# ASSESSMENT OF THE WEST COAST OF NEWFOUNDLAND HERRING STOCKS IN 1985 

by<br>I.H. McQuinn<br>Direction de la Recherche sur les Pêches Ministère des Pêches et des Ocēans C.P. 15500<br>901 Cap Diamant<br>Quēbec, Quēbec, G1K 7 Y7

1 This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author.

1 Cette sērie documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considērēs comme des énoncēs finals sur les sujets traités mais plutôt comme des rapports d'ētape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyē au secrētariat.

Herring landings in NAFO Division 4R in 1985 were approximately 9,100 $t$, from a TAC of $10,000 \mathrm{t}$. Spring spawner gillnet catch rates generally declined from 1978 to 1983 and then increased from 1984 to 1985. The fall spawner CPUE decreased from 1977 to 1982, increased in 1983 and has been relatively stable to the present. Spring spawners have generally dominated the annual catch since 1966. Historically, this spawning group has been dominated by the 1968 and 1974 year-classes. In 1985, the 1980 year-class represented $62 \%$ of the catch in numbers. The fall spawners had been dominated by the $11+$ age group until 1983. In 1985, the 1979 year-class made up $63 \%$ of the catch in numbers. Cohort analyses showed that the spring spawner population biomass has decreased from $192,000 \mathrm{t}$ in 1972 to $45,000 \mathrm{t}$ in 1985. The fall spawner population biomass in 1985 stands at approximately $12,000 \mathrm{t}, 12 \%$ of the historical high in 1966. Poor recruitment has been the major reason for the decline of these two stocks. Projections using the expected 1986 catch of $10,000 \mathrm{t}$ of spring spawners would result in $\mathrm{Ft}=0.3$ and a slight decrease in population biomass from 44,700 t in 1986 to $41,100 \mathrm{t}$ in 1987. The 1987 F0.1 catch would be $8,800 \mathrm{t}$. The expected 1986 fall spawner catch of $7,000 \mathrm{t}$ would result in an $\mathrm{Ft}=0.95$ and a drop in the $4+$ biomass from $15,900 \mathrm{t}$ in 1986 to $9,400 \mathrm{t}$ in 1987 . The 1987 F0. 1 catch would be $1,600 \mathrm{t}$.

RÉSUMÉ

Les débarquements de hareng dans la division $4 R$ de l'OPANO en 1985 étaient d'environ 9100 t , sur un TPA de 10000 t . Les taux de captures des filets maillants pour la population du printemps montrent une baisse générale entre 1978 et 1983, et ensuite une augmentation de 1984 à 1985. Quant aux reproducteurs d'automne, les PUE ont indiqué un déclin d'abondance entre 1977 et 1982, et ensuite une augmentation en 1983. Elles ont depuis été stables. Les reproducteurs de printemps sont généralement dominants dans la capture depuis 1966. Les classes d'âge de 1968 et 1974 ont dominé les captures historiques de ce groupe reproducteur. La classe d'âge de 1980 a représenté $62 \%$ de la capture en nombre en 1985. Les captures de reproducteurs d'automne ont compris une forte proportion de poissons âgés de plus de 11 ans entre 1966 et 1983. En 1985, la classe d'âge de 1979 a dominé ( $63 \%$ ) la capture en nombre. Les analyses de cohorte ont démontré que la biomasse de reproducteurs de printemps a passé de 192000 t en 1972 à 45000 t en 1985. La biomasse des reproducteurs d'automne en 1985 est d'environ $12000 \mathrm{t}, 12 \%$ du maximum observé en 1966. La cause des déclins observés est attribuée à l'insuffisance du recrutement. La capture de 10000 t de reproducteurs de printemps en 1986 résulterait en un taux de mortalité de 0,3 et la biomasse totale passerait alors de 44700 t en 1986 à 41100 t en 1987. Une mortalitē par la pêche de Fo,1 en 1987 permettrait de capturer 8800 t . La capture de 7000 t de reproducteurs d'automne prévue pour 1986 occasionnerait un taux de mortalité de 0,95 et une baisse de la biomasse (4+) de 15900 t en 1986 à 9400 t en 1987. En pêchant à un taux de $\mathrm{F}_{0,1}$ en 1987, on récolterait 1600 t .

## INTRODUCTION

Total herring landings from the west coast of Newfoundland (NAFO division 4R) had ranged between 3,000 and 6,000 t from 1966 to 1970 when in 1971, a dramatic increase began which peaked at $27,000 \mathrm{t}$ in 1973 (Table 1, Figure 1). Landings decreased sharply in 1974 and 1975 as the number of seiners in the commercial fleet was greatly reduced and then increased steadily until 1980 . Since 1980, official landings have again declined, presumably due to depressed markets. In 1985, improved market conditions allowed for a marginal increase in landings.

Historically, these herring stocks have been exploited by both fixed (mainly anchored gillnets) and mobile gears (mainly purse seines). However, the proportion of the total catch taken by each gear component in each unit area has been extremely variable, and complete disappearance of one or the other fishery has occurfed in some years (Table 1, Figure 2). In 1985, the gillnet proportion of the total landings dropped from 41\% in 1984 to 10\%.

Total allowable catches (TAC) have been in effect since 1977, when the west coast of Newfoundland was defined as a herring management unit. The TAC has been exceeded every year except in 1981 and from 1983 to 1985 (Table 1). In order to prevent overexploitation of local stocks, the TAC was originally broken down into quotas for three areas (Moores and Winters, 1978): (1) St. George's Bay (area 4Rd), (2) Cape St. George to Cape St. Gregory (area 4Rc) and (3) Cape St. Gregory to Cape Norman (areas $4 \mathrm{Rb}+4 \mathrm{Ra}$ ) (Figure 3). In recent years, the TAC has been divided between the purse seine (55\%) and the gillnet (45\%) fisheries. In addition, the purse seine quota has been proportioned among the five remaining vessels and the gillnet allocation has been divided evenly between the regions north and south of Cape St. Gregory.

Historical Fishing Patterns:

The fishing pattern of the herring fleet has varied greatly over time. Before 1971 most of the catch was reported in area 4 Rb , while from 1971 to 1978 area 4 Rd was the single most important fishing zone (Figure 4c). More recently, the proportion of the total catch reported in area 4Rd has slowly diminished while increasing in area 4 Rc and again in area 4 Rb .

The purse seine fleet, being very mobile, can direct its fishing effort wherever success and markets are optimal. The fishing pattern of the fleet has therefore fluctuated considerably over time in response to shifting concentrations of herring schools and the accessability to buyers (Figure 4a). For instance, in the southern fishery (areas 4Rc +4 Rd ) during the 70's, most of the catch was reported in area 4Rd. As the
proportion of market size fish decreased in St. George's Bay in the early 80's, more and more catches had been reported from area 4Rc. In 1983 and 1984, catches were taken almost exclusively in area 4Rc. In the spring of 1985, the seiners once again began fishing in St. George's Bay and reduced their effort in area 4Rc, resulting in catches being split almost evenly between these two areas (Table 2).

In the northern fishery (areas 4Ra +4 Rb ), Moores and Winters (1980) noted that in 1979, the bulk of the catch, which previously came from St. John's Bay (area 4Ra), was now being reported from south of Pointe Riche (area 4 Rb ). Since then, this shift has become more and more pronounced resulting in catches from area 4 Rb being 4 times higher than in area 4Ra in 1983 (Figure 4a). In 1984 and 1985, there was virtually no purse seine catch taken in area 4 Ra (Table 2).

The nearshore fishery, made up of all gears other than purse seines (mostly gillnets), has also gone through pronounced changes since 1966. In the late sixties, the dominance of this fishery in the southern areas rapidly declined (Figure 4b). From 1971 to 1978 , most of the catch was reported from area 4Ra. After 1975, the development of a major spring gillnet fishery south of Cape St. Gregory (Moores and Winters, 1980) resulted in a steady increase in landings reported from areas 4Rc and 4Rd. Since 1979, almost equal proportions of the total gillnet catch have been taken from the southern and the northern zones, although the total gillnet landings from these fisheries have declined in both regions since 1980 (Table 1).

## Recent Trends and Market Conditions:

The TAC was set at 10,000 t from 1982 to 1985 . In 1982 and 1983, purse seine catches in St. George's Bay were below the area allocations (no catches were reported in 1983), due to the dominance of fish below market size. During the same period, all other purse seine area allocations were overrun. In 1984, area allocations were not set, but the fishing pattern was similar to the previous year (Table 2) with little catch being taken in St. George's Bay and over 20\% of the purse seine landings being reported from between Cape St. George to Pointe Richie (areas 4Rb + 4Rc). In 1985, the spring fishery resumed in St. George's Bay (area 4Rd) as the fish were once again of marketable size. The easy availability of large concentrations of herring in Bonne Bay (area 4 Rb ) throughout the autumn and early winter of 1985, resulted in $71 \%$ of the total purse seine catch being reported from this fishery.

The fixed gear allocations were overrun in all areas in 1982 but have not been reached since. In 1985, very few landings were reported from the gillnet fishery ( 937 t ) as there was little market demand for gillnetted herring. In 1984, the gillnet catches in areas 4 Rc and 4Rd were taken almost exclusively in

April and May (Table 2). Again in 1985, the majority of the landings from unit areas $4 \mathrm{Rd}, 4 \mathrm{Rc}$ and 4 Rb were reported in the spring of the year. Most of the annual gillnet catch (66\%) was taken in St. George's Bay in May and north of Pointe Riche in the fall.

## INPUT DATA

## Population Abundance Indices:

Catch rate indices have been calculated for the gillnet and purse seine fisheries for both the spring and fall seasons.

The Gillnet Fishery:
Gillnet catch rates (t/fisherman/day) were calculated using landings from all available purchase slips from 1977 to 1985. All pertinent information, including the name of the fisherman, was computerized in order to conduct a series of detailed analyses to find and correct for a number of the known biases associated with these data (HERRING CPUE v1.0).

It was known that certain fishermen would often split their daily catch among the crew members who would then sell their shares separately. This resulted in several slips being issued for the same catch. Purchase slips were therefore sorted by day and amount landed to identify those groups of fishermen who repeatedly sold the same amount of fish on the same day. These split landings were then combined. In addition, some fisherman were issued several slips on the same day, either because the catch was separated during weighing and a slip was issued for each batch or because the fisherman made several trips during the day to empty his nets. In either case, the sum of the day's landings represented one day of fishing and therefore the amounts on the slips were combined.

The percent of spring and fall spawners in the commercial gillnet samples were tabulated by month and unit area to determine during which periods the fishery has historically been directed upon only one of each of the spawning components. From this table, the major spawning sites were determined to be areas 4Rc and 4Rd in April and May for the spring spawners, and area 4Ra in August for the fall spawners (Table 3). A weekly catch rate index was then calculated for the weeks within these areas for which the catch was $>85 \%$ of only one spawning stock (Table 4). The weekly catch rates during these periods varied greatly from one week to the next in most years (eg. Figure 5). It was felt that this was due to changes in catchability as the herring migrated in and out of the fishing areas in preparation for spawning. The abundance indices were therefore calculated as the unweighted mean of the weekly catch rates (where slips were available) over the entire period.

In 1985, there were only 2 purchase slips issued in area 4Ra in August, therefore an abundance index for the fall spawners could not be calculated from these data. The catch rate was therefore calculated using data from logbooks filled out by gillnet fishermen during this period. It was felt that these data were consistant with the historic series as the 1984 logbook and purchase slip catch rate estimates were virtually identical (Figure 5).

The resulting indices were then adjusted for gang size, to account for annual changes in the number of nets fished per day. The estimated number of nets per gang for 1977 to 1981 were based on surveys carried out on the Newfoundland east coast. For 1982 to 1985, the gang size was obtained from written surveys conducted on the west coast in 1984 and 1985. The number of nets fished from 1981 to 1983, recorded on the licence applications, was used to standardize the two series of data. The gang size estimates for 1982 to 1985 were calculated using the average number of nets fished by those fishermen who sold the majority of their catches, so as not to include bait fishermen who did not receive purchase slips. The gang size estimates were normalized to 1978. The adjusted catch rates (Table 5) were used to calibrate the cohort analyses for the two spawning stocks.

The spring gillnet catch rates showed a generally declining trend in abundance from 1978 to 1983 (Figure 6). This trend was reversed in 1984 and 1985 as the index increased to above the 1981 value. For the fall spawners, the gillnet catch rates followed a constant decline between 1977 and 1982. In 1983, the CPUE increased slightly and has remained stable to the present.

The Purse Seine Fishery:
Catch and effort data from purse seine logbooks have also been analysed for trends in abundance. Historical catch and effort data were more consistently available for the months of April and May in areas 4Rc and 4Rd for the spring fishing season and for the months of November and December in areas 4Ra and 4Rb for the fall fishing season. Catch rates, weighted by the corresponding purse seine catches of each category (month and unit area), were calculated for these selected months and areas.

Historical trends in c/set and c/night were very similar (Table 6, Figure 7). From 1980 to 1983 , the spring catch rates were generally much higher than the fall catch rates; the weighted average $c / s e t$ and $c / n i g h t$ being 2.5 and 2 times higher, respectively. In $1984, \mathrm{c} / \mathrm{ni}$ ght was still higher in the spring, but c/set was similar for the two seasons. All catch rate indices increased in 1985.

In the spring fishery, catch rates were relatively stable between 1975 and 1980, but have been variable since then. In the fall fishery, catch rates dropped steadily between 1978 and 1981, similar to the decrease in the gillnet abundance index for the
fall spawners during the same period. In 1982, both $\mathrm{c} / \mathrm{set}$ and c/night increased sharply and then decreased until 1984. If we assume that the spring catch is mainly comprised of spring spawners and the fall catch is of both spring and fall spawners (Table 7), the more or less constant decline in catch rate, most evident in the fall fishery between 1978 and 1981 and again from 1982 to 1984, could indicate a decrease in the fall spawner fishable biomass. The fact that all measurements of purse seine CPUE increased in 1985 could be interpreted as a recent increase in the biomass available to the purse seine fleet.

The validity of purse seine catch rates as representative of pelagic fish population abundance has often been discussed (Powles, 1981; Pope, 1978; Ulltang, 1978; Cleary, 1982) and is generally considered to be difficult to interpret. In addition, logbook coverage has been rather limited in most years and particularly from 1981 to 1985. Consequently, these data were not used to calibrate the cohort analyses, but are presented only as additional information on trends in abundance.

## Age Composition of the Commercial Catch:

Random samples from the commercial fishery were collected by port samplers, by gillnet fishermen hired to keep detailed catch and effort data on herring caught on the spawning grounds and by observers on the purse seine vessels. Because of the number of people involved, coverage of the major commercial landings was more than adequate (Annex 1). These samples were frozen and sent to the Quebec laboratory for analyses (length, weight, gonad weight, maturity stage and otolith collection).

Individual herring were assigned as either spring or fall spawners by relating the maturity stage to the date of capture and ages were determined from the otoliths (Cleary et al., 1982).

Catch-at-age data from 1966 to 1983 were taken from McQuinn and Cleary (1985). The 1984 catch at age was updated with the most recent 1984 landing statistics. As official landings were not available at the time of the assessment, the 1985 catch at age was calculated using inshore landings provided from the Moncton Statistics Branch and from the purse seine Quota Reports.

The catch at age was calculated by first multiplying the proportion of each spawning group caught in each category (gear, month and unit area) by the corresponding landings and dividing by the mean weight to produce the total number of fish of each spawning group caught per category. The total number of fish of each spawning group was then multiplied by the proportion at age of each category and summed across categories to give the total catch at age by spawning group (programme CAT $\triangle A G E$ v1.0).

The Spring Spawner Catch:
Spring spawners have dominated the catch in every year since 1966, except for 1971 (Table 8) and from 1974 to 1983, averaged 77\% of the catch in numbers. The 1968 year-class was the largest ever observed in the spring spawner catch and completely dominated from 1970 to 1978 (Table 9). Between 1971 and 1982, the only significant recruitment to the spring spawning stock came from the 1974 year-class. In 1983 about 39\% of the catch consisted of the 1979 and 1980 year-classes, which again dominated the 1984 fishery, representing $49 \%$ of the catch in numbers. In 1985, the 1980 year-class was the dominant cohort and the most important since 1974, contributing 62\% of the catch in numbers. Consequently, the mean age of the spring spawners dropped to 5 years old in 1985; the lowest recorded average.

The Fall Spawner Catch:
Herring of the $11+$ age group have historically dominated the fall spawner catch. In 1984, the 1979 year-class strongly recruited into the fishery and contributed to more than $46 \%$ of the catch in numbers. In 1985, this same cohort increased its dominance to an historical high of 63\%. The mean age of fall spawners in the catch has therefore decreased in recent years, from 10 years old in 1976 to 6 years old in 1985; again an historical low.

## Lenath Frequencies of Commercial and Research Catches:

Length frequencies of herring landed, as well as discarded, have been recorded by observers on board the vessels since 1982 (Figure 8). Sets were released if the percentage of fish too small for the market was judged to be too high.

In 1982 and 1983, the dominant lengths of landed fish were between 340 and 400 mm . In 1984 and 1985 , the modal length group was much smaller, from 300 to 340 mm . The length distributions of fish discarded in 1982 and 1983 were bimodal, with peak lengths below 280 mm . In 1984, the situation was quite different. The dominant length group of discarded fish was the same as in the landed catch. Moreover, very few fish less than 220 mm were observed in 1984 in either the landed or discarded samples. In 1985, the discarded set length frequency was polimodal, with a significant number of fish below 240 mm and two additional peaks between 280 and 300 mm and 320 to 340 mm .

Length frequencies of herring caught during the January bottom trawl surveys in 1982 and 1983 also indicated that herring smaller than 280 mm were available. The modes in the 1983 research data corresponded very closely to those of the landed catch and discarded sets. In January 1985 and 1986, the proportion of fish smaller than 300 mm was negligible in the research catch. There were however concentrations of fish similar
in length to the landed samples ( $300-340 \mathrm{~mm}$ ) as well as older fish ( $360-400 \mathrm{~mm}$ ).

These data indicate that the length distribution of herring available to the commercial fishery has changed considerably since 1982. According to the proportion-at-age matrix (Table 9), the proportion of "bigger" fish, which are preferred for commercial purposes and which have dominated the fishery for many years, has decreased.

A comparison of the commercial and research length frequency data showed clearly that the purse seine fishery has been very selective in most years. Length frequencies from the discarded sets and the groundfish cruises indicated that both smaller and larger fish were available but were not being picked up in the commercial purse seine fishery.

## ESTIMATION OF PARAMETERS

## Natural Mortality Rate:

An value of 0.2 for the instantaneous natural mortality rate (M) was assumed for the present analyses. This value was used in the previous assessment (McQuinn and Cleary, 1985) and is consistent with that for other herring stocks (Lea, 1930; Runnstrom, 1936; Beverton, 1963).

Partial Recruitment:

Partial recruitment for ages 4, 5 and 6 were estimated for the two spawning stocks from a purse seine selectivity coefficient, derived from the ratio of the proportion at age from the commercial landings and the discarded sets (Table 10). However, the selectivity coefficient estimated for age 4 spring spawners was felt to be too high, given the small catch of this cohort. It was therefore adjusted downward to the value of the fall spawner 5 year olds, which were approximately the same length. Partial recruitment for ages 2 and 3 were were set to the historical mean from 1974 to 1982 for spring spawners and 1972 to 1982 for fall spawners. Spring spawners 5 years and older and fall spawners 6 years and older were considered to be fully recruited. The resulting partial recruitment vectors were as follows:

| AGE | 2 | 3 | 4 | 5 | 6 | $7+$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| SS | .04 | .26 | .63 | 1 | 1 | 1 |
| FS | .001 | .04 | .26 | .63 | 1 | 1 |

These partial recruitment vectors differ from the previous assessment (McQuinn and Cleary, 1985) because of the dominance of the 1979 and 1980 year-classes. This has led to a concentration of fishing effort on these cohorts and therefore ages 5 and 6 for spring and fall spawners, respectively, were fully recruited in 1985.

## Fishing Mortality for the Oldest Ages:

The vector of fishing mortalities for the oldest ages (Fo) was estimated in the following manner: the Fo for age 10 , when there is an 11+ group, was calculated by (a) determining the population numbers and Fo for the $10+$ group from the $10+$ catch and the $11+$ population numbers of the following year, and (b) partitioning the $10+$ numbers between age 10 and the $11+$ group, assuming the same $F$ applies to both. The resulting vector is used as input for cohort analysis starting at age 10. The $11+$ population numbers are then concatinated to the population matrix (FISH $\triangle$ HER v1.0).

## Weights at Age:

Mean weights at age were calculated as the average weights for the first half of the year for spring spawners and for the second half of the year for fall spawners (Table 11).

## Calibration of Cohort Analyses:

Cohort analysis was run separately for spring and fall spawners. Population biomasses were calculated for the beginning of the year for spring spawners and mid-year for fall spawners as these were the biomasses available during the periods for which the gillnet catch rates were estimated.

A series of cohort analyses was run at various values of terminal fishing mortality (Ft) (Table 12). Least squares regression of mature (4+) population biomass on gillnet CPUE was used to calibrate the cohort analyses for the two stocks. The Ft for each spawning stock was determined by choosing the regression line with the best combination of (a) correlation coefficient and intercept, (b) the closeness of the 1985 point to the regression line and (c) the sums of squares of the standardized residuals for the 1983 to 1985 points.

## ASSESSMENT RESULTS

## Cohort Analyses:

Cohort analyses indicated an Ft in 1985 of 0.15 and 0.35 for spring and fall spawners, respectively (Table 12 , Figure 9 a,b). The spring spawner population biomass has remained relatively constant at around $45,000 \mathrm{t}$ since 1982 (Table 13), mainly due to the strength of the 1980 year-class and the low fishing mortality exerted on this component over this period (Table 14a,b). This biomass level is however only $23 \%$ of the historical high of 192,000 $t$ in 1972 (Table 13). This drop in abundance has occurred even though the annual fully recruited fishing mortality rates, weighted on population numbers, have been below the F0. 1 value of .3 in all years except for 1980 to 1982 (Table 14b). The decline of this stock since the early 70's (Figure 10) has been due to the poor recruitment experienced in the last decade. Since 1972, only the 1974 and, more recently, the 1980 year-classes have contributed significantly to the stock. During the decade following the entry of the 1968 year-class into the fishery, recruitment at age 2 has been substantially below previous levels (1966-1971: $218 \times 106$ fish vs 1972-1981: $34 \times 106$ ).

The results of cohort analysis indicated a gradual decline in the fall spawner population numbers since 1981 (Table 15a). The population biomass now stands at $22,000 \mathrm{t}, 12 \%$ of the historical high in 1966 (Table 16). Except for 1979, the annual fully recruited fishing mortality rates, weighted on population numbers, had been below F0. 1 until 1983 but have been above this level since then (Table 15 b ). Again, the lack of recruitment appears to be the dominant reason for the constant drop in biomass since 1967 (Figure 10), as the only recruitment of significance since the 1958 and 1963 year-classes has been from the 1979 year-class.

## PROGNOSES

Catch and Biomass Projections:

Projections for 1986 and 1987 were run using population numbers obtained from the cohort analyses and recruitment at age 2 for 1985 to 1987 set to the geometric mean of the estimated recruitment from 1974 to 1982 for spring spawners and 1972 to 1982 for fall spawners (FISH $\triangle H E R$ v1.0). It was assumed that the 1986 TAC would be taken as allocated and that the proportion of spring and fall spawners in the catch would be the same as was observed in the 1985 catch. Projections for 1987 were calculated using the assumed FO.1 value of 0.3.

## Spring Spawners:

According to the present projections, the expected catch of $10,000 \mathrm{t}$ in 1986 will result in a fishing mortality of $\mathrm{F}=.30$ on fully recruited ages (Table $17 a$ ). The relatively strong 1980 year-class will help to maintain the population biomass at 40,100 $t$ in 1987, a slight decrease from 44,700 $t$ in 1986. The estimated 1987 F0. 1 catch would therefore be $8,800 t$.

## Fall Spawners:

Assuming the expected 1986 catch of $7,000 \mathrm{t}$ is taken, the projected fishing mortality will be $\mathrm{F}=.95$ on fully recruited ages (Table 17 b ). At this level of exploitation, the mature (4+) biomass would be reduced from 15,900 t in 1986 to $9,400 \mathrm{t}$ in 1987, 6\% of the 1967 historical high. The 1987 F0.1 catch would therefore drop to $1,600 \mathrm{t}$ (Table 17 b ). It is clear from the present analyses, that this spawning component cannot support this level of fishing and therefore a reduction in fishing effort on the fall spawners is strongly advised.

Figure 1. Commercial herring landings ( t ) by fishing area from NAFO division 4R from 1966 to 1985. Stars indicate annual TAC's.

Figure 2. Proportions of herring catches taken by purse seines and all other gears for each fishing area and all areas combined from 1966 to 1985.

Figure 3. Newfoundland fishing areas.

Figure 4. Proportions of herring catches from each fishing area for (a) purse seines, (b) all other gears and (c) all gears combined from 1966 to 1985.

Figure 5. Weekly gillnet catch rates (t/fisherman/day) calculated from purchase slips and logbooks for area $N$ in 1984. The catch rate for the fall spawning stock was calculated as the mean of the weekly rates between the hashed lines.

Figure 6. Gillnet catch rates, adjusted for gang size, for spring and fall spawners in NAFO division 4R from 1977 to 1985.

4Rc-4Rd (APRIL-MAY)

4Ra-4Rb(NOVEMBER-DECEMBER)

Figure 7. Purse seine catch rates, standardized to 1980 , from spring and fall fisheries in NAFO division 4R from 1969 to. 1985.

RESEARCH GATCH

Figure 8. Herring length frequencies ( 20 mm ) from the purse seine commercial samples (landed and discarded) from 1982 to 1985 and from the bottom trawl research surveys of 1982, 1983, 1985 and 1986 in NAFO division 4R.
(a)

(b)

Figure 9. Least square regression of (a) spring spawner mature (4+) January population biomass and gillnet catch rate for areas $K$ and $L$ in April and May from 1978 to 1985 and (b) fall spawner mature (4+) population biomass and gillnet catch rate for area $N$ in August from 1977 to 1985.

Figure 10. Mature (4+) population biomass estimates ( $\times 10^{-6} t$ ) for spring and fall spawing herring in NAFO division 4R from 1966 to 1985. Estimates for spring spawners are for the beginning of the year and for fall spawners are for mid-year.

Annex 1. Number of herring sampled (shadow print) and commercial landings in 4 R by month, area and gear in 1985.
