Sequential Population Analysis of the Nain Assessment Unit Arctic Charr Population

## by

J. B. Dempson and L. J. LeDrew

Fisheries Research Branch
Department of Fisheries and Oceans
P.O. Box 5667

St. John's, Newfoundland A1C 5X1

1 This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

1 Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échëanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des ēnoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiēs dans 1a langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrētariat.

#### Abstract

Tag recapture information indicated that the Nain assessment unit consists of the following subareas: Anaktalik Bay, Nain Bay, Tikkoatokak Bay and Webb Bay for the inshore zone, and Dog Island and Black Island for the offshore zone. Annual landings from this assessment unit have ranged from 34 to 76 t (mean $=56 \mathrm{t}$ ) and from 1977-1985 have represented $36 \%$ of the total commercial production from the Nain Fishing Region. The total allowable catch in 1985 for the Anaktalik Bay and Tikkoatokak Bay subareas, including an offshore component was 30.5 t. Landings for the Nain assessment unit in 1985 totaled 41 t and were $6 \%$ higher than the previous year. A sequential population analysis was carried out on catch at age data from 1977-85 and indicated a fishing mortality of 0.45 in 1985. A projection of the TAC in 1986 fishing at $F_{0.1}(=0.40)$ indicates a yield of $44 t$.

## Résumé

Si l'on se fonde sur les données provenant des étiquettes récupérēes, l'unitē d'évaluation de Nain couvre les sous-zones suivantes : les baies Anaktalik, Nain, Tikkoatokak et Webb, pour la zone côtière, et les îles Dog et Black, pour la zone hauturière. Pour cette unité, les débarquements annuels se sont situēs entre 34 et 76 t (moyenne de 56 t), reprēsentant $36 \%$ de la production commerciale totale dans la région de Nain de 1977 à 1985. En 1985, le total des prises admissibles pour les sous-zones des baies Anaktalik et de Tikkoatokak, y compris un segment de la zone hauturière, était de $30,5 \mathrm{t}$. Les dēbarquements pour l'unité d'ēvaluation de Nain se sont èlevēs à 41 t en 1985 , soit $6 \%$ de plus que l'année précédente. Une analyse séquentielle de population effectuée sur les prises par catēgorie d'âge de 1977 à 1985 rēvèle une mortalitē due à la pêche de 0.45 en 1985. Une projection du TPA pour 1986, à raison de $\mathrm{F}_{0,1}=0,40$, ètablit le rendement à 44 t .

## Introduction

In previous years individual assessments were conducted separately on Arctic charr populations from Nain-Tikkoatokak and Anaktalik Bay. Quotas were applied to both these areas beginning in 1979. With increasing catches in the offshore areas of Dog Island and Black Island, an attempt was made to apportion these catches back into the respective inshore fishing areas in order to account for total losses from the population (Dempson and LeDrew 1985).

Analyses of information on tag recaptures at sea indicates that charr from these areas should be considered as one stock complex consisting of the following subareas: Anaktalik Bay, Nain Bay, Tikkoatokak Bay and Webb Bay for the inshore zone, and Dog Island and Black Island for the offshore component (Fig. 1). Annual landings from this assessment unit have ranged from 34 to 76 t (mean $=56 \mathrm{t}$ ) and from 1977-1985 have represented $36 \%$ of the total commercial production from the entire Nain Fishing Region. The TAC in 1985 for the Anaktalik and Tikkoatokak-Nain subareas, including the offshore component, was 30.5 t .

This paper summarizes results of the 1985 fishery and provides a forecast of available harvest in 1986.

## Stock Assessment

## Catch and effort data

Catch and effort data for the Nain assessment unit are summarized in Table 1 for 1974-85. The highest catch of 76 t occurred in 1977, the lowest of 34 t was in 1975. Landings in 1985 totaled 41 t and were $6 \%$ higher than the previous year. Effort increased by $3 \%$ while catch per unit effort was also about $3 \%$ higher than in 1984. By grouping subareas in this way it can be seen (Table 1) that the TAC has been exceeded in all but one year. Total landings from 1979 to 1985 of 395 t have exceeded the total of the TACs ( 323 t ) by $22 \%$. It should be remembered, however, that the TAC did not apply to all subareas within the Nain assessment unit over this period.

Trends in the catch series can be more clearly seen by separating inshore and offshore zones. Landings in the inshore zone have decreased from a total of 200 t for 1977-79 to 81 t for 1983-85. Landings from the offshore zone have changed from 21 t to 52 t over the two time periods (Fig. 1). Differences in abundance between zones and among years were tested by a Kruskal-Wallis one-way analysis of variance (Sokal and Rohlf 1969) using data from all weeks for years 1977 to 1985. Results indicated a highly significant difference between inshore and offshore zones ( $\mathrm{X}^{2}=85.0$, $\mathrm{df}=1$, $\mathrm{P}<0.0001$ ) but no difference in abundance for the two zones combined over time ( $X^{2}=2.3$, $d f=8, P=0.97$ ) (Fig. 2). When analyzed separately, there were significant differences among years for both the inshore ( $X^{2}=17.6, \mathrm{df}=8, \mathrm{P}=0.02$ ) and the offshore zone $\left(X^{2}=16.7, d f=8, P=0.03\right)$.

Another factor examined was timing of catches in the commercial fishery. Cumulative weekly proportion of catch and catch per unit effort were compiled for the three time periods 1977-79, 1980-82, and 1983-85 (Fig. 3). Based on either catch or CUE, these data suggest that charr were more abundant at sea later in the summer during the last several years in comparison with the two previous time periods. This appears to be related to the increased abundance of charr in the offshore fishing zone during the past several years.

Numbers at age were available since 1977 and are summarized in Table 2. Data were derived from annual commercial sampling programs. Where possible, numbers at age were estimated for each inshore subarea individually then added together while numbers at age were estimated for the two offshore subareas combined then added to the inshore total. If necessary, numbers were then adjusted to reflect the total estimated number of fish caught for the entire assessment unit as estimated in the commercial landings summary for all subareas combined. Mean age has varied from 8.5 to 9.8 years with a slight drop during the past several years.

Weights at age were calculated from commercial samples (1974, 1977-78 for yield per recruit analysis, and 1983-85 for stock projections) and were converted from gutted head-on to whole weight using the conversion factor 1.22 (Dempson 1984) (Table 3).

Total mortality (Z) was calculated using the Paloheimo method (Ricker 1975) and the average value from all years (1977-78 to 1984-85) was 0.57. Average Z of 0.64 for the past three years (1982-83 to 1984-85) was reasonably constant. Assuming a natural mortality rate as in past assessments of 0.2 yields an estimate of fishing mortality of 0.44. An estimate of total mortality was also derived from a catch curve using catch per unit effort at age data from 1983-85. This indicated a $Z$ of 0.70 .

As in past years, an estimate of fishing mortality was derived from:

$$
\mu=1-e^{-F} \text { (Ricker 1975) }
$$

where $\mu$ was estimated from tag recaptures. Previously no estimate was incorporated for natural mortality, tagging mortality, tag loss or non-reporting of tags. In order to estimate a more representative value for fishing mortality, the total number of tag recaptures were divided by total number of tags applied less $10 \%$. Therefore:

$$
\mu=116 / 363=0.320
$$

Rate of fishing mortality was calculated to be 0.39 (95\% C.L. $=0.31-$ 0.48).

An initial cohort analysis was run using partial recruitment values and terminal fishing mortality ( $F_{T}$ ) from the 1985 assessment (Dempson and LeDrew 1985) ( $F_{T}=0.40$ ). An iterative procedure was used to obtain estimates of fishing mortality for the oldest age group ( $F_{B}$ ). The iteration process stops when the input and output values of $F_{B}$ differ by 0.005 or less (Rivard 1982). Following this the cohort analysis procedure was rerun using the newly derived values for $F_{B}$.

Partial recruitment rates were calculated using the historical averaging method from the matrix of fishing mortality rates generated from the last SPA (sequential population analysis) and are presented in Table 3.

Yield per recruit was calculated by the method of Thompson and Bell (Ricker 1975) using partial recruitment rates and mean weight at age. $F_{0 .}$ was 0.38 at a yield per recruit of 0.91 kg . For the projection, $F_{0.1}$ was rounded to 0.4.

Cohort analyses were performed using a range of terminal fishing mortality rates from 0.2 to 0.7 using the newly derived estimates of partial recruitment. In each run, fishing mortality rates for the oldest age group ( $F_{B}$ ) were re-evaluated using the iterative procedure. Regressions of $F$ on effort and population biomass of age $10^{+}$fish on catch per unit effort of age $10^{+}$fish were used in tuning the analysis to key in on an appropriate value for $F_{T}$ in 1985.

Regressions of F on effort produced the highest correlations at $\mathrm{F}_{\mathrm{T}}=0.3$ and 0.35 (Table 4). The best predicted values for $F_{T}$ in 1985 were obtained with a cohort run of $F_{I}=0.55$ although regressions were not statistically significant beyond 0.45 (Table 4). Regressions of biomass on catch per unit effort had the highest correlations at $F_{T}=0.4$ and 0.45 with the best predicted value when $F_{T}=0.45$ (Table 4 ). Average fishing mortality from the Paloheimo method for the past several years was 0.44 and from tagging results 0.4. Thus the best estimate of terminal F in 1985 was estimated to be 0.45 . Table 5 summarizes population numbers and fishing mortality matrix for the cohort analysis run with $\mathrm{F}_{\mathrm{T}}=0.45$.

A projection was run using 1985 population numbers from a cohort analysis run at $F_{T}=0.45$. Recruitment was estimated from the geometric mean of age six population numbers for the years 1977-83. Weights at age for the projection were based on 1983-85 data. The projected TAC for the Nain assessment unit in 1986 is 44 t (Table 6). This is approximately $7 \%$ higher than landings in 1985 but $27 \%$ lower than the average during the past 10 years.

Fig. 1. Location of subareas within the Nain stock unit. Graphs illustrate change in catch and CUE for inshore and offshore zones for the periods 1977-79, 1980-82, 1983-85.

Fig. 2. Difference in abundance of Arctic charr (CUE) between inshore and offshore zones of the Nain stock unit from 1977-1985.

Fig. 3. Cummulative proportion of catch per unit effort and catch as a function of time for Arctic charr caught in the Nain stock unit of northern Labrador over three time periods 1977-79, 1980-82 and 1983-85.
