Results of the Acoustic Survey of Herring in the Southern Gulf of St. Lawrence and Sydney Bight, November 1985

Ъy

R. Shotton Marine Ecology Laboratory Department of Fisheries and Oceans Bedford Institute of Oceanography P.O. Box 1006 Dartmouth, Nova Scotia B2Y 4A2

¹ This series documents the scientific basis for fisheries management advice in Atlantic Canada. As such, it addresses the issues of the day in the time frames required and the Research Documents it contains are not intended as definitive statements on the subjects addressed but rather as progress reports on ongoing investigations.

Research Documents are produced in the official language in which they are provided to the Secretariat by the author. ¹ Cette série documente les bases scientifiques des conseils de gestion des pêches sur la côte atlantique du Canada. Comme telle, elle couvre les problèmes actuels selon les échéanciers voulus et les Documents de recherche qu'elle contient ne doivent pas être considérés comme des énoncés finals sur les sujets traités mais plutôt comme des rapports d'étape sur les études en cours.

Les Documents de recherche sont publiés dans la langue officielle utilisée par les auteurs dans le manuscrit envoyé au secrétariat. Abstract

Preliminary results of an acoustic survey of herring in the Gaspé - Baie de Chaleur area and Sydney Bight in November 1985 are presented. In the Baie de Chaleur area, most herring were encountered in the Chandler-Newport area with lesser amounts about Miscou Island. In Sydney Bight, a relatively large concentration of herring was found that extended along the coast from Neil Harbor to Wreck Point. Many smaller schools occurred in the inshore area of Glace Bay - New Waterford. A brief exploration at the end of the cruise also located herring schools at the entrance to Gabarus Bay.

The estimated total area scattering coefficient for the Baie de Chaleur area is 19 100 sr⁻¹. Using values of 0.2188 m⁻² sr⁻¹t⁻¹ (Halldorson and Reynisson 1983) and 0.3049 m⁻² sr⁻¹t⁻¹ (Edwards and Armstrong 1983) gives biomass estimates of 87 200 t and 62 600 t respectively. In Sydney Bight, the estimated total area scattering coefficient for the regions surveyed is 38 300 or 45 600 sr⁻¹, depending on assumptions regarding herring behavior. Using the same conversion coefficients, this gives biomass estimates of 174 300 t and 210 000 t (Halldorson and Reynesson) and 125 000 and 152 000 t (Edwards and Armstrong 1983) respectively. The best estimate is taken as 38 900 sr⁻¹ (177 900 t).

A striking feature of the results of the 1985 survey was the similarity in the geographical distribution of herring schools to that observed in 1984. This indicates that acoustic surveys of these stocks during November could provide a good annual index of herring abundance.

Résumé

On présente les résultats préliminaires du relevé acoustique du hareng effectuée en novembre 1985 dans la région de Gaspé - Baie des Chaleurs et de Sydney Bight. Dans la région de la Baie des Chaleurs, on a constaté que la plus forte concentration de harengs se trouvait dans la région de Chandler - Newport et qu'elle était moindre aux alentours de l'île Miscou. Dans Sydney Bight, on a trouvé une concentration relativement importante de hareng le long de la côte, entre Neils Harbour et la pointe Wreck. Beaucoup de bancs de moindre concentration ont été repérés dans la région côtière de Glace Bay - New Waterford. Une brève exploration en fin du relevé a également permis de repérer des bancs de harengs à l'entrée de la baie Gabarus.

Le coefficient de diffusion estimé pour l'ensemble de la région de la Baie des Chaleurs est de 19 100 sr⁻¹. En utilisant des valeurs de 0.2188 $m^{-2}sr^{-1}t^{-1}$ (Halldorson et Reynisson 1983), et de $0.3049 \text{ m}^{-2} \text{sr}^{-1} t^{-1}$ (Edwards et Armstrong 1983), on obtient des estimations de biomasse de 87 200 t et de 62 600 t respectivement. Dans Sydney Bight, le coefficient de diffusion estimé pour l'ensemble des régions explorés est de 38 300 ou de 45 600 sr⁻¹, selon les hypothèses concernant le comportement du hareng. En utilisant les mêmes coefficients de conversion, on obtient des estimations de biomasse de 174 300 t et de 210 000 t (Halldorson et Reynisson) et de 125 000 t et 152 000 t (Edwards et Armstrong 1983) respectivement. La meilleure estimation est de 38 900 sr⁻¹ (177 900 t).

Une caractéristique frappante des résultats du relevé de 1985 est la similarité de la distribution géographique des bancs de hareng avec celle de 1984. On en découle que le relevé acoustique de ces stocks en novembre pourrait donner un bon indice annuel de l'abondance de hareng.

1. Introduction

This report presents the results of the acoustic research cruise of the herring stocks in the NAFO areas 4T and 4Vn. The cruise had several objectives:

(1) To obtain an estimate of abundance of herring and determine their geographical distribution and relative abundance,

(2) To obtain information which would enable development of "optimal" sampling methods in the case of highly aggregated and mobile fish populations,

(3) Contribute to the understanding of the biology of herring in the survey area through increased knowledge of their spatial and temporal distribution.

This cruise (Needler #55), during November 1985, followed a similar cruise done in much the same area during the same period in 1984. Information on the distribution of herring encountered in 1984 was used in designing the cruise sample design in 1985. The principal differences in the cruise design were:

(1) The area adjacent to the $N.W.\ coast of Cape Breton (Cheticamp to Cape North) was$ not surveyed in 1985 because of northwesterly gales during the time available. Herring were located in this area in 1984.

(2) The Souris - Cardigan Bay area adjacent to the eastern coast of Prince Edward Island was surveyed in 1985. No transects were undertaken in this area in 1984.

(3) Transects were run in the Cape Gabarus area in 1985. This area was not covered in 1984.

For the first part of this cruise - which covered the Gaspé - Baie de Chaleur area continual problems were encountered with the magnetic tape drive. This occurred mainly while sampling in the strata L and M (Baie de Malbaie and Baie de Gaspé respectively). No schools were found (as indicated on the chart recorder) in stratum M. Schools were encountered in stratum L when the acoustic system was not working, but while the ship was steaming survey transects. When the transects were repeated, with the acoustic system operating normally, no schools were recorded. Thus while no herring are reported for Baie de Malbaie, some herring are known to have occurred in that stratum.

Two measures of herring abundance have been derived from the survey results. One is an acoustic measure, the area scattering coefficient $(s_{v/a})$, with units of sr⁻¹. The other, the biomass estimate (t) is derived from this using a coefficient whose value is subject to a number of assumptions, most of which cannot be tested, or which can be investigated only with great difficulty. This coefficient for herring, the backscattering cross section per tonne (σ_b / t) , is given different values by different investigators. It will be affected by behavioral differences of the herring, their size and the (unknown) state of inflation of their swimbladders. Any change in the opinion as to the appropriate value of σ_b/t will result in an equivalent linear change in the estimated biomass.

2. Survey Area

Figure 1 shows the locations of the strata in the survey area. Figures 2-16 show the locations of the transects within the various strata. In strata where the existence of herring was believed to be minimal or unlikely, sampling was done along a continuous zig-zag transect. This was done in stratum P (north of North Point, western PEI, Figure 2), eastern PEI (strata CB,EP,BP, Figure 9) and Lorraine Head (stratum GA, Figure 16). In strata where herring had been found in relative abundance in 1984, replicated randomized transects were run. A minimum of two transects were completed in each stratum.

A different tactic was adopted during the night along the coast between Neil Harbor (Stratum NH) and Wreck Point (Sydney Bight)-Stratum WP); here herring occurred as a continuous band adjacent to the coast. In this area, in addition to randomized transects, a zig-zag track was adapted (Figures 13 and 15). The estimation of abundance derived from these data follows a method similar to that used by Buerkle (1985). Table 1 lists the areas of the sample strata.

3. Sampling Methods

3.1 Acoustic System

Acoustic data was collected using the ECOLOG system. During this survey a single beam transducer was used though data were recorded on the system's two channels. The relevant details of this system are described by Shotton and Randall (1982). The system was run with a pulse rate of 125/s, a pulse width of 0.4 ms, and an echo sample frequency of 10 kHz. The transducer has an equivalent beam angle of 0.00640 sr. Power transmitted is approximately 5 kw. Ship speed along transects was 8 knots. The transmitter and receiver that were used have been calibrated (May 1985) at the acoustic barge in Bedford Basin (Table 5).

3.2 Sample Dates

The dates that the areas were sampled are as follows:

	November
Gaspé - Western PEI	7 - 13
Eastern PEI	26 - 27
Sydney Bight	21 - 25
Lorraine Head (off Gabarus) (overnight)	28 - 29

More detailed information on sampling times is given in Table 2. The actual time spent sampling can be less than the difference between and starting and finishing time because in some transects, sampling was interrupted to fish or because of system failures. In some cases other strata were sampled between the first and last transects in a stratum, e.g., SY and HB, Figure 10.

3.3 Calculation of the Area Backscattering Coefficient

s

The area scattering coefficient $(s_{v/a})$ was calculated using the conventional acoustic integration model (Forbes and Nakken 1972).

$$v = \frac{I_r R^2 e^{2\beta R}}{I_0 (c\tau)/2 \int^{2\pi} b(\theta)^2 d\Omega}$$
(1)

where

S.,

 $I_r = echo intensity at the transducer$

= volume backscattering coefficient

 R^2 = range of reverberation volume which returned the echo

- β = coefficient of sound absorption in seawater
- I_0 = intensity of sound transmitted from the transducer
- c = speed of sound in seawater (1500 ms⁻¹)

 $\tau = pulse length$

 $b(\theta) = directivity function of the transducer$

6

The area scattering coefficient, $s_{v/a}$, for the kth pulse was calculated by:

$$s_{v/a,k} = \sum_{j=1}^{J} 0.075 s_{v,j}$$

where J = number of echo samples in the jth pulse.

The summed area scattering for the ith transect is:

$$s_{\nu/\alpha,i} = \sum_{k=1}^{K} s_{\nu/\alpha,k}$$

where K = number of pulses in the ith transect.

The total area scatter for a stratum is calculated by:

$$\Sigma s_{v/a} = \frac{area}{P} \sum_{i=1}^{l} s_{v/a,i}$$

where P = total number of pulses in the stratum.

I = number of transects in stratum.

3.4 Estimation of Biomass

The estimation of the herring biomass from the summed area backscattering coefficients, $\Sigma s_{v/a}$, requires use of an appropriate value for the backscattering cross section area per unit weight of herring. Determination of this value is difficult because it is hard to determine and because it is likely to change with the behavior of the herring, i.e., the daytime backscattering cross section per unit biomass may differ to that at night. The difficulties in selecting an appropriate value are discussed by Shotton (1985) and Buerkle (1985). Both authors tabulate values of backscattering cross sections per kilogram of herring cited in the literature. The value used by Buerkle (1985) was derived from the relation of Halldorson (1983),

$$\overline{TS}_{kg} = -14.7 \log L - 10.3 \log P - 10.9 \, dB \, ref 1 \, m^2$$
,

where L = length in cm

P = pressure.

The value Buerkle (1985) used was 1.380 x 10⁻⁴ m⁻² sr⁻¹ kg⁻¹. Buerkle (pers. comm.) has since learnt that Halldorson and his collegue, Reynisson use their 1983 relation; apparently they believe it is better. This gives

$$\overline{TS}_{kg} = -10.9 \log L - 20.9 \quad dB$$

٥r

$$\sigma_{b/kg} = 10^{-2.09} L^{-1.09} \tag{2}$$

The relationship I have previously used (Shotton and Randall 1982) is that given by Edwards and Armstrong (1983),

$$TS_{ba} = -17.09 \log L - 10.6 \ dB,$$

٥r

$$b_{kg} = 10^{-1.06} L^{-1.709}$$

(3)

The results of Halldorson and Reynisson (1983) were obtained from *in situ* observations, which is why Buerkle prefers them. The results of Edwards and Armstrong (1983) were obtained from measurements on herring in cages.

For the distribution of herring lengths observed during this survey (Section 3.6), the result of Edwards and Armstrong (Equation 3) gives a value of $3.049 \times 10^{-4} \text{ m}^2 \text{ sr}^{-1} \text{ kg}^{-1}$, that of Halldorson and Reynisson (Equation 2), $2.188 \times 10^{-4} \text{ m}^2 \text{ sr}^{-1} \text{ kg}^{-1}$, i.e., this latter value will give biomass estimates 39% higher than that using the relation of Edwards and Armstrong. The relation of Halldorson and Reynisson has been used in the main part of the text. Any error (of which some must occur) in the value of the backscattering cross section per kilogram of herring used here, will result in a linearly proportional error in the herring biomass estimates.

3.5 Estimation of Variance of Population Totals

σ

The estimates of the standard deviation of the population totals given in the results (Table 1) measure only the sampling variance, i.e., they do not include the contributions from the variances of the components of the acoustic integration model (Eq. 1).

In several strata, the survey consisted of a single continuous zig-zag transect, i.e. there was no replication of sampling. In these cases the variance has not been estimated. Where transects have been replicated within a stratum, the variance of the population total has been estimated as follows

$$Var(Y_{tot}) = \frac{1}{n-1} \frac{\Sigma P_i (Y_i - \overline{Y})^2}{\Sigma P_i}$$
(4)

where $Y_{tot} = stratum total estimate (m² sr⁻¹).$

n = number of transects in the stratum

 P_i = number of samples (i.e., pulses) in the stratum

 Y_i = stratum estimate derived from the ith transect

where A = area of stratum

 $s_{v/a} = mean area scattering coefficient,$

$$\overline{Y} = \frac{1}{n} \Sigma Y_i$$

This estimate of precision is conservative, i.e., it should give relatively large estimates

of the variance. I prefer to use this (large) variance estimate in the absence of satisfactory understanding of the reliability of those variance estimators that use measures of the autocorrelation of successive observations obtained along transects, and which ignore trends in the observations. This topic remains to be further investigated.

3.6 Herring Length Frequencies

Table 3 lists the locations where midwater trawls were successful in catching herring. The herring length frequencies are shown in Figs 17 & 18. The mean length of herring caught in the Baie de Chaleur was 29.4 cm (s.d.= 1.84); mean length of herring caught in the Sydney Bight was 28.3 cm (s.d.= 4.33).

4. Results

4.1 Introduction

The cruise results are presented in terms of tonnes of herring, not because I am fully confident in the values of the conversion coefficient (the backscattering cross section per tonne) I use, but because tonnes biomass is a more comprehensible measure than the area scattering coefficient (sr⁻¹).

4.2 Baie de Chaleur and Region

The results for this area are as follows:

Region	<u>Stratum</u>	<u>Biomass (t)</u>	% of regional total
Cape Gaspé	N	0	0
Baie de Gaspé	М	0	0
Baie de Malbaie	L	0	0
Isle de Bonaventure	К	8260	14.8
Cap d'Espoir - Pte			
de Pespébiac (Chandler-Newport)	I/J	22 000	39.3
Western Miscou	G	36 400	9.3
Northern Miscou	Н	0	0
Eastern Shippegan Is,			
- Miscou Bank	E	20 400	36.5
Northern North Point,			
Western PEI	P	71	0.1
		87 100	

While an estimate of zero is given for stratum L (Baie de Malbaie), herring were

encountered in this area, but because of a failure of the acoustic system, they were not recorded by the system.

4.3 Sydney Bight

The results for this area are as follows:

Region	Stratum	Biomass (t)
Aspy Bay	AB	5590
Neil Harbour	NH	31 600
	NH (south)	27 300
Wreck Point	WP	59 200
Wreck Point	(Post Stratification & with extra sampling)	
centre coastal		34 700 56 000
centre wide		44 000
south		269
Haddock Bank	HB	9870
Sydney	SY	25 700
New Waterford	NW	39 800
Donkin	DON	6120

The Neil Harbor estimates refer to two separate continuous line transects in that area. During the second replication, the northern region was not surveyed because there appeared to be no herring in that part of the stratum.

In the Wreck Pt stratum, different parts of the stratum received different intensities of sampling effort. First a continuous zig-zag transect was run. This covered the southern, centre coastal, and northern substrata. This gave the first estimate in the preceeding list. Because it appeared that herring schools occurred beyond the offshore boundary of the stratum in the central section, an additional substratum was sampled that covered the central region, and extended further offshore. In returning to the this substratum an additional transect was run in the northern substratum. Thus three estimates are possible for the Wreck Pt stratum:

(1) From the single zig-zag transect covering the whole stratum (12 900 sr⁻¹)

(2) From the post-stratified estimate for the southern substratum (59 sr⁻¹), plus the estimate from the mean of the two transects in the northern substratum (7600 sr⁻¹) plus the estimate from the single (post stratified) transect in the centre section (12 300 sr⁻¹).

(3) As for (2), but using the estimate from the centre 'wide' substratum rather than the single transect centre 'coastal' sample, 59 + 7600 + 9630 sr⁻¹. These three estimates are as follows:

(1) single	1	59 200 t		
(2) as for	(1) but replicated transect in north	ern substratum	91 000 t	
(3) as for	(2) but with the estimate for the 'ce	ntral' substratum from rep	licated	
transects in the 'wid	e' substratum:	-	79 000 t	
If the relative bias of	f all the substratum estimates was	the same, then the values f	from (1) and (2)	
should estimate the	same population total. Estimate (3) should include the popula	ation that is	
estimated by (1) and	by (2) plus that occurring in the m	arginal area surveyed.		

Because the herring in the Wreck Pt stratum appeared to be relatively mobile, it is possible that the differences in the three estimates obtained arise, not from sampling variability, but from changes in the population being sampled. Thus the estimates from (1) is least likely biased while those from (2) and (3), because of the delay in time prior to sampling, could be. Thus no matter which estimate is chosen, some subjectively will be involved in the estimate.

There are at least two possible ways to estimate a regional total when two estimates of a population total have been obtained; if both estimates are unbiased, then a simple mean of the two estimates can be taken, or if one or other of the estimates is believed to be biased, one can be selected as being the least biased. In the Neil Harbor - Bentinck Point area, both in 1984 and 1985, the herring populations encountered appeared to be quite mobile. Thus, large differences in population estimates from two replications are more likely to arise from an actual change in the population size (due to school movement) within a stratum than from sampling variability. For example, there was a change from 57 to 1 in the number of schools encountered in the Neil Harbor region in samples separated in time by approximately 22 hours. In contrast replication of the sequences of transects in the central part of the Wreck Point stratum resulted in little difference in the population estimate, in this case only 21%; these transect replications were only 2.5 hours apart. Thus two population total estimates are possible for the western Sydney Bight stratum:

	low <u>estimate</u> (t)	high <u>estimate</u> (t)
North of Cape Smoky:		
Aspy Bay (AB)	5590	5590
Neil Harbor (NH)	27 300	31 600
South of Cape Smokey		
Wreck Pt (WP1)	59 200	91 000

This gives a range of 92 000 to 128 000 t. Because it appears that the low estimate for Neil Harbour was caused by a reduction in the size of the population over the period the area was surveyed, I judge the high estimate, here, to be best for this stratum. South of Cape Smokey (Wreck Pt), the delay between sampling successive substrata could give rise to double counting', i.e., schools counted in one substratum moving to another and being counted a second time. Thus I judge the low estimate to be a conservative and appropriate estimate for this stratum, i.e., 59 200 t. Thus, based on these data, my preferred estimate for the western side of Sydney Bight is (5590 + 31 600 + 59 200) 96 400 t. Thus one estimate for all of Sydney Bight is: North of Cape Smokey. 37 200

North of Cape Shokey	51200
South of Cape Smokey	<u>59 200</u>
	96 400 t
Southern coast of Bight	<u>81 600</u>
Total (t)	178 000t

Another estimate of the herring biomass occurring along the western edge of Sydney Bight can be obtained from the survey results from two successive nights when zig-zag transects covered a continuous aggregation of herring. (See Figures 13 and 15 for the survey path). On the first night (November 24-25) sampling started just north of Bentinck Point and continued northward finishing at Cape Smokey at daybreak. At this time, the aggregation could no longer be located, and subsequent survey effort indicated that it had formed discrete schools which had moved offshore. It is most likely that the entire aggregation was not sampled on this night. On the following night (November 25-26) sampling started at Cape Egmont and continued southward finishing south of Wreck Point at daybreak. No schools were located near the southern range of the survey area and only a few relatively dispersed schools near Cape Egmont. I am confident that the entire herring aggregation was surveyed on the second night. On both nights a continuous inshore zig-zag pattern was used.

The biomass estimates obtained are as follows:

Night 1:

	South of Wreck Point:	62 700 t
<u>Night 2</u> :		
	Cape Egmont - Bentinck Point	119 600 t

Thus two additional estimates for the western side of the Sydney Bight are possible.

Using Nov. 24:

North of Cape Smokey	37 200
South of Cape Smokey (Zig-Zag Design)	<u>62 700</u>
	99 900 t
<u>Using Nov. 24-25</u> :	
Aspy Bay (randomized transects)	5590
Cape Egmont South (Zig-Zag Design)	<u>120 000</u>
	126 000

The zig-zag design estimates compare with those from the randomized transects design of: 59 200 and 141 000 t respectively. The estimate for Night 1 (south of Wreck Point) was almost identical to that obtained from the randomized transects design, 106.0%, for the same area. The estimate from the zig-zag pattern for Night 2 was 29.9% greater than that given by the randomized transect design, but it was only 97.6% of the highest possible estimate obtained from the corresponding area, i.e., 128 000 t.. If the means of the corresponding estimates (littoral zig-zag and randomized transect

design) one taken, the results are:

(1) With results from zig-zag design, Nov. 23-24:

Western	Bight average,	
---------	----------------	--

(99 900 + 59 200) ÷ 2 Southern Bight (Haddock Bk, Sydney, New Waterford and Donkin):	79 500 <u>81 600</u>		
	161 000		
(2) With results from zig-zag design, Nov. 24-25:			
Western Bight average,			
(126 000 + 96 400) ÷ 2	111 200		
Southern Bight (HB + SY + NW + DON)	<u>81 600</u>		
	192 800		

The similarity of these estimates strongly supports the view that the different survey designs, which were used in very different circumstances of herring distribution, did survey the same populations. The details relevant to the 'zig-zag' estimates are given inTable 4:

5. The Distribution of Herring

5.1 Introduction

-Although acoustic surveys of the herring in the southern Gulf and Sydney Bight have been done for only two years, (1984 and 1985) the distribution of the herring encountered was surprisingly consistent. The main difference has been an apparent increase in abundance in 1985 relative to that of 1984.

In the Gaspé region scattered schools were encountered in both years, concentrated in the area from Pte St. Pierre to Grande Rivire. Relatively greater concentrations occurred between Chandler and Newport. During the night the herring in this region formed a near-continuous distribution along the coast, in some cases extending inshore further than was possible to go with the research vessel. Small schools were scattered throughout the waters of Miscou Bank, and in the area west and north of Miscou Island. A similar distribution of scattered schools occurred in depths from 10 to 40 m in the area east of Miscou Is. and Shippegan Island.

In 1985 several moderately large schools were observed while enroute along the northern coast of PEI in the area offshore from Monticello-Long Pt, (i.e. near the eastern end of the Island); no schools were encountered in this area in 1984. Inclement weather prevented completion of the transects planned for this area later during the 1985 cruise so the question of herring abundance in that area in 1985 remains unanswered. No herring were encountered along the eastern coast of the Island (Souris - Cardigan Bay) where the weather enabled survey transects to be completed. In 1984 a few small schools were encountered along the north-western coast of Cape Breton Island (between White Cape and Cape St. Lawrence), but the same northwesterly gales which prevented sampling along the northern coast of PEI also prevented sampling in this area in 1985. In both 1984 and 1985, the largest concentration of herring encountered occurred in the area between Neil Harbor and Bentinck Point, on the west coast of Sydney Bight. In 1984 there appeared to be both an inshore-offshore movement in the band within 5 nm of the coast and an along-shore movement from north to south of Ingonish. No schools were encountered in Aspy Bay or in St. Ann's Bay in 1984. In 1985 scattered schools encountered in Aspy Bay and large schools in St. Ann's Bay about Ciboux Island.

The herring in the Aspy Bay - St. Ann's Bay area displayed a diel behavior similar to that observed in the Baie de Chaleur between Newport and Chandler. During the day the schools occurred as discrete entities and occurred upto (at least) 5 nm from the coast. At night the herring formed a continuous band-like distribution along the coast. On the first night this was sampled in detail, the distribution extended from about 1 km north of Black Rock to South Ingonish Bay (where sampling ceased), a distance of approximately 10 nm. The width of the band varied from about 200 m to about 1 km. This aggregation was encountered during the morning of November 24th; sampling continued from 0220 to 0600. The following night (November 24-25th) a more extensive aggregation was surveyed. It extended from Cape Egmont, in the north, to about a nautical mile south of Wreck Pt, a distance of 28 nautical miles. Again the width of the aggregation was variable, up to 1 km. The water depth ranged from 40 m to depths too shallow for the vessel to navigate. The vertical distribution of the herring aggregation was up to 30 m in extent. During both nights the sky was cloudless and a bright moon shone. Full moon was on November 27.

The nature of herring school distribution along the south coast of Sydney Bight was similar in 1984 and 1985; scattered schools were found along the coast but occurred most frequently in the region of Glace Bay - New Waterford. Sampling did not extend beyond about 5 nm from the coast, and about 50 m in depth as most schools occurred well inshore from this limit.

In 1985, while en route to Halifax, a number of transect legs were sampled between Main-A-Dieu Passage and Cape Gabarus. At the very end of the inshore leg of the last transect, herring were encountered, and a subsequent search resulted in the location of several schools inshore to where the previous transects had terminated. No estimation of abundance was made for this area. The existence of herring in this area raises several interesting possibilities. Herring distribution at the time of the survey may be continuous from Sydney Bight to much further south, perhaps to Chedabucto Bay and beyond. Future surveys may then ideally continue south along this section of the coast until the herring distribution ceases.

No survey effort was expended along the south-west coast of Newfoundland in 1985 because the survey effort in this area in 1984 found no trace of herring in that area. Consideration should be given to extending the survey to the Banquerau area in 1986 in view of the past herring fishery in that area.
