay was not surveyed, the biomass estimate for the White Bay-Notre Dame Bay stock complex was determined by prorating the Notre Dame Bay estimate using information on relative seasonal stock size from tagging studies (Wheeler and Winters 1984a). Biomass estimates for Bonavista Bay and Trinity Bay in 1984 were combined to give total biomass for that stock complex and the 1984 ratio between Bonavista Bay and Trinity Bay biomasses was used to prorate the 1983 biomass estimate which was for Bonavista Bay only.

Assessment Results

1. Population Numbers at age:

Total population numbers were obtained for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay from biomass estimates calculated from acoustic surveys as described above and from the mean weights of fish sampled during the surveys (Table 28). Population numbers at age were obtained by applying the weighted age composition of the population derived the acoustic surveys to the total population numbers. These numbers at age were then used to represent populations in October 1983 and 1984. Similar biomass estimates were not available for Conception Bay-Southern Shore as there were no acoustic surveys in the area. Instead the strength of the 1982 yearclass for this area was based upon a comparison of the 1982 yearclass to the 1968 yearclass for the areas acoustically surveyed both along the east coast and southeast coast (Wheeler and Dalley 1985). These comparisons (Table 29) were determined from cohort analyses initiated with the empirical population age structures, back-calculated to the beginning of 1984, as derived from the 1984 acoustic survey.

A north-south cline existed in the relationship of the two yearclasses for the acoustically surveyed areas; a value of 0.45 was chosen to estimate the 1982 yearclass in relation to that of 1968 for Conception Bay-Southern Shore. Cohort analyses were conducted for Conception Bay-Southern Shore to derive an estimate of F_t (0.018) which when combined with the partial recruitment pattern derived from the survey provided this relationship (0.45) between the two yearclasses and stock size estimates at age for 1984. Similarly cohort analyses were conducted to derive estimates of F_t for White Bay-Notre Dame Bay (0.050) and Bonavista Bay-Trinity Bay (0.011) which best approximated empirical 1984 population age structures derived from the acoustic survey.

2) Trends in Biomass and Fishing Mortality:

In all areas, 2+ biomass levels have increased substantially with the recruitment of the 1982 yearclass (Tables 30-32). In White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay, B_2+ has increased approximately 50% from 1983. In Conception Bay-Southern Shore, the increase has been greater, approximately 137%. In all areas, the present 2+ biomass is approximately 21-23% of maximum historical levels.

As a result of the recruitment of the 1979 yearclass, 5+ biomass levels have decreased slightly from 1983 to 1984 in White Bay-Notre Dame Bay, increased slightly in Bonavista Bay-Trinity Bay, and more than doubled (2.01) in Conception Bay-Southern Shore. Similar trends were evident in the commercial and research age compositions (Fig. 9-10) which showed increased percentages of five-year-olds (1979 yearclass) in southern areas.

Fishing mortality (5+) estimates were low and showed the same trends for all areas, peaking in 1978 or 1979 and declining ever since. This decline is as expected with reduced TAC's in the early 1980's and closure of the fishery in 1983. Fishing mortality rates have exceeded $F_{0.1}$ = 0.30 only once in one area (Conception Bay-Southern Shore) over the time series suggesting that stock declines have been mainly due to recruitment failure of yearclasses produced during the 1970's rather than excessive fishing pressure.

3) Trends in Recruitment:

As shown before (Table 29), recruitment estimates of the 1982 yearclass from the acoustic survey suggest that this yearclass is strong, approximately 70% that of the 1968 yearclass at age 2 in White Bay-Notre Dame Bay, 50% in Bonavista Bay-Trinity Bay, and 45% in Conception Bay-Southern Shore. This also agrees with the age composition of samples from the research gillnet program in 1984 (Fig. 10).

Although the 1979 yearclass shows increasing dominance in commercial catches, it is not strong in any area and is presently 5% the size of the 1968 yearclass (at age 5) in White Bay-Notre Dame Bay, 6% that of the 1968 yearclass in Bonavista Bay-Trinity Bay, and 5% in Conception Bay-Southern Shore. It should be noted, however, that these percentages represent spring spawners only and that from commercial and research gillnet age compositions (Fig. 9 and 10) it appears that approximately 30-50% of the 1979 yearclass are autumn spawners.

Other recent yearclasses (1980 and 1981) appear to be very poor in most areas. There is one possible exception; the 1980 yearclass in Conception Bay-Southern Shore is approximately 80% of the size of the 1979 yearclass and thus 3% of the size of the 1968 yearclass at age 4.

Prognoses

1) Catch Projections:

The population vectors for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay derived from the acoustic survey (Table 28) and that for Conception Bay-Southern Shore derived from cohort analysis (Table 32) were projected to 1986 assuming the following catches in 1985: 2000 t in White Bay-Notre Dame Bay, 800 t in Bonavista Bay-Trinity Bay, and 200 t in Conception Bay-Southern Shore. These catches were assumed reasonable as there has been a 1500 t TAC allocated for the spring fishery and a similar TAC is anticipated for the fall fishery in 1985. The population vectors, used to initiate the projections in 1985, were corrected to allow for natural mortality from the time of the acoustic survey to the beginning of 1985. Mean weights at age were those derived from samples collected in 1984 (Table 9); $F_{0.1}$ was assumed to be 0.30. Recruitment at age 2 in 1986 was

assumed to equal the average recruitment of the 1970-81 yearclasses (i.e. excluding the large 1968 and 1982 yearclasses). These recruitment values were as follows:

	White Bay-Notre Dame Bay	Bonavista Bay-Trinity Bay	Conception Bay-Southern Shore
R ($x10^3$)	10,000	5,000	500

Two options of partial recruitment patterns were used in the projections (Table 33), one based upon historical combined purse seine and gillnet fisheries (Winters and Moores 1977) and the second for a gillnet fishery only (Wheeler et al. 1984). These projections (Tables 34-36) show catches for 1986 of approximately 33,000 t for a combined purse seine and gillnet fishery and 25,000 t for a gillnet fishery only.

2) Management Implications:

These projections are based entirely upon population estimates derived from acoustic surveys. Although such estimates are independent of the commercial fishery, they are still very preliminary in nature as this survey concept is new and hence the techniques require continuing refinement. However, initial observations suggest that such surveys offer excellent potential for independent estimates of stock size. Furthermore, throughout all calculations, attempts have been made to choose conservative parameters wherever possible.

For these herring stocks, at the northernmost edge of their range, strong recruitment tends to be very sporadic, 14 years between the 1968 and 1982 yearclasses. Illustrative projections have been made to 1990 for each stock area (Tables 37-39) assuming no strong recruitment during that time. Projections have been made using the population vectors derived from the acoustic survey for White Bay-Notre Dame Bay and Bonavista Bay-Trinity Bay and that derived from cohort analysis for Conception Bay-Southern Shore. Recruitment was assumed to be equal to the historical geometric mean, 36.2×10^6 for White Bay-Notre Dame Bay, 19.6×10^6 for Bonavista Bay-Trinity Bay, and 3.2×10^6 for Conception Bay-Southern Shore. Partial recruitment values were for a combined purse seine and gillnet fishery (Table 33). To compensate for sporadic strong recruitment, projections have been made assuming two levels of fishing mortality, $F = 0.30$ and $F = 0.20$. Results show that with average recruitment within six to eight years, stock biomass will decline to levels observed prior to the recruitment of the 1982 yearclass, even at $F = 0.20$.

The short-term future of the east coast Newfoundland herring stocks looks secure with the recruitment of the 1982 yearclass. However, the long-term future will depend both upon management strategies and recruitment success within the next several years. From a biological point of view, fisheries should be conducted on or near the spawning grounds. Fall

fisheries, which exploit mixed stocks, have the potential to destroy a particular spawning group. Spring fisheries on or near the spawning ground, if regulated properly, will ensure continued viability of all spawning stock components. However, should such a management strategy be adopted, it may be necessary to redefine stock delineation as presented in this assessment.

Acknowledgements

We would like to thank all technical staff who were involved in the herring research program, in particular, C. I. Barbour, senior research technician who retired this year after 35 years service, M. F. Dawson, who continued to administer the research gillnet program in an excellent manner, and our "dedicated" samplers, P. Williams, B. Slaney, and J. O'Brien. We would also like to thank our secretary, M. Y. Hynes, for typing this script.
